NOTES ON THE CHAMBER ORGAN.—III.

BY GEORGE ASHDOWN AUDSLEY, F.R.I.B.A.

I NOW come to the consideration of the most important matters connected with the Chamber Organ—matters on which the true beauty and distinctive character of the instrument depend. I allude to the scaling, voicing, and disposition of the speaking stops; their selection for combination, solo, and accompanimental purposes; and the means to be provided for imparting expression to them. It must be obvious, in an instrument of a very limited number of stops, such as I have contemplated in the foregoing remarks, that the selection of the speaking stops is a matter of the highest importance; and that their scaling, winding, and voicing must be most carefully calculated and adapted, so as to secure the maximum variety and purity of tone, combined with perfect mixing qualities. These conditions of excellence are, it is to be regretted, seldom met with together, even in large instruments by modern builders; in small instruments they are, it may be said, never seriously aimed at. Herein lies the cause of the insipid and sometimes almost offensive tonal character of the ordinary Chamber Organs of the day.

The construction of a Chamber Organ which shall be worthy of the name, and which shall be to the domestic music-room or drawing-room what the great concert organ is to the public concert-hall, is a problem quite worthy of both the professional builder's and the musician's earnest attention. That the problem can be solved I have, at least to my mind, satisfactorily proved; and that its solution is not attended with extreme difficulty can be safely asserted. For a successful issue, it is necessary that the individual who makes the essay should approach the matter without any prejudice or preconceived ideas founded on the ordinary existing examples. To this openness of mind must, of course, be added a knowledge of the nicities of the art of organ building, and a refined and cultivated ear for musical sounds.

In the following Notes will be found the results of many years' earnest study of the subject, necessarily in a very brief and condensed form; but, I trust, sufficiently full to convey my meaning to readers interested in, and somewhat acquainted with, organ building.

Speaking Stops.

The first matter claiming attention with reference to the speaking stops is their scaling—that is, the dimensions and relative proportions of the transverse sections of their respective pipes. On the question of scaling not a little uncertainty and difference of opinion obtains amongst experts; and, accordingly, it is extremely difficult to lay down any hard and fast rules. The commonly accepted notion of deriving the scales of the subordinate stops from the principal stop (*Open Diapason*) is out of all reason with reference to a small Chamber Organ of fifteen or twenty stops. It would be reasonable if the oldfashioned specification still obtained of planting the Great wind-chest with an *Open Diapason*, *Stopped Diapason*, *Principal*, *Twelfth*, and *Fifteenth* only; but in an instrument where such a time-worn idea finds no fruition it is unnecessary and undesirable to adopt any traditional notions respecting derived scales.

It is imperative that all the stops of a Chamber Organ should be of delicate and refined intonation, with, at the same time, sufficient brilliancy and distinctive character to render them effective, both as combination and as solo registers. Such a class of tone may be secured by two distinctly different methods of procedure—namely, by adopting very small scales and a moderately high pressure of wind, or by adopting medium scales and a low pressure of wind.

At this point it is desirable to discuss the question of wind pressure, with the view of arriving at some conclusion anent that most suitable for a Chamber Organ. In my opinion, the maximum pressure should be set at 2½in. and the minimum at 1½in. The adoption of a higher pressure than the maximum above given is not to be recommended, even when very small scales are used, because it tends to impart a harsh and screaming intonation. Experience has taught me that a pressure of 2⅜in. is perfectly suitable for medium scaled stops which are required to yield tones combining fulness with brilliancy. At this pressure, a sufficient amount of wind can be supplied to all pipes to produce, with consistent and skilful voicing, the smooth and round tones so desirable in a Chamber Organ, but without any unpleasant windiness.

It must be borne in mind that a Chamber Organ must be literally *all tone*—that is, the tone must be entirely free from the hiss of escaping wind, or from any objectionable quality which interferes with its purity. In the case of my Chamber Organ, which has a wind pressure, for both manual and pedal departments, of 2⅜in., I have succeeded in so scaling, voicing, and regulating its 1,162 pipes that even the full tone is innocent of any hissing noise or other trace of windiness. I am free to admit that much care, to say nothing of skill, is required to arrive at so desirable a result; but it is satisfactory to know that it *can* be arrived at.

At the pressure of 2⅜in. or 2¼in., scales sufficiently large can be introduced to yield tones of great fulness and purity. For instance, the Principale, 16ft. (Pedal *Open Diapason*) in my organ measures 10in. by 8in., internally, at the C C C pipe; while the C C pipe of the Principale Grande, 8ft. (Great *Open Diapason*), is 5¼in. in diameter. With this pressure sufficient character can also be obtained from medium-scaled reed stops, without the disagreeable buzz inherent in reed pipes on 3in. and still higher pressures. Another and very important advantage attending the 2⅜in. pressure is that it is perfectly suitable for both the pedal and manual departments. If a much lighter wind is adopted for the manuals, the 2⅜in. will have to be retained for all the Pedal registers, for they will not speak promptly on a very light pressure. In a small instrument, and where space is limited, it is inconvenient, if not impossible, to have different pressures of wind; but where there is a separate bellows-chamber provided, under or adjoining the apartment in which the organ is located, there will probably be no difficulty in accommodating the two reservoirs required for the different pressures.

There are several flue stops, highly suitable for the Chamber Organ, especially if they are not to be inclosed in a swell-box, which can be voiced to yield tones of singular richness and beauty on wind of 2in. pressure; but this is certainly the lowest pressure that should ever be used for entire manual departments. Lower pressures should only be employed for a few stops, which may, for the sake of distinction, be designated echo stops. The so-called *Vox Angelica* may be voiced to yield whispering tones of exquisite quality on 1½in. wind.

It will be gathered from the preceding brief remarks that I am not in favour of the wholesale adoption of small scales for the stops of a properly-appointed Chamber Organ. For the more important stops, or those which form the vertebræ, so to speak, of the tonal structure, I advocate what, for the purpose of a Chamber Organ, may be considered large scales; depending upon skilful voicing, well-regulated winding, and moderate

pressure to produce the dignified, round, and absolutely pure tones required. These remarks apply specially to the fundamental unison registers. When we come to consider the octave and super-octave stops we must recognise the necessity of subduing their tones, so as to avoid any tendency to impart a screaming character to the combinations they may be called upon to enter. Considerable judgment must be exercised in the selection of the octave stops, because in a small organ they must not only be generally available in combination with unisons of various strengths of tone, but also as solo stops. It should never be overlooked that in a *small* Chamber Organ every stop must be equally useful, even including the Mixture when such a stop is inserted. In my own organ this idea has been consistently carried out, and it is not too much to say that in it every manual register is equally useful. Two extreme instances are sufficient to prove this statement. The Voce Umana fulfils its special office when assisted by the Tremolant: it can also be used in combination with any of the other stops, or entirely alone (without the Tremolant) as a quiet unison reed, in either melody or harmony. Again, the Ripieno di cinque (Mixture, V ranks) can be used to impart richness and brilliancy to the full organ, or be used with any *one* of the softer unison registers, producing combinations of exquisite quality and of singularly sympathetic character.

But to return to the scales of the octave stops. When an *Open Diapason* is introduced, the Tenor C pipe of which measures 3¼in. in diameter, and a derived Octave is likewise inserted, the C C pipe of the latter should not exceed 2¾in. in diameter. In addition to this reduction of scale, it should have less wind and be accordingly voiced to yield a tone much softer and of a more "silvery" quality than that of the fundamental unison. Such an Octave is perfectly suitable for solo and combination purposes generally. In very small instruments, or on one or other of the manuals of a larger organ, it may be advisable to insert the octave stop in the form of a 4ft. Flute of medium scale. There can be no question as to the utility of such an arrangement.

In a Chamber Organ it is not at all necessary —indeed, in the generality of cases it is inexpedient—to introduce a Twelfth; but if such a mutation stop is contemplated, let it be kept very small in scale, so that its tone may do little more than enhance the second harmonic upper partial tones of the unison stops. It should be little, if anything, larger than an ordinary *Dulciana* in scale.

When we come to consider the Super-octave or Fifteenth, taste must decide in what form the stop had best be introduced. Shall it follow the oldfashioned lines, and be merely a part of the so-called "*Diapason-work*," made to a scale somewhat less than that of the Octave; or shall it assume an entirely different nature, with the view of becoming a useful solo as well as a combination stop? Questions such as these crop up at almost every turn in Chamber Organ building, and demand careful consideration. In an instrument of from fifteen to twenty stops, it is safe to say that only one Super-octave is really necessary; indeed, it is most inadvisable to sacrifice any of the more important stops which such an organ ought to contain for the sake of duplicating so acute a register. The most useful form for the Super-octave is that of a Flute; and when such is adopted the stop becomes a Piccolo, perfectly suitable for both solo and combination purposes. In tone this stop should be much more prominent than the Twelfth, but less so than the true Octave above spoken of. As a solo register its tone should be sufficiently bright to be self-assertive, but totally devoid of anything approaching a screaming character.

In Chamber Organs of the size here contemplated it is unusual to introduce "harmonic-corroborating" stops; but this, I think, is a great mistake. Without a Mixture of some kind it is impossible to secure that quality of tone which contributes so largely to the glory of the organ. The old masters and those who followed them calculated the scales of their Mixtures from those of the foundation stops, hence their great brilliancy and assertive character. Such compound registers are more than "harmonic-corroborating" stops, to use Dr. Hopkins's expressive term; they are in truth *harmonic-creating* registers. I question the wisdom of introducing large-scaled and loudly-voiced Mixtures even in large instruments; in small organs I am quite satisfied they are out of place. It must be obvious if they are loud and assertive they can only be used in combinations in which all the foundation-work is present. This is an undesirable narrowing of their utility, and one that should systematically be avoided. In a properly balanced Chamber Organ a Mixture is of immense value and interest; but, of course, that value and interest entirely depend upon the nature of the stop in question. It must be of exceptional quality, and the softest possible intonation, secured by smallness of scale and careful voicing. I am not speaking without experience in the matter, for, after due consideration, I inserted in my own Chamber Organ a Mixture of five ranks, which, while it has sufficient "harmonic-corroborating" power to enrich the full organ tone, can be used, even in full chords and with a most pleasing effect, in combination with the Principale Dolce (a soft-toned *Dulciana*) only.

This is a test which I venture to think very few old or modern Mixtures of five ranks could be successfully subjected to; but it is one which every Chamber Organ Mixture should stand in a perfectly satisfactory manner. The Mixture, whatever the number of its ranks or its component intervals may be, must be formed of pipes of an extremely small scale, voiced and regulated in such a manner as to give the mutation ranks less prominence than those which present such intervals as the 8ve, 15th, 22nd, and 29th. The compositions of the Mixtures to be recommended for the Chamber Organ are given further on.

The scales of what may be considered the solo stops, such as the Flute, Violin, Violoncello, Oboe, Clarinet, Horn, Trumpet, &c., should be kept sufficiently large to produce the characteristic tones respectively aimed at. In all, however, a perfect mixing quality is quite as important as the individual or solo tone; and this consideration dictates a decided leaning towards small scales in stops of so assertive a character. As it is impossible in an article like this to do more than give the merest outline of this branch of my subject, I must content myself with the above general hints, and pass on to the consideration of the stops which are most suitable for the class of Chamber Organ I am advocating.

In an organ of the moderate size contemplated in this essay, a chief unison stop of the true English *Open Diapason* species should certainly be introduced in the leading manual department, and should extend throughout the compass of the instrument. Its tone should be full and round, devoid of any hissing or windiness. Again I must touch on this subject of windiness. Perhaps nothing is more objectionable in an organ, which has to be listened to at so short a distance, than the unmusical sound of escaping wind or the hiss which so commonly characterises loudly and badly voiced organ pipes, and no pains should be spared to get rid of the nuisance. The usual organ builder's expedient of boxing up the pipes with the view of subduing any such objectionable quality does not altogether cure the evil. If it diminishes the noise complained of, it also detracts very materially from the freedom and richness of the musical tone of the pipes—it reduces one evil only to create another. The noise must be cured in the pipes themselves, by skilful voicing and the exact adjustment of their supply of wind. This fact must never be overlooked in Chamber Organ building.

Taking it for granted that an important unison register, as above mentioned, has been decided on for the chief manual department, let us designate it by its proper name, Principal, 8ft.,* and turn our attention to the question respecting the most appropriate Octave to combine with it. If only one stop of 4ft. is to be inserted in this department, it is advisable to depart from the commonly accepted practice of introducing an Octave of the same species as the Principal, 8ft., and to adopt in its stead a stop which shall at once fulfil the ordinary office of an Octave in combination, and be a useful solo register. When two 4ft. stops are to be inserted, one should certainly be a cylindrical metal stop, considerably smaller in scale, but generally resembling the unison Principal in character. Its tone should, as already pointed out, be lighter and more "silvery," so as to render it useful as an Octave in combination with other unisons than the Principal. The second register should be a Flute, 4ft., of medium strength. This arrangement secures diversity of tone, an advantage in a Chamber Organ never to be lost sight of. When only one Flute of 4ft. is introduced, it should be constructed and voiced to imitate as closely as possible the tones of the orchestral instrument, and be, accordingly, labelled Orchestral Flute or Flauto Traverso. In an instrument of, say, fifteen speaking stops there may be four and in one of twenty stops five flute-toned registers inserted with advantage. When the Chamber Organ is used in concerted music along with stringed instruments and the piano, the flute quality is of the greatest value. It enables the organ to hold itself distinct, and to add a very desirable quality to the *ensemble*.

When four Flutes are introduced, there should be two of unison pitch, of different qualities and strengths of tone; one an open stop (open from Tenor C) of the *Clarabella* type, and the other a covered stop of the *Lieblich Gedact* character: one open Flute of 4ft. (Orchestral Flute), and one open Flute or Piccolo of 2ft. When five Flutes are inserted there may either be another covered unison of different intonation, or a second octave Flute of the *Lieblich Gedact* type, voiced much softer than the Orchestral Flute. This may be a small-scaled half-covered wood stop throughout. I may just mention by way of a practical illustration that in my own Chamber Organ, of nineteen speaking stops, there are the following six flute-toned registers in the manual departments:—1. Flauto Primo (*Doppel-flöte*), 8ft. tone. 2. Flauto Secondo (*Lieblich Gedact*), 8ft. tone. 3. Flauto Tedesca (a species of *Clarabella*, open from Tenor C), 8ft. 4. Flauto Traverso, 4ft. 5. Flauto d'Amore (small-scaled register, half-covered throughout), 4ft. tone. 6. Piccolo, 2ft. The diversity in strength and character of tone, as well as in pitch, presented by these stops renders them invaluable.

As I have already dwelt on the subject of the Twelfth and Super-octave stops, while speaking more particularly of scales, it is unnecessary to again allude to it. With the view of impressing the reader with certain most important matters for consideration, I have, perhaps, more than once repeated myself already, but need not continue the practice, when nothing is to be gained by it.

In addition to the full-toned Principal, 8ft., already discussed, the Chamber Organ should certainly contain a delicate unison

* See my previous article on "Organ-Stop Nomenclature" in ENGLISH MECHANIC, present volume, p. 319.

stop of pure organ tone. The stop known as the *Dulciana* exactly supplies what is required. As this register will be in a swell-box, it will be inconvenient, if not impossible, in all ordinary cases to carry it down in open pipes to CC. Beautiful as the lowest octave is when voiced by a master, its omission is not a serious matter. The octave may be grooved into the bass of some other soft stop, or may be inserted in stopped pipes of very small scale and quiet intonation. When space will permit, the open metal pipes should be carried down to Gamut G. If a still softer unison is required, the so-called *Vox Angelica* may be resorted to. This stop must not, however, be confounded with the duplex *Voix Célestes*. In its proper form, it is an open, cylindrical metal stop, of the smallest scale yet introduced; in tone it may be said to be an echo *Dulciana*. I question the utility of its introduction, however, and should certainly not insert it in any instrument unless there was a distinct Echo department to receive it.

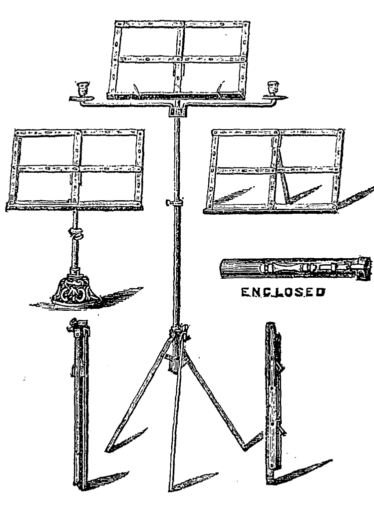
(*To be continued.*)

TOBACCO-GROWING IN ENGLAND.

AS most of our readers are aware, several experimental plots of tobacco-plants are being cultivated this year in England with the view of determining whether it will be profitable to grow the "weed" as a regular branch of agricultural industry. For many years Nicotiana macrophylla has been grown in large gardens as a border-plant, its general appearance recommending it to gardeners, while the leaves dried and cured in a rough-and-ready fashion were found useful for fumigating the greenhouses. Those interested in the cultivation of the plant for purposes of trade will, of course, pay a visit to Kew, where, in a bed opposite No. 2 Museum, they can see the different species of Nicotiana, and form their own conclusions as to the sorts likely to yield a return for the trouble and labour. In Norfolk, Lord Walsingham has a large plot, and in Kent both Lord Harris and Mr. Faunce de Laune have experimental plots of about half an acre, all of which are, we believe, doing as well as can be expected considering the season. At Plaistow, in Kent, Messrs. Carter have about three-quarters of an acre devoted to a number of varieties which are known to grow well and to yield excellent tobacco. The most promising of these are the varieties which are long-jointed and broad-leaved, for they carry the foliage clear of the soil, and are, therefore, less liable to be injured by slugs or disfigured by dirt, while the air, having freer circulation they ripen better or earlier. Tobacco in this country must be treated much in the same way as half-hardy plants—dahlias, for instance. The seeds must be raised early in heat, and the plants be kept growing in frames, so as to be ready for planting-out as early as possible in June. The ground, too, must be properly prepared, and be thrown up into flat-topped ridges or hillocks, so that the plants stand well up from the general level with about 4ft. between the rows, and 3ft. between the individuals. At Sharsted Court, near Sittingbourne, Mr. De Laune's place, the ground chosen was formerly part of a hop-garden, and the tobacco "plantation" is surrounded and sheltered by hops, the manure used being "farmyard" and sheep droppings. Here the plants have grown so luxuriantly that there is now scarcely sufficient space to get between them to pull off the heads of seed from time to time. Some of them have attained a height of 5ft. with about ten serviceable leaves, the dimensions of which are often 3ft. by 18in.; but, as a number of varieties are grown, there is naturally great diversity in the habit—some being close and dwarf, while others are tall and straggling, with all sorts of shades of green in the leaves. Stopping the main stems and removing laterals provides plenty of work for labourers; but it remains to be seen whether, even in favoured parts, tobacco can be grown as a profitable crop. It is stated by those who should know that the money value of a crop of tobacco is considerably higher than a similar area of wheat, barley, or oats will yield, but owing to the comparatively tender nature of the plant there are more expenses in rearing it, and we suspect more still in cultivating and finally curing it; but if it can be grown, as it is, in Germany, it may be that by judicious selection of varieties we may also find in tobacco a profitable crop for our farmers, especially if the land can be made to yield something else in between—even if only sheep feed. In Kent there is not likely to be much difficulty experienced in drying and curing the leaves, for there hop-oasts are plentiful, and the different methods of curing can be tried without much expenditure of capital; but although there praiseworthy experiments have been made, it is well known that the majority of those who have undertaken the work have only a hope that they will be successful. It is known well enough that the tobacco-plant will grow and ripen its leaves in this country, but as the value of the crop depends on its quality, we must wait and see how the produce of the experimental plots turns out before we can form a definite opinion as to the profitable nature of the cultivation. It is for this reason that so many different varieties have been tried—some of them for the first time in this country—and it may be that possibly we shall find one or more which equal the famed growths of Havannah, Virginia, and Maryland: but it must be confessed that it will be an agreeable surprise if they do. We understand that Mr. Jenkins, the Secretary of the Royal Agricultural Society, is preparing a report on the experimental plots from personal inspection, and on his conclusions a great deal will depend, not only as to the future cultivation of tobacco in the United Kingdom, but also as to the excise regulations which the Government will make.

PEENE'S PATENT PORTABLE MUSIC STAND.

THE legs in this Stand, which we illustrate, are expanded by sliding them down the central tube, and when at bottom of tube, by



merely pressing on top connection, the legs will open into position. The desk is opened for use by pulling up the two ladders, the one to the left, the other to the right, and then both the uprights are inserted in the V-shaped clip. These stands are suited for orchestral societies, bands, or for drawing-room use. They will be found to take up very little space when folded, the legs folding perfectly flat against the central tube. The desk also closes in a very small compass, and the patentee says they are considerably less in price than other stands of a similar kind.

The Stand has received a certificate of merit from the "Inventions," Science and Art Department, Section No. 12, Wolverton. A light stand suitable for carrying in violin case is also made by the inventor.

BRITISH ASSOCIATION.

PRESIDENT'S ADDRESS.

THE fifty-sixth annual meeting of the British Association for the Advancement of Science was opened in Birmingham on Wednesday last, the 1st inst., when the president, Sir J. William Dawson, C.M.G., M.A., LL.D., F.R.S., F.G.S., principal and vice-chancellor of McGill University, Montreal, delivered an address, from which we extract the following:—After some introductory remarks, in which the president referred to the last meeting in Birmingham and the founding of the Mason College, he said:—

In a recent address, the late President of the Royal Society called attention to the fact that within the lifetime of the older men of science of the present day, the greater part of the vast body of knowledge included in the modern sciences of physics, chemistry, biology, and geology, has been accumulated, and the most important advances made in its application to such common and familiar things as the railway, ocean navigation, the electric telegraph, electric lighting, the telephone, the germ theory of disease, the use of anæsthetics, the processes of metallurgy, and the dyeing of fabrics. Even since the last meeting in this city, much of this great work has been done, and has led to general results of the most marvellous kind. What at that time could have appeared more chimerical than the opening up by the enterprise of one British colony of a shorter road to the East by way of the extreme west, realising what was happily called by Milton and Cheadle "the new North-west Passage," making Japan the next neighbour of Canada on the west, and offering to Britain a new way to her Eastern possessions? or than the possibility of this Association holding a successful meeting on the other side of the Atlantic? To have ventured to predict such things in 1865 would have appeared quite visionary, yet we are now invited to meet in Australia, and may proceed thither by the Canadian Pacific Railway and its new lines of steamers, returning by the Suez Canal. To-day this is quite as feasible as the Canadian visit would have been in 1865. It is science that has thus brought the once widely-separated parts of the world nearer to each other, and is breaking down those geographical barriers which have separated the different portions of our widely extended British race. Its work in this is not yet complete. Its goal to-day is its starting-point to-morrow. It is as far as at any previous time from seeing the limit of its conquests, and every victory gained is but the opening of the way for a farther advance. By its visit to Canada the British Association has asserted its imperial character, and has consolidated the scientific interests of Her Majesty's dominions, in advance of that great gathering of the industrial products of all parts of the empire now on exhibition in London, and in advance of any political plans of Imperial federation. There has even been a project before us for an international scientific convention, in which the great English republic of America shall take part, a project the realisation of which was to some extent anticipated in the fusion of the members of the British and American Associations at Montreal and Philadelphia in 1884. As a Canadian, as a past President of the American Association, and now honoured with the Presidency of this Association, I may be held to represent in my own person this scientific union of the British Islands, of the various Colonies, and of the great Republic, which, whatever the difficulties attending its formal accomplishment at present, is certain to lead to an actual and real union for scientific work. In furtherance of this I am glad to see here to-day influential representatives of most of the British Colonies, of India, and of the United States. We welcome here also delegates from other countries, and though the barrier of language may at present prevent a larger union, we may entertain the hope that Britain, America, India, and the Colonies, working together in the interests of science, may ultimately render our English tongue the most general vehicle of scientific thought and discovery, a consummation of which I think there are at present many indications. But, while science marches on from victory to victory, its path is marked by the resting-places of those who have fought its battles and assured its advance. In looking back to 1865 there rise before me the once familiar countenances of Phillips, Murchison, Lyell, Forbes, Jeffreys, Jukes, Rolleston, Miller, Spottiswoode, Fairbairn, Gassiot, Carpenter, and a host of others, present in full vigour at that meeting, but no more with us. These were veterans of science; but, alas! many then young and rising in fame are also numbered with the dead. It may be that before another Birmingham meeting many of us, the older members now, will also have passed away. But these men have left behind them ineffaceable monuments of their work, in which they still survive, and we rejoice to believe that, though dead to us, they live in that company of the great and

good of all ages who have entered into that unseen universe where all that is high and holy and beautiful must go on accumulating till the time of the restitution of all things. Let us follow their example and carry on their work, as God may give us power and opportunity, gathering in precious stores of knowledge and of thought, in the belief that all truth is immortal, and must go on for ever bestowing blessings on mankind. Thus will the memory of the mighty dead remain to us as a power which—

Like a star
Beacons from the abode where the eternal are.

I do not wish, however, to occupy your time longer with general or personal matters, but rather to take the opportunity afforded by this address to invite your attention to some topics of scientific interest. In attempting to do this I must have before me the warning conveyed by Prof. Huxley, in the address to which I have already referred, that in our time Science, like Tarpeia, may be crushed with the weight of the rewards bestowed on her. In other words, it is imposible for any man to keep pace with the progress of more than one limited branch of science, and it is equally impossible to find an audience of scientific men of whom anything more than a mere fraction can be expected to take an interest in any one subject. There is, however, some consolation in the knowledge that a speaker who is sufficiently simple for those who are advanced specialists in other departments, will of necessity be also sufficiently simple to be understood by the general public who are specialists in nothing. On this principle a geologist of the old school, accustomed to a great variety of work, may hope to so scatter his fire as to reach the greater part of the audience. In endeavouring to secure this end, I have sought inspiration from that ocean which connects rather than separates Britain and America, and may almost be said to be an English sea—the North Atlantic. The geological history of this depression of the earth's crust, and its relation to the continental masses which limit it, may furnish a theme at once generally intelligible and connected with great questions as to the structure and history of the earth, which have excited the attention alike of physicists, geologists, biologists, geographers, and ethnologists. Should I, in treating of these questions, appear to be somewhat abrupt and dogmatic, and to indicate rather than state the evidence of the general views announced, I trust you will kindly attribute this to the exigencies of a short address.

The Geology of the Atlantic.

If we imagine an observer contemplating the earth from a convenient distance in space, and scrutinising its features as it rolls before him, we may suppose him to be struck with the fact that eleven-sixteenths of its surface are covered with water, and that the land is so unequally distributed that from one point of view he would see a hemisphere almost exclusively oceanic, while nearly the whole of the dry land is gathered in the opposite hemisphere. He might observe that the great oceanic area of the Pacific and Antarctic Oceans is dotted with islands—like a shallow pool with stones rising above its surface—as if its general depth were small in comparison with its area. He might also notice that a mass or belt of land surrounds each pole, and that the northern ring sends off to the southward three vast tongues of land and of mountain chains, terminating respectively in South America, South Africa, and Australia, towards which feebler and insular processes are given off by the Antarctic continental mass. This, as some geographers have observed, gives a rudely three-ribbed aspect to the earth, though two of the three ribs are crowded together and form the Europ-asian mass or double continent, while the third is isolated in the single continent of America. He might also observe that the northern girdle is cut across, so that the Atlantic opens by a wide space into the Arctic Sea, while the Pacific is contracted towards the north, but confluent with the Antarctic Ocean. The Atlantic is also relatively deeper and less cumbered with islands than the Pacific, which has the higher ridges near its shores, constituting what some visitors to the Pacific coast of America have not inaptly called the "back of the world," while the wider slopes face the narrower ocean, into which for this reason the greater part of the drainage of the land is poured. The Pacific and Atlantic, though both depressions or flattenings of the earth, are, as we shall find, different in age, character, and conditions; and the Atlantic, though the smaller, is the older, and from the geological point of view, in some respects, the more important of the two. If our imaginary observer had the means of knowing anything of the rock formations of the continents, he would notice that those bounding the North Atlantic are in general of great age, some belonging to the Laurentian system. On the other hand, he would see that many of the mountain ranges along the Pacific are comparatively new, and that modern igneous action occurs in connection with them. Thus he might be led to believe that the Atlantic, though comparatively narrow, is an older feature of the earth's surface, while the Pacific belongs to more modern times. But he would note in connection with this that the oldest rocks of the great continental masses are mostly towards their northern ends, and that the borders of the northern ring of land and certain ridges extending southwards from it constitute the most ancient and permanent elevations of the earth's crust, though now greatly surpassed by mountains of more recent age nearer the Equator. Before leaving this general survey we may make one further remark. An observer looking at the earth from without would notice that the margins of the Atlantic and the main lines of direction of its mountain chains are north-east and south-west, and north-west and south-east, as if some early causes had determined the occurrence of elevations along great circles of the earth's surface tangent to the Polar circles. We are invited by the preceding general glance at the surface of the earth to ask certain questions respecting the Atlantic. (1) What has at first determined its position and form? (2) What changes has it experienced in the lapse of geological time? (3) What relations have these changes borne to the development of life on the land and in the water? (4) What is its probable future?

The Interior of the Earth.

Before attempting to answer these questions, which I shall not take up formally in succession, but rather in connection with each other, it is necessary to state as briefly as possible certain general conclusions respecting the interior of the earth. It is popularly supposed that we know nothing of this beyond a superficial crust perhaps averaging 50,000 to 100,000ft. in thickness. It is true we have no means of exploration in the earth's interior; but the conjoined labours of physicists and geologists have now proceeded sufficiently far to throw much inferential light on the subject, and to enable us to make some general affirmations with certainty; and these it is the more necessary to state distinctly, since they are often treated as mere subjects of speculation and fruitless discussion. (1) Since the dawn of geological science, it has been evident that the crust on which we live must be supported on a plastic or partially liquid mass of heated rock, approximately uniform in quality under the whole of its area. This is a legitimate conclusion from the wide distribution of volcanic phenomena, and from the fact that the ejections of volcanoes, while locally of various kinds, are similar in every part of the world. It led to the old idea of a fluid interior of the earth; but this is now generally abandoned, and this interior heated and plastic layer is regarded as merely an under-crust. (2) We have reason to believe, as the result of astronomical investigations, that, notwithstanding the plasticity or liquidity of the under-crust, the mass of the earth—its nucleus as we may call it—is practically solid and of great density and hardness. Thus we have the apparent paradox of a solid yet fluid earth; solid in its astronomical relations, liquid or plastic for the purposes of volcanic action and superficial movements. (3) The plastic sub-crust is not in a state of dry igneous fusion; but in that condition of aqueo-igneous or hydro-thermic fusion which arises from the action of heat on moist substances, and which may either be regarded as a fusion or as a species of solution at a very high temperature. This we learn from the phenomena of volcanic action, and from the composition of the volcanic and plutonic rocks, as well as from such chemical experiments as those of Daubrée, and of Tilden and Shenstone. (4) The interior sub-crust is not perfectly homogeneous, but may be roughly divided into two layers or magmas, as they have been called: an upper, highly silicious or acidic, of low specific gravity and light-coloured, and corresponding to such kinds of plutonic and volcanic rocks as granite and trachyte; and a lower, less silicious or more basic, more dense, and more highly charged with iron, and corresponding to such igneous rocks as the dolerites, basalts, and kindred lavas. It is interesting here to note that this conclusion, elaborated by Durocher and Von Waltershausen, and usually connected with their names, appears to have been first announced by John Phillips in his "Geological Manual," and as a mere common-sense deduction from the observed phenomena of volcanic action and the probable results of the gradual cooling of the earth. It receives striking confirmation from the observed succession of acidic and basic volcanic rocks of all geological periods and in all localities. It would even seem, from recent spectroscopic investigations of Lockyer, that there is evidence of a similar succession of magmas in the heavenly bodies, and the discovery by Nordenskiöld of native iron in Greenland basalts, affords a probability that the inner magma is in part metallic. (5) Where rents or fissures form in the upper crust, the material of the lower crust is forced upwards by the pressure of the less supported portions of the former, giving rise to volcanic phenomena either of an explosive or quiet character, as may be determined by contact with water. The underlying material may also be carried to the surface by the agency of heated water, producing those quiet discharges which Hunt has named crenitic. It is to be observed here that explosive volcanic phenomena, and the formation of cones, are, as Prestwich has well remarked, characteristic of an old and thickened crust; quiet ejection from fissures and hydro-thermal action may have been more common in earlier periods and with a thinner over-crust. (6) The contraction of the earth's interior by cooling and by the emission of material from below the over-crust, has caused this crust to press downwards, and therefore laterally, and so to effect great bends, folds, and plications; and these modified subsequently by surface denudation constitute mountain chains and continental plateaus. As Hall long ago pointed out, such lines of folding have been produced more especially where thick sediments had been laid down on the sea bottom. Thus we have here another apparent paradox—namely, that the elevations of the earth's crust occur in the places where the greatest burden of detritus has been laid down upon it, and where consequently the crust has been softened and depressed. We must beware, in this connection, of exaggerated notions of the extent of contraction and of crumpling required to form mountains. Bonney has well shown, in lectures delivered at the London Institution, that an amount of contraction, almost inappreciable in comparison with the diameter of the earth, would be sufficient; and that as the greatest mountain chains are less than 1,600th of the earth's radius in height, they would on an artificial globe 1ft. in diameter be no more important than the slight inequalities that might result from the paper gores overlapping each other at the edges. (7) The crushing and sliding of the over-crust implied in these movements raise some serious questions of a physical character. One of these relates to the rapidity or slowness of such movements, and the consequent degree of intensity of the heat developed, as a possible cause of metamorphism of rocks. Another has reference to the possibility of changes in the equilibrium of the earth itself as resulting from local collapse and ridging. These questions in connection with the present dissociation of the axis of rotation from the magnetic poles, and with changes of climate, have attracted some attention, and probably deserve further consideration on the part of the physicists. In so far as geological evidence is concerned, it would seem that the general association of crumpling with metamorphism indicates a certain rapidity in the process of mountain-making, and consequent development of heat, and the arrangement of the older rocks around the Arctic basin forbids us from assuming any extensive movement of the axis of rotation, though it does not exclude changes to a limited extent. I hope that Professor Darwin will discuss these points in his address to the Physical Section. I wish to formulate these principles as distinctly as possible, and as the result of all the long series of observations, calculations, and discussions since the time of Werner and Hutton, and in which a vast number of able physicists and naturalists have borne a part, because they may be considered as certain deductions from our actual knowledge, and because they lie at the foundation of a rational physical geology. We may popularise these deductions by comparing the earth to a drupe or stone-fruit, such as a plum or peach, somewhat dried up. It has a large and intensely hard stone and kernal, a thin pulp made up of two layers, an inner more dense and dark-coloured, and an outer less dense and light-coloured. These constitute the under-crust. On the outside it has a thin membrane or over-crust. In the process of drying it has slightly shrunk, so as to produce ridges and hollows of the outer crust, and this outer crust has cracked in some places, allowing portions of the pulp to ooze out—in some of these its lower dark substance, in others its upper and lighter material. The analogy extends no further, for there is nothing in our withered fruit to represent the oceans occupying the lower parts of the surface or the deposits which they have laid down. Keeping in view these general conclusions, let us now turn to their bearing on the origin and history of the North Atlantic.

The Basin of the Atlantic.

Though the Atlantic is a deep ocean, its basin does not constitute so much a depression of the crust of the earth as a flattening of it, and this, as recent soundings have shown, with a slight ridge or elevation along its middle, and banks or terraces fringing the edges, so that its form is not so much that of a basin as that of a shallow plate with its middle a little raised. Its true permanent margins are composed of portions of the over-crust folded, ridged up, and crushed, as if by lateral pressure emanating from the sea itself. We cannot, for example, look at a geological map of America without perceiving that the Appalachian ridges, which

intervene between the Atlantic and the St. Lawrence valley, have been driven bodily back by a force acting from the east, and that they have resisted this pressure only where, as in the Gulf of St. Lawrence and the Catskill region of New York, they have been protected by outlying masses of very old rocks, as, for example, by that of the island of Newfoundland and that of the Adirondack Mountains. The admirable work begun by my friend and fellow-student Prof. James Nicol, followed up by Hicks, Lapworth, and others, and now, after long controversy, fully confirmed by the recent observations of the geological survey of Scotland, has shown the most intense action of the same kind on the east side of the ocean in the Scottish highlands; and the more widely distributed Eozoic rocks of Scandinavia may be appealed to in further evidence of this. If we now inquire as to the cause of the Atlantic depression, we must go back to a time when the areas occupied by the Atlantic and its bounding coasts were parts of a shoreless sea in which the earliest gneisses or stratified granites of the Laurentian age were being laid down in vastly-extended beds. These ancient crystalline rocks have been the subject of much discussion and controversy, and as they constitute the lowest and probably the firmest part of the Atlantic sea-bed, it is necessary to inquire as to their origin and history. Dr. Bonney, the late President of the Geological Society, in his anniversary address, and Dr. Sterry Hunt, in an elaborate paper communicated to the Royal Society of Canada, have ably summed up the hypotheses as to the origin of the oldest Laurentian beds. At the bases of these hypotheses lies the admission that the immensely thick beds of orthoclase gneiss, which are the oldest stratified rocks known to us, are substantially the same in composition with the upper or siliceous magma or layer of the under-crust. They are, in short, its materials either in their primitive condition or merely rearranged. One theory considers them as original products of cooling, owing their lamination merely to the successive stages of the process. Another view refers them to the waste and rearrangement of the materials of a previously massive granite. Still another holds that all our granites really arise from the fusion of old gneisses of originally aqueous origin, while a fourth refers the gneisses themselves to molecular changes effected in granite by pressure. These several views, in so far as they relate to the oldest or fundamental Laurentian gneiss, may be arranged under the following heads: (1) *Endoplutonic*, or that which regards all the old gneisses as molten rocks cooled from without inward in successive layers. (2) *Exoplutonic*, or that which considers them as made up of matter ejected from below the upper crust in the manner of volcanic action. (3) *Metamorphic*, which supposes the old gneisses to arise from the crystallisation of detrital matter spread over the sea-bottom, and either igneous or derived from the decay of igneous rocks. (4) *Chaotic* or *Thermo-chaotic*, or the theory of deposit from the turbid waters of a primeval ocean either with or without the aid of heat. In one form this was the old theory of Werner. (5) *Crenitic* or Hydro-thermic, which supposes the action of heated waters penetrating below the crust to be constantly bringing up to the surface mineral matters in solution and depositing these so as to form felspathic and other rocks. It will be observed, in regard to these theories, that none of them supposes that the old gneiss is an ordinary sediment, but that all regard it as formed in exceptional circumstances, these circumstances being the absence of land and of sub-aërial decay of rock, and the presence wholly or principally of the material of the upper surface of the recently hardened crust. This being granted, the question arises, Ought we not to combine these several theories and to believe that the cooling crust has hardened in successive layers from without inward; that at the same time fissures were locally discharging igneous matter to the surface; that matter held in suspension in the ocean and matter held in solution by heated waters rising from beneath the outer crust were mingling their materials in the deposits of the primitive ocean? It would seem that the combination of all these agencies may safely be invoked as causes of the pre-Atlantic deposits. This is the eclectic position which I endeavoured to maintain in my address before the Minneapolis Meeting of the American Association in 1883, and which I still hold to be in every way probable.

Metamorphism.

A word here as to metamorphism, a theory which, like many others, has been first run to death and then discredited, but which to the moderate degree in which it was originally held by Lyell is still valid. Nothing can be more certain than that the composition of the Laurentian gneisses forbids us to suppose that they can be ordinary sediments metamorphosed. They are rocks peculiar in their origin, and not paralleled unless exceptionally in later times. On the other hand, they have undoubtedly experienced very important changes, more especially as to crystallisation, the state of combination of their ingredients, and the development of disseminated minerals; and while this may in part be attributed to the mechanical pressure to which they have been subjected, it requires also the action of hydrothermic agencies. Any theory which fails to invoke both of these kinds of force must necessarily be partial and imperfect. But all metamorphic rocks are not of the same character with the gneisses of the Lower Laurentian. Even in the Middle and Upper Laurentian we have metamorphic rocks—e.g., quartzite and limestone, which must originally have been ordinary aqueous deposits. Still more in the succeeding Huronian and its associated series of beds, and in the Lower Palæozoic, local metamorphic change has been undergone by rocks quite similar to those which in their unaltered state constitute regular sedimentary deposits. In the case of these later rocks it is to be borne in mind that, while some may have been of volcanic origin, others may have been sediments rich in undecomposed fragments of silicates. It is a mistake to suppose that the ordinary decay of stratified siliceous rocks is a process of kaolinisation so perfect as to eliminate all alkaline matters. On the contrary, the fact, which Judd has recently well illustrated in the case of the mud of the Nile, applies to a great number of similar deposits in all parts of the world, and shows that the finest sediments have not always been so completely lixiviated as to be destitute of the basic matters necessary for their conversion into gneiss, mica-schist, and similar rocks when the necessary agencies of metamorphism are applied to them, and this quite independently of any extraneous matters introduced into them by water or otherwise. Still, it must be steadily kept in view that many of the old pre-Cambrian crystalline rocks must have been different originally from those succeeding them, and that consequently these last, even when metamorphosed, present different characters. I may remark here that, though a palæontologist rather than a lithologist, it gives me great pleasure to find so much attention now given in this country to the old crystalline rocks, and to their study microscopically and chemically as well as in the field, a work in which Sorby and Allport were pioneers. As a pupil of the late Prof. Jameson, of Edinburgh, my own attention was early attracted to the study of minerals and rocks as the stable foundations of geological science; and as far back as 1841 I had learnt of the late Mr. Sanderson, of Edinburgh, who worked at Nicol's sections, how to slice rocks and fossils; and since that time I have been in the habit of examining everything with the microscope. The modern developments in this direction are therefore very gratifying to me, even though, as is natural, they may sometimes appear to be pushed too far or their value overestimated. That these old gneisses were deposited not only in what is now the bed of the Atlantic, but also on the great continental areas of America and Europe, anyone who considers the wide extent of these rocks represented on the map recently published by Prof. Holl can readily understand. It is true that Holl supposes that the basin of the Atlantic itself may have been land at this time, but there is no evidence of this, more especially as the material of the gneiss could not have been detritus derived from sub-aërial decay of rock.

The Cooling of the Earth.

Let us suppose, then, the floor of old ocean covered with a flat pavement of gneiss, or of that material which is now gneiss, the next question is how and when did this original bed become converted into sea and land. Here we have some things certain, others most debatable. That the cooling mass, especially if it was sending out volumes of softened rocky material, either in the exoplutonic or in the crenitic way, and piling this on the surface, must soon become too small for its shell, is apparent; but when and where would the collapse, crushing, and wrinkling inevitable from this cause begin? Where they did begin is indicated by the lines of mountain-chains which traverse the Laurentian districts; but the reason why is less apparent. The more or less unequal cooling, hardening, and conductive power of the outer crust we may readily assume. The driftage unequally of water-borne detritus to the south-west by the bottom currents of the sea is another cause, and, as we shall soon see, most effective. Still another is the greater cooling and hardening of the crust in the polar regions, and the tendency to collapse of the equatorial protuberance from the slackening of the earth's rotation. Besides these the internal tides of the earth's substance at the times of solstice would exert an oblique pulling force on the crust, which might tend to crack it along diagonal lines. From whichever of these causes, or the combination of the whole, we know that within the Laurentian time folded portions of the earth's crust began to rise above the general surface in broad belts running from N.E. to S.W., and from N.W. to S.E., where the older mountains of Eastern America and Western Europe now stand, and that the subsidence of the oceanic areas allowed by this crumpling of the crust permitted other areas on both sides of what is now the Atlantic to form limited table-lands. This was the beginning of a process repeated again and again in subsequent times, and which began in the Middle Laurentian, when for the first time we find beds of quartzite, limestone, and iron ore, and graphitic beds, indicating that there was already land and water, and that the sea, and perhaps the land, swarmed with animal and plant life of forms unknown to us, for the most part, now. Independently of the questions as to the animal nature of Eozoon, I hold that we know, as certainly as we can know anything inferentially, the existence of these primitive forms of life. If I were to conjecture what were the early forms of plant and animal life, I would suppose that just as in the Palæozoic the acrogens culminated in gigantic and complex forest trees, so in the Laurentian the algæ, the lichens, and the mosses grew to dimensions and assumed complexity of structure unexampled in later times, and that in the sea the humbler forms of Protozoa and Hydrozoa were the dominant types, but in gigantic and complex forms. The land of this period was probably limited, for the most part, to high latitudes, and its aspect, though more rugged and abrupt and of greater elevation, must have been of that character which we still see in the Laurentian hills. The distribution of this ancient land is indicated by the long lines of old Laurentian rock extending from the Labrador coast and the north shore of the St. Lawrence, and along the eastern slopes of the Appalachians in America, and the like rocks of the Hebrides, the Western Highlands, and the Scandinavian mountains. A small but interesting remnant is that in the Malvern Hills, so well described by Holl. It will be well to note here and to fix on our minds that the ancient ridges of Eastern America and Western Europe have been greatly denuded and wasted since Laurentian times, and that it is along their eastern sides that the greatest sedimentary accumulations have been deposited. From this time dates the introduction of that dominance of existing causes which forms the basis of uniformitarianism in geology, and which had to go on with various and great modifications of detail, through the successive stages of the geological history, till the land and water of the northern hemisphere attained to their present complex structure.

Growth of Continents and Seas.

So soon as we have a circumpolar belt or patches of Eozoic land and ridges running southward from it, we enter on new and more complicated methods of growth of the continents and seas. Here we are indebted to Le Conte for clearly pointing out that our original Eozoic tracts of continent were in the earliest times areas of deposition, and that the first elevations of land out of the primeval ocean must have differed in important points from all that have succeeded them; but they were equally amenable to the ordinary laws of denudation. Portions of these oldest crystalline rocks, raised out of the protecting water, were now eroded by atmospheric agents, and especially by the carbonic acid, then existing in the atmosphere perhaps more abundantly than at present, under whose influence the hardest of the gneissic rocks gradually decay. The Arctic lands were subjected in addition to the powerful mechanical force of frost and thaw. Thus every shower of rain and every swollen stream would carry into the sea the products of the waste of land, sorting them into fine clays and coarser sands; and the cold currents which cling to the ocean bottom, now determined in their courses, not merely by the earth's rotation, but also by the lines of folding on both sides of the Atlantic, would carry south-westward, and pile up in marginal banks of great thickness, the *débris* produced from the rapid waste of the land already existing in the Arctic regions. The Atlantic, opening widely to the north, and having large rivers pouring into it, was especially the ocean characterised, as time advanced, by the prevalence of these phenomena. Thus throughout the geological history it has happened that, while the middle of the Atlantic has received merely organic deposits of shells of Foraminifera and similar organisms, and this probably only to a small amount, its margins have had piled upon them beds of detritus of immense thickness. Prof. Hall, of Albany, was the first geologist who pointed out the last cosmic importance of these deposits, and that the mountains of both sides of the Atlantic owe their origin to these great lines of deposition, along with the fact, afterwards more fully insisted on by Rogers, that the portions of the crust which received these masses of *débris* became thereby weighted down and softened, and were more liable than other parts to lateral crushing. Thus in the later Eozoic and early Palæozoic times, which succeeded the first foldings of the oldest Laurentian, great ridges were thrown up, along the edges of which were beds of limestone, and on their summits and sides

thick masses of ejected igneous rocks. In the bed of the central Atlantic there are no such accumulations. It must have been a flat, or slightly-ridged, plate of the ancient gneiss, hard and resisting, though perhaps with a few cracks, through which igneous matter welled up, as in Iceland and the Azores in more modern times. In this condition of things we have causes tending to perpetuate and extend the distinctions of ocean and continent, mountain and plain, already begun; and of these we may more especially note the continued subsidence of the areas of greatest marine deposition. This has long attracted attention, and affords very convincing evidence of the connection of sedimentary deposit as a cause with the subsidence of the crust. We are indebted to a French physicist, M. Faye, for an important suggestion on this subject. It is that the sediment accumulated along the shores of the ocean presented an obstacle to radiation, and consequently to cooling of the crust, while the ocean floor, unprotected and unweighted, and constantly bathed with currents of cold water, having great power of convection of heat, would be more rapidly cooled, and so would become thicker and stronger. This suggestion is complementary to the theory of Professor Hall, that the areas of greatest deposit on the margins of the ocean are necessarily those of greatest folding and consequent elevation. We have thus a hard, thick, resisting ocean-bottom which, as it settles down toward the interior, under the influence of gravity, squeezes upward and folds and plicates all the soft sediments deposited on its edges. The Atlantic area is almost an unbroken cake of this kind. The Pacific area has cracked in many places, allowing the interior fluid matter to ooze out in volcanic ejections. It may be said that all this supposes a permanent continuance of the ocean-basins, whereas many geologists postulate a Mid-Atlantic continent to give the thick masses of detritus found in the older formations both in Eastern America and Western Europe, and which thin off in proceeding into the interior of both continents. I prefer, with Hall, to consider these belts of sediment as in the main the deposits of northern currents, and derived from Arctic land, and that like the great banks of the American coast at the present day, which are being built up by the present Arctic current, they had little to do with any direct drainage from the adjacent shore. We need not deny, however, that such ridges of land as existed along the Atlantic margins were contributing their quota of river-borne material, just as on a still greater scale the Amazon and Mississippi are doing now, and this especially on the sides toward the present continental plateaus, though the greater part must have been derived from the wide tracts of Laurentian land within the Arctic Circle or near to it. It is further obvious that the ordinary reasoning respecting the necessity of continental areas in the present ocean basins would actually oblige us to suppose that the whole of the oceans and continents had repeatedly changed places. This consideration opposes enormous physical difficulties to any theory of alternations of the oceanic and continental areas, except locally at their margins. I would, however, refer you for a more full discussion of these points to the address to be delivered to-morrow by the president of the Geological Section. But the permanence of the Atlantic depression does not exclude the idea of successive submergences of the continental plateaus and marginal slopes, alternating with periods of elevation, when the ocean retreated from the continents and contracted its limits. In this respect the Atlantic of to-day is much smaller than it was in those times when it spread widely over the continental plains and slopes, and much larger than it has been in times of continental elevation. This leads us to the further consideration that, while the ocean-beds have been sinking, other areas have been better supported, and constitute the continental plateaus; and that it has been at or near the junctions of these sinking and rising areas that the thickest deposits of detritus, the most extensive foldings, and the greatest ejections of volcanic matter have occurred. There has thus been a permanence of the position of the continents and oceans throughout geological time, but with many oscillations of these areas, producing submergencies and emergencies of the land. In this way we can reconcile the vast vicissitudes of the continental areas in different geological periods with that continuity of development from north to south, and from the interiors to the margins, which is so marked a feature. We have for this reason to formulate another apparent geological paradox—namely, that while in one sense the continental and oceanic areas are permanent, in another they have been in continual movement. Nor does this view exclude extension of the continental borders or of chains of islands beyond their present limits at certain periods; and, indeed, the general principle already stated, that subsidence of the ocean bed has produced elevation of the land, implies in earlier periods a shallower ocean and many possibilities as to volcanic islands, and low continental margins creeping out into the sea; while it is also to be noted that there are, as already stated, bordering shelves, constituting shallows in the ocean, which at certain periods have emerged as land. We are thus compelled to believe in the contemporaneous existence in all geological periods, except perhaps the earliest of them, of three distinct conditions of areas on the surface of the earth. (1) Oceanic areas of deep sea, which always continued to occupy in whole or in part the bed of the present ocean. (2) Continental plateaus and marginal shelves, existing as low flats or higher table-lands liable to periodical submergence and emergence. (3) Lines of plication and folding, more especially along the borders of the oceans, forming elevated portions of land, rarely altogether submerged, and constantly affording the material of sedimentary accumulations, while they were also the seats of powerful volcanic ejections. In the successive geological periods the continental plateaus, when submerged, owing to their vast extent of warm and shallow sea, have been the great theatres of the development of marine life and of the deposition of organic limestones, and when elevated they have furnished the abodes of the noblest land faunas and floras. The mountain belts, especially in the north, have been the refuge and stronghold of land life in periods of submergence, and the deep ocean basins have been the perennial abodes of pelagic and abyssal creatures, and the refuge of multitudes of other marine animals and plants in times of continental elevation. These general facts are full of importance with reference to the question of the succession of formations and of life in the geological history of the earth.

The History of the Atlantic.

So much time has been occupied with these general views that it would be impossible to trace the history of the Atlantic in detail through the ages of the Palæozoic, Mesozoic, and Tertiary. We may, however, shortly glance at the changes of the three kinds of surface already referred to. The bed of the ocean seems to have remained on the whole abyssal, but there were probably periods when those shallow reaches of the Atlantic which stretch across its most northern portion, and partly separate it from the Arctic basin, presented connecting coasts or continuous chains of islands sufficient to permit animals and plants to pass over. At certain periods also there were not unlikely groups of volcanic islands, like the Azores, in the temperate and tropical Atlantic. More especially might this be the case in that early time when it was more like the present Pacific; and the line of the great volcanic belt of the Mediterranean, the mid-Atlantic banks, the Azores, and the West India Islands point to the possibility of such partial connections. These were stepping-stones, so to speak, over which land organisms might cross, and some of these may be connected with the fabulous or prehistoric Atlantic. In the Cambrian and Ordovician periods the distinctions, already referred to, into continental plateaus, mountain ridges, and ocean depths were first developed, and we find already great masses of sediment accumulating on the seaward sides of the old Laurentian ridges, and internal deposits thining away from these ridges over the submerged continental areas, and presenting very dissimilar conditions of sedimentation. It would seem also that, as Hicks has argued for Europe, and Logan and Hall for America, this Cambrian age was one of slow subsidence of the land previously elevated, accompanied with or caused by thick deposits of detritus along the borders of the subsiding land, which was probably covered with the decomposing rock arising from long ages of sub-aërial waste. In the coal-formation age, its characteristic swampy flats stretched in some places far into the shallower parts of the ocean. In the Jurassic the American continent probably extended further to sea than at present. In the Wealden age there was much land to the west and north of Great Britain, and Professor Bonney has directed attention to the evidence of the existence of this land as far back as the Trias, while Mr. Starkie Gardiner has insisted on connecting links to the southward as evidenced by fossil plants. So late as the Post-Glacial, or early human period, large tracts now submerged formed portions of the continents. On the other hand the internal plains of America and Europe were often submerged. Such submergencies are indicated by the great limestones of the Palæozoic, by the chalk and its representative beds in the Cretaceous, by the Nummulitic formation in the Eocene, and lastly by the great Pleistocene submergence, one of the most remarkable of all, one in which nearly the whole northern hemisphere participated, and which was probably separated from the present time by only a few thousands of years. These submergencies and elevations were not always alike on the two sides of the Atlantic. The Salina period of the Silurian, for example, and the Jurassic, show continental elevation in America not shared by Europe. The great subsidences of the Cretaceous and the Eocene were proportionally deeper and wider on the eastern continent, and this and the direction of the land being from north to south cause more ancient forms of life to survive in America. These elevations and submergences of the plateaus alternated with the periods of mountain-making plication, which was going on at intervals at the close of the Eozoic, at the beginning of the Cambrian, at the close of the Siluro-Cambrian, in the Permian, and in Europe and Western America in the Tertiary. The series of changes, however, affecting all these areas was of a highly complex character, and embraces the whole physical history of the geological ages. We may note here that the unconformities caused by these movements and by subsequent denundation constitute what Le Conte has called "lost intervals," one of the most important of which is supposed to have occurred at the end of the Eozoic. It is to be observed, however, that as every such movement is followed by gradual subsidence, the seeming loss is caused merely by the overlapping of the successive beds deposited. We may also note a fact which I have long ago insisted on, the regular pulsations of the continental areas, giving us alternations in each great system of formations of deep-sea and shallow-water beds, so that the successive groups of formations may be divided into triplets of shallow-water, deep-water, and shallow-water strata, alternating in each period. But I must here call you attention to still another geological paradox —namely, that the deep sea, which is so great a barrier to the passage of the shallow-water animals, seems, under certain conditions, to afford facilities for the transmission of land animals and plants. The connections established by the observations of the *Challenger*, and so well expounded by Wallace and Hemsley, between the floras of oceanic islands and the continents establish this conclusively. Thus the Bermudas, altogether recent islands, have been stocked, by the agency chiefly of the ocean currents and of birds, with nearly 150 species of continental plants, and the facts collected by Hemsley as to the present facilities of transmission, along with the evidence afforded by older oceanic islands which have been receiving animal and vegetable colonists for longer periods, go far to show that, time being given, the sea actually affords facilities for the migrations of the inhabitants of the land greater than those of continuous continents.

The Climate of the Atlantic.

We can scarcely doubt that the close connection of the Atlantic and Arctic oceans is one factor in those remarkable vicissitudes of climate experienced by the former, and in which the Pacific area has also shared in connection with the Antarctic Sea. No geological facts are indeed at first sight more strange and inexplicable than the changes of climate in the Atlantic area, even in comparatively modern periods. We know that in the early Tertiary perpetual summer reigned as far north as the middle of Greenland, and that in the Pleistocene the arctic cold advanced, until an almost perennial winter prevailed, half way to the equator. It is no wonder that nearly every cause available in the heavens and the earth has been invoked to account for these astounding facts. It will, I hope, meet with the approval of your veteran glaciologist, Dr. Crosskey, if, neglecting most of these theoretical views, I venture to invite your attention in connection with this question chiefly to the old Lyellian doctrine of the modification of climate by geographical changes. Let us, at least, consider how much these are able to account for. The ocean is a great equaliser of extremes of temperature. It does this by its great capacity for heat and by its cooling and heating power when passing from the solid into the liquid and gaseous states, and the reverse. It also acts by its mobility, its currents serving to convey heat to greater distances or to cool the air by the movement of cold, icy waters. The land, on the other hand, cools or warms rapidly, and can transmit its influence to a distance only by the winds, and the influence so transmitted is rather in the nature of a disturbing than an equalising cause. It follows that any change in the distribution of land and water must affect climate, more especially if it changes the character or course of the ocean currents. At the present time the North Atlantic presents some very peculiar and in some respects exceptional features, which are most instructive with reference to its past history. The great internal plateau of the American continent is now dry land; the passage across Central America between the Atlantic and Pacific is blocked; the Atlantic opens very widely to the north; the high mass of Greenland towers in its northern part. The effects are that the great equatorial current running across from Africa, and embayed in the Gulf of Mexico, is thrown northward and eastward in the Gulf Stream, acting as a hot-water apparatus to heat up to an exceptional degree the western coast of Europe. On the other hand, the cold Arctic current from the Polar seas is thrown to the westward, and runs down from Greenland past the American shore. The pilot chart for June of this

year shows vast fields of drift ice on the western side of the Atlantic as far south as the latitude of 40°. So far, therefore, the Glacial Age in that part of the Atlantic still extends; this at a time when, on the eastern side of the ocean, the culture of cereals reaches in Norway beyond the Arctic Circle. Let us inquire into some of the details of these phenomena. The warm water thrown into the North Atlantic not only increases the temperature of its whole waters, but gives an exceptionally mild climate to Western Europe. Still, the countervailing influence of the Arctic currents and the Greenland ice is sufficient to permit icebergs which creep down to the mouth of the Strait of Belle Isle, in the latitude of the south of England, to remain unmelted till the snows of a succeeding winter fall upon them. Now let us suppose that a subsidence of land in tropical America were to allow the equatorial current to pass through into the Pacific. The effect would at once be to reduce the temperature of Norway and Britain to that of Greenland and Labrador at present, while the latter countries would themselves become colder. The northern ice, drifting down into the Atlantic, would not, as now, be melted rapidly by the warm water which it meets in the Gulf Stream. Much larger quantities of it would remain undissolved in summer, and thus an accumulation of permanent ice would take place, along the American coast at first, but probably at length even on the European side. This would still further chill the atmosphere, glaciers would be established on all the mountains of temperate Europe and America, the summer would be kept cold by melting ice and snow, and at length all Eastern America and Europe might become uninhabitable, except by arctic animals and plants, as far south as perhaps 40° of north latitude. This would be simply a return of the Glacial age. I have assumed only one geographical change; but other and more complete changes of subsidence and elevation might take place with effects on climate still more decisive; more especially would this be the case if there were a considerable submergence of the land in temperate latitudes. We may suppose an opposite case. The high plateau of Greenland might subside or be reduced in height, and the openings of Baffin's Bay and the North Atlantic might be closed. At the same time the interior plain of America might be depressed, so that, as we know to have been the case in the Cretaceous period, the warm waters of the Mexican Gulf would circulate as far north as the basins of the present great American lakes. In these circumstances there would be an immense diminution of the sources of floating ice, and a correspondingly vast increase in the surface of warm water. The effects would be to enable a temperate flora to subsist in Greenland, and to bring all the present temperate regions of Europe and America into a condition of subtropical verdure.

The Glacial Period.

We have in America ancient periods of cold as well as warmth. I have elsewhere referred to the boulder conglomerates of the Huronian, of the Cambrian and Ordovician, of the Millstone-grit period of the Carboniferous and of the early Permian; but would not venture to affirm that either of these periods was comparable in its cold with the later glacial age, still less with that imaginary age of continental glaciation assumed by certain of the more extreme theorists. These ancient conglomerates were probably produced by floating ice, and this at periods when in areas not very remote temperate floras and faunas could flourish. The glacial periods of our old continent occurred in times when the surface of the submerged land was opened up to the northern currents, drifting over it mud, and sand, and stones, and rendering nugatory, in so far, at least, as the bottom of the sea was concerned, the effects of the superficial warm streams. Some of these beds are also peculiar to the eastern margin of the continent, and indicate ice-drift along the Atlantic coast in the same manner as at present, while conditions of greater warmth existed in the interior. Even in the more recent Glacial age, while the mountains were covered with snow and the lowlands submerged under a sea laden with ice, there were interior tracts in somewhat high latitudes of America in which hardy forest trees and herbaceous plants flourished abundantly; and these were by no means exceptional "interglacial" periods. Thus we can show that while from the remote Huronian period to the Tertiary the American land occupied the same position as at present, and while its changes were merely changes of relative level as compared with the sea, these have so influenced the ocean currents as to cause great vicissitudes of climate. Without entering on any detailed discussion of that last and greatest Glacial period which is best known to us, and is more immediately connected with the early history of man and the modern animals, it may be proper to make a few general statements bearing on the relative importance of sea-borne and land ice in producing those remarkable phenomena attributable to ice action in this period. In considering this question it must be borne in mind that the greater masses of floating ice are produced at the seaward extremities of land glaciers, and that the heavy field-ice of the Arctic regions is not so much a result of the direct freezing of the surface of the sea as of the accumulation of snow precipitated on the frozen surface. In reasoning on the extent of ice action, and especially of glaciers in the Pleistocene age, it is necessary to keep this fully in view. Now in the formation of glaciers at present—and it would seem also in any conceivable former state of the earth—it is necessary that extensive evaporation should conspire with great condensation of water in the solid form. Such conditions exist in mountainous regions sufficiently near to the sea, as in Greenland, Norway, the Alps, and the Himalayas; but they do not exist in low Arctic lands like Siberia or Grinnel-land nor in inland mountains. It follows that land glaciation has narrow limits, and that we cannot assume the possibility of great confluent and continental glaciers covering the interior of wide tracts of land. No imaginable increase of cold could render this possible, inasmuch as there could not be a sufficient influx of vapour to produce the necessary condensation; and the greater the cold, the less would be the evaporation. On the other hand, any increase of heat would be felt more rapidly in the thawing and evaporation of land ice and snow than on the surface of the sea. Applying these very simple geographical truths to the North Atlantic continents, it is easy to see that no amount of refrigeration could produce a continental glacier, because there could not be sufficient evaporation and precipitation to afford the necessary snow in the interior. The case of Greenland is often referred to, but this is the case of a high mass of cold land with sea, mostly open on both sides of it, giving, therefore, the conditions most favourable to precipitation of snow. If Greenland were less elevated, or if there were dry plains around it, the case would be quite different, as Nares has well shown by his observations on the summer verdure of Grinnel-land, which, in the immediate vicinity of North Greenland, presents very different conditions as to glaciation and climate. If the plains were submerged, and the Arctic currents allowed free access to the interior of the continent of America, it is conceivable that the mountainous regions remaining out of water would be covered with snow and ice, and there is the best evidence that this actually occurred in the Glacial period; but with the plains out of water this would be impossible. We see evidence of this at the present day in the fact that in unusually cold winters the great precipitation of snow takes place south of Canada, leaving the north comparatively bare, while as the temperature becomes milder the area of snow-deposit moves further to the north. Thus a greater extension of the Atlantic, and especially of its cold ice-laden Arctic currents, becomes the most potent cause of a glacial age. I have long maintained these conclusions on general geographical grounds, as well as on the evidence afforded by the Pleistocene deposits of Canada; and in an address the theme of which is the ocean I may be excused for continuing to regard the supposed terminal moraines of great continental glaciers as nothing but the southern limit of the ice-drift of a period of submergence. In such a period the southern margin of an ice-laden sea where its floe-ice and bergs grounded, or where its ice was rapidly melted by warmer water, and where consequently its burden of boulders and other *débris* was deposited, would necessarily present the aspect of a moraine, which by the long continuance of such conditions might assume gigantic dimensions. Let it be observed, however, that I fully admit the evidence of the great extension of local glaciers in the Pleistocene age, and especially in the times of partial submergence of the land. I am quite aware that it has been held by many able American geologists that in North America a continental glacier extended in temperate latitudes from sea to sea, or at least from the Atlantic to the Rocky Mountains, and that this glacier must, in many places, have exceeded a mile in thickness. The reasons above stated appear, however, sufficient to compel us to seek for some other explanation of the observed facts, however difficult this may at first sight appear.

Transmission of Animal Life Across the Ocean.

With reference to the transmission of living beings across the Atlantic, we have before us the remarkable fact that from the Cambrian age onwards there were on the two sides of the ocean many species of invertebrate animals which were either identical or so closely allied as to be possibly varietal forms. In like manner the early plants of the Upper Silurian, Devonian, and Carboniferous present many identical species; but this identity becomes less marked in the vegetation of the more modern times. In so far as plants are concerned, it is to be observed that the early forests were largely composed of cryptogamous plants, and the spores of these in modern times have proved capable of transmission for great distances. In considering this we cannot fail to conclude that the union of simple cryptogamous fructification with arboreal stems of high complexity, so well illustrated by Dr. Williamson, had a direct relation to the necessity for a rapid and wide distribution of these ancient trees. It seems also certain that some spores, as, for example, those of the Rhizocarps, a type of vegetation abundant in the Palæozoic, and certain kinds of seeds, as those named *Ætheotesta* and *Pachytheca*, were fitted for flotation. Further, the periods of Arctic warmth permitted the passage around the northern belt of many temperate species of plants, just as now happens with the Arctic flora; and when these were dispersed by colder periods they marched southward along both sides of the sea on the mountain chains. The same remark applies to northern forms of marine invertebrates, which are much more widely distributed in longitude than those further south. The late Mr. Gwyn Jeffreys, in one of his latest communications to this Association, stated that 54 per cent. of the shallow-water mollusks of New England and Canada are also European, and of the deep-sea forms 30 out of 35; these last, of course, enjoying greater facilities for migration than those which have to travel slowly along the shallows of the coasts in order to cross the ocean and settle themselves on both sides. Many of these animals, like the common mussel and sand clam, are old settlers which came over in the Pleistocene period, or even earlier. Others, like the common periwinkle, seem to have been slowly extending themselves in modern times, perhaps even by the agency of man. The older immigrants may possibly have taken advantage of lines of coast now submerged, or of warm periods, when they could creep around by the Arctic shores. Mr. Herbert Carpenter and other naturalists employed on the *Challenger* collections have made similar statements respecting other marine invertebrates, as, for instance, the Echinoderms, of which the deep-sea crinoids present many common species, and my own collections prove that many of the shallow-water forms are common. Dall and Whiteaves have shown that some mollusks and Echinoderms are common even to the Atlantic and Pacific coasts of North America; a remarkable fact, testifying at once to the fixity of these species and to the manner in which they have been able to take advantage of geological changes. Some of the species of whelks common to the Gulf of St. Lawrence and Pacific are animals which have no special locomotive powers even when young, but they are northern forms not proceeding far south, so that they may have passed through the Arctic seas. In this connection it is well to remark that many species of animals have powers of locomotion in youth, which they lose when adult, and that others may have special means of transit. I once found at Gaspé a specimen of the Pacific species of Coronula, or whale-barnacle, the *C. reginæ* of Darwin, attached to a whale taken in the Gulf of St. Lawrence, and which had probably succeeded in making that passage around the north of America which so many navigators have essayed in vain. It is to be remarked here that while many plants and marine invertebrates are common to the two sides of the Atlantic, it is different with land animals, and especially vertebrates. I do not know that any fossil insects or land snails or millipedes of Europe and America are specifically identical, and of the numerous species of batrachians of the Carboniferous and reptiles of the Mesozoic all seem to be distinct on the two sides. The same appears to be the case with the Tertiary mammals, until in the later stages of that great period we find such genera as the horse, the camel, and the elephant appearing on two sides of the Atlantic; but even the species seem different, except in the case of a few northern forms. Some of the longer-lived mollusks of the Atlantic furnish suggestions which remarkably illustrate the biological aspect of these questions. Our familiar friend the oyster is one of these. The first known oysters appear in the Carboniferous in Belgium and in the United States of America. In the Carboniferous and Permian they are few and small, and they do not culminate till the Cretaceous, in which there are no less than 91 so-called species in America alone; but some of the largest known species are found in the Eocene. The oyster, though an inhabitant of shallow water, and very limitedly locomotive when young, has survived all the changes since the Carboniferous age, and has spread itself over the whole northern hemisphere. I have collected fossil oysters in the Cretaceous clays of the coulées of Western Canada, in the lias shales of England, in the Eocene and Cretaceous beds of the Alps, of Egypt, of the Red Sea, of Judea, and the heights of Lebanon. Everywhere and in all formations they present forms which are so variable and yet so similar that one might suppose all the so-called species to be mere varieties. Did the oyster

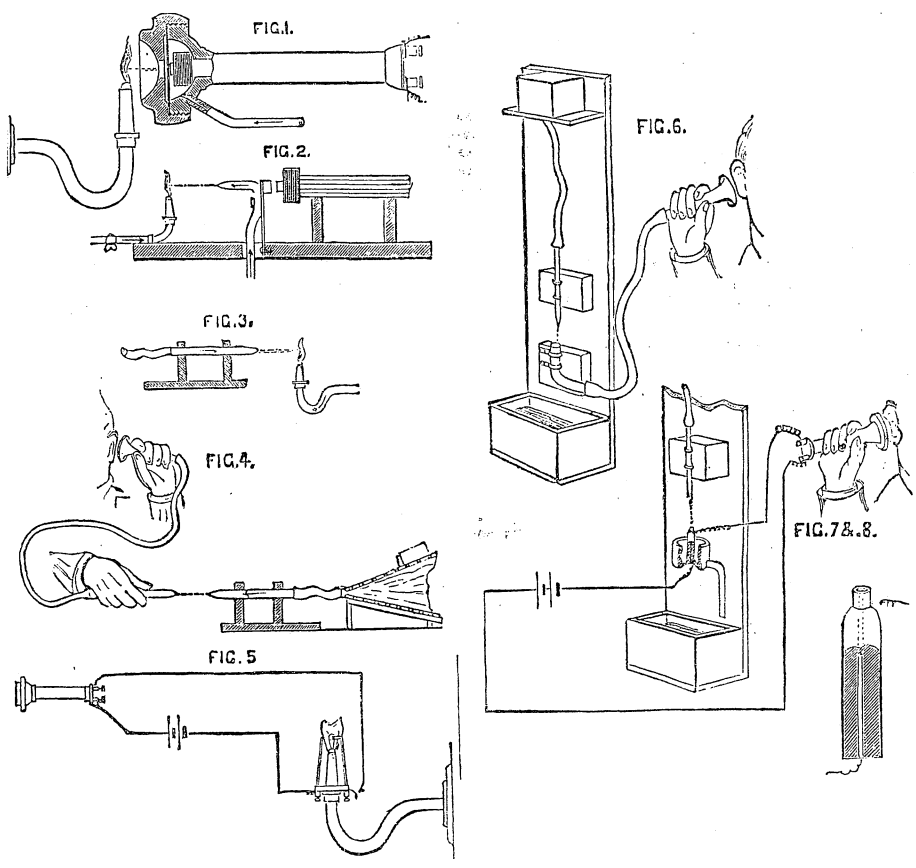
originate separately on the two sides of the Atlantic, or did it cross over so promptly that its appearance seems to be identical on the two sides? Are all the oysters of a common ancestry, or did the causes, whatever they were, which introduced the oyster in the Carboniferous act over again in late periods? Who can tell? This is one of the cases where causation and development —the two scientific factors which constitute the basis of what is vaguely called evolution—cannot easily be isolated. I would recommend to those biologists who discuss these questions to addict themselves to the oyster. This familiar mollusk has successfully pursued its course and has overcome all its enemies, from the flat-toothed selachians of the Carboniferous to the oyster-dredgers of the present day, has varied almost indefinitely, and yet has continued to be an oyster, unless, indeed, it may at certain portions of its career have temporarily assumed the disguise of a Gryphæa or an Exogyra. The history of such an animal deserves to be traced with care, and much curious information respecting it will be found in the report which I have cited. But in these respects the oyster is merely an example of many forms. Similar considerations apply to all those Pliocene and Pleistocene mollusks which are found in the raised sea-bottoms of Norway and Scotland, on the top of Moel Tryfaen in Wales, and at similar great heights on the hills of America, many of which can be traced back to early Tertiary times, and can be found to have extended themselves over all the seas of the northern hemisphere. They apply in like manner to the ferns, the conifers, and the angiosperms, many of which we can now follow without even specific change to the Eocene and Cretaceous. They all show that the forms of living things are more stable than the lands and seas in which they live. If we were to adopt some of the modern ideas of evolution, we might cut the Gordian knot by supposing that, as like causes can produce like effects, these types of life have originated more than once in geological time, and need not be genetically connected with each other. But while evolutionists repudiate such an application of their doctrine, however natural and rational, it would seem that nature still more strongly repudiates it, and will not allow us to assume more than one origin for one species. Thus the great question of geographical distribution remains in all its force, and, by still another of our geological paradoxes, mountains become ephemeral things in comparison with the delicate herbage which covers them, and seas are in their present extent but of yesterday when compared with the minute and feeble organisms that creep on their sands or swim in their waters.

Destiny of the Atlantic.

The question remains, Has the Atlantic achieved its destiny and finished its course, or are there other changes in store for it in the future? The earth's crust is now thicker and stronger than ever before, and its great ribs of crushed and folded rock are more firm and rigid than in any previous period. The stupendous volcanic phenomena manifested in Mesozoic and early Tertiary times along the borders of the Atlantic have apparently died out. These facts are in so far guarantees of permanence. On the other hand, it is known that movements of elevation along with local depression are in progress in the Arctic regions, and a great weight of new sediment is being deposited along the borders of the Atlantic, especially on its western side, and this is not improbably connected with the earthquake shocks and slight movements of depression which have occurred in North America. It is possible that these slow and secular movements may go on uninterruptedly until considerable changes are produced; but it is quite as likely that they may be retarded or reversed. It is possible, on the other hand, that after the long period of quiescence which has elapsed there may be a new settlement of the ocean-bed, accompanied with foldings of the crust, especially on the western side of the Atlantic, and possibly with renewed volcanic activity on its eastern margin. In either case a long time relatively to our limited human chronology may intervene before the occurrence of any marked change. On the whole the experience of the past would lead us to expect movements and eruptive discharges in the Pacific rather than in the Atlantic area. It is therefore not unlikely that the Atlantic may remain undisturbed, unless secondarily and indirectly, until after the Pacific area shall have attained to a greater degree of quiescence than at present. But this subject is one too much involved in uncertainty to warrant us in following it further. In the meantime the Atlantic is to us a practically permanent ocean, varying only in its tides, its currents, and its winds, which science has already reduced to definite laws, so that we can use if we cannot regulate them. It is ours to take advantage of this precious time of quietude, and to extend the blessings of science and of our Christian civilisation from shore to shore until there shall be no more sea, not in the sense of that final drying-up of old ocean to which some physicists look forward, but in the higher sense of its ceasing to be the emblem of unrest and disturbance; and the cause of isolation. I must now close this address with a short statement of the general objects which I have had in view in directing your attention to the geological development of the Atlantic. We cannot, I think, consider the topics to which I have referred without perceiving that the history of ocean and continent is an example of progressive design, quite as much as that of living beings. Nor can we fail to see that, while in some important directions we have penetrated the great secret of Nature, in reference to the general plan and structure of the earth and its waters, and the changes through which they have passed, we have still very much to learn, and perhaps quite as much to unlearn, and that the future holds out to us and to our successors higher, grander, and clearer conceptions than those to which we have yet attained. The vastness and the might of ocean, and the manner in which it cherishes the feeblest and most fragile beings, alike speak to us of Him who holds it in the hollow of His hand, and gave to it of old its boundaries and its laws; but its teaching ascends to a higher tone when we consider its origin and history, and the manner in which it has been made to build up continents and mountain chains, and at the same time to nourish and sustain the teeming life of sea and land.

SYMPATHETIC VIBRATION OF JETS —THE GRAPHOPHONE.

WE have already called attention to the investigations of Prof. Graham Bell and Mr. Chichester Bell, who, with Mr. Taintor, have recently obtained patents throughout the world for their "graphophone," as it is called, and we now give an abstract of the paper which Mr. C. A. Bell read before the Royal Society. Mr. Bell states that his attention was directed to the subject by the accidental observation that a pulsating air jet directed against a flame caused the latter to emit a musical sound. The pitch of this sound depended solely on the rapidity of the jet pulsations; but its intensity was found to increase in a remarkable way with the distance of the flame from the orifice. In order to study the phenomenon, air was allowed to escape against the flame from a small orifice in the diaphragm of an ordinary telephone, the chamber behind the diaphragm being placed in communication with a reservoir of air under gentle pressure (Fig. 1). Vibratory motions being then excited in the diaphragm, by means of a battery and a microphone or rheotome in a distant apartment, the discovery was made that speech as well as musical and other sounds could be quite loudly reproduced from the flame. Certain observations led the author to suspect that motion of the orifice, rather than compression of the air in the chamber, was the chief agent in the phenomenon; and, in fact, precisely similar results were obtained when a light glass jet tube was cemented to a soft iron armature, mounted on a spring in front of the telephone magnet (Fig. 2). Experiment also showed that an air jet at suitable pressure directed against a flame repeats all sounds or words uttered in the neighbourhood (Fig. 3). Except, however, where the impressed vibrations do not differ widely in pitch from the normal vibrations of the jet (discovered by Sondhauss and Masson), these effects are likely to escape notice, owing to the inability of the ear to distinguish between the disturbing sounds and their echo-like reproduction from the flame. In these experiments the primary action of the impressed vibrations was undoubtedly exerted on the air jet; but a singular and perplexing fact was that no sound, or at best very faint sounds, could be heard from the latter when the flame was removed, and the ear, or the end of a wide tube connected with the ear, was substituted for it. Suspecting, finally, that the changes in the jet, effective in producing sound from the flame, must be relative changes of different parts of it, the author was led to try a very small hearing orifice, about as large as the jet orifice (Fig. 4). The results were most striking. By introducing this little hearing orifice into the path of a vibrating air jet, the vibrations can be heard over a very wide area. Close to the jet orifice they are so faint as to be scarcely audible; but they increase in intensity in a remarkable way as the hearing orifice is moved away along the axis of the jet, and reach their maximum at a certain distance. Experiments with smoked air showed that this point of maximum sound is that at which the jet loses its rod-like character, and expands rapidly; it has been named the "breaking point," because just beyond it the sounds heard from the jet acquire a broken or rattling character, and at a greater distance are completely lost. The distance of the breaking point from the orifice diminishes as the intensity of the disturbing vibrations is increased, and also depends to some extent on their pitch and on the velocity of the jet. With orifices of from 1mm. to 1.5mm. in diameter, it usually varies from 1cm. to 6cm. The vibrations of an air jet may also be heard at points not situated on the axis; but they are always most intense along the axis, and become rapidly fainter as the distance from it increases.

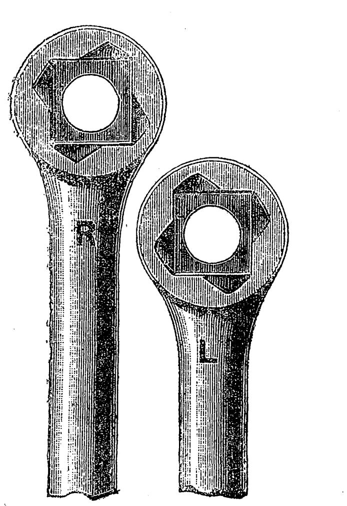


When a vibrating air jet plays against a small flame, the best sounds are heard when the stream strikes the flame just below the apex of the blue zone. At the point of contact an intensely blue flame ring appears, and this ring vibrates visibly when the jet is disturbed. The production of sound from it doubtless depends on changes in the

rate of the combustion of the gas. This may be proved by inserting into the ring a fine slip of platinum, connected in circuit with a battery and telephone shown in Fig. 5. When the jet is thrown into vibration, the consequent variations in the temperature of the platinum affect its conductivity, and hence a feeble reproduction of the jet vibration may be heard in the telephone. In order to assist the action of aërial sound waves on the fluid, it is advisable to attach the jet tube rigidly to a pine soundboard about ⅜in. thick. The surfaces of the board should be free, otherwise it may be supported in any way. The receiving membrane is formed by a piece of thin sheet rubber tied over the end of a brass tube about ⅜in. in internal diameter. A wide flexible hearing tube, furnished with an ear-piece, is attached to the brass tube. The jet tube is connected with an elevated reservoir by an india-rubber pipe, indicated in Fig. 6; with an apparatus of this kind and a tolerably wide jet tube, having an orifice about 0·7mm. in diameter, a pressure of about 15 decimètres of water is required to bring the jet into condition to respond to all the tones and overtones of the speaking voice (except hissing sounds) and those employed in music. At a somewhat higher pressure it will reproduce hissing sounds. To get an accurate and faithful reproduction of the jet vibrations, it is simply necessary to insert into the nappe two platinum electrodes in circuit with a telephone and a battery having an electromotive force of from 12 to 30 volts. Loud sounds can thus be obtained from a jet which is finer than the finest needle, and the arrangement constitutes a highly sensitive "transmitter," shown in Figs. 7 and 8. The foregoing are little more than the outlines of a new theory of jet vibrations. The author hopes to supply in the future further experimental evidence in support of it.

A WRENCH WITH LIFTING CAMS.

THE wrench shown in the annexed engraving has been recently patented in the United States by Mr. A. Wood, of Trenton, New Jersey, and has some features which will commend it to



the attention of those who have frequent occasion to use the wrench or spanner.

The opposite sides of the socket are, it will be seen, formed with cams to act against a nut to lift the wrench between successive turns, thus making a tool which can be used conveniently in place of a ratchet wrench. The square corners or faces which abut against the nut to turn it in one direction are adapted for making a right hand turn on one side of the tool, while the other side has these square corners adapted for making a left hand turn, the withdrawing or backward movement of the wrench being in each case aided by the cams at the corners of the socket adjacent to each angular face that bites on the nut. With this wrench it is only required to move the hand back and forth as the cams lift the wrench to the top of the nut upon the back stroke, and gravity causes it to drop again over the nut.

A BRITISH Iron Trade Association return of the production of Bessemer steel ingots in the United Kingdom during the half-year ending the 30th June, 1886, compared with that for the corresponding half of the previous year, shows a net increase of make in 1886 of 89,565 tons.

THE production of open-hearth steel ingots during 1885 was 583,918 tons; the production for the first half of 1886 is at the rate of 94,552 tons per annum in excess of the production of 1885. This increase has again, as in 1885, chiefly taken place in the Cleveland district.

SCIENTIFIC NEWS.

THE death is announced of Frederick Settle Barff, whose chemical works and Cantor Lectures have made his name widely known. The deceased, who was born at Hackney in 1823, was at one time curate of St. Nicholas, Leicester; but his religious convictions caused a complete change in his career, and in 1864 he took up the study of chemistry under Dr. Williamson at University College, at which institution he became assistant professor of chemistry, and subsequently Professor of Chemistry at the Royal Academy. He also filled the similar post in the Catholic University College at Kensington, and in the Jesuits' College, Beaumont. The late Prof. Barff made his name more widely known by the method of preventing iron from rusting by producing a coat of magnetic or black oxide on its surface, and his discovery of the antiseptic properties of boroglyceride has been of world-wide usefulness. The secret of kreochyle, we understand, has died with him; but it is known to be a solution of pure albumen, of great value in the sick-room.

The death is also announced of Alexander Krapotkin, at Tomsk, at the age of forty-five. He had translated into Russian "The Principles of Biology" of Herbert Spencer, Page's "Philosophy of Geology," Maxwell's "Theory of Heat," and for several years contributed to Russian periodicals reviews of the progress of physical astronomy, much prized by Russian astronomers. In 1874 he was exiled to Minusinsk, in E. Siberia, and there he helped Dr. Martianoff in organising a local museum, and carried on for several years meteorological observations. When at Minusinsk, and later on, at Tomsk, he busily worked at a great astronomical undertaking, in which he submitted to a strongly scientific criticism all our present knowledge on the structure of the stellar systems and the architectonics of the stellar groups. Every known source was ransacked for data, but Krapotkin was unable to bring his work down to a later date than 1879.

The death is reported from Kazan of the St. Petersburg Professor of Chemistry, A. M. Boutlerof, honourably known for his investigations on organic compounds, his papers in the *Annalen für Physik und Chemie*, the *Zeitschrift für Chemie*, &c., and his efforts in behalf of the higher education of women.

The eclipse of the sun seems to have been observed with a fair measure of success at Grenada. According to a telegram, good photometric observations were made by Prof. Thorpe. The light during the middle of totality was less than from the full moon. Good corona pictures were taken by Captain Darwin and by Dr. Schuster.

Dr. Dreyer has published a "Second Armagh Catalogue," containing the places of 3,300 stars determined from the observations of 1864—1883.

Dr. R. Engelmann, of Leipsic, has published in *Astronomische Nachrichten* a series of double-star measures, consisting mainly of those made by him in 1885.

With reference to the photograph of the lightning flash which we engraved and reproduced on p. 569, last week, we are requested by Mr. H. Schleusner, of Antwerp, to state that the negative was taken by Mr. E. B. Vignoles and himself.

Prof. Peters, of Clinton, N.Y., has named the small planet discovered by him on June 28 Aletheia. It is No. 259 in the general list.

Earthquakes and volcanic eruptions have apparently as much influence on the weather as sunspots. A curious result of the volcanic eruption in New Zealand (according to the *Colonies and India*) is alleged to have been found in the sudden breaking up of the drought in Australia. It is said that the great Java earthquake of 1883 was the immediate forerunner of a long spell of dry weather in Queensland in that year, and that a welcome fall of rain in the same colony followed immediately upon the eruption of Mount Tarawera.

In connection with the British Association, now in session at Birmingham, it may be mentioned that altogether twenty-seven excursions have been arranged for the Saturday and Thursday, Sept. 4 and 9. The most important of these will extend from the 9th to the 15th, and will consist of a geological excursion to the Lower Palæozoic district of Shropshire, under the leadership of Prof. Lapworth.

An important and remarkable discovery in synthetical chemistry has been made by Mr. Creswell Hewett, after many years of assiduous research. It seems that in 1869 the late Dr. Matthiessen suggested to Mr. Hewett the synthetical manufacture of quinine, and we understand that he has at length succeeded in producing the valuable alkaloid at a price of about four shillings a pound. Only about 2 per cent. of quinine is extracted from the bark of cinchona trees; but by Mr. Hewett's process it can be manufactured in a simple manner from materials which can be obtained in abundance in any part of the world.

M. Sibiriakov's steamer, the *Nordenskjöld*, has been forced to put back to Vardoe, after several ineffectual efforts to reach the mouth of the Petchora. The mouth of that river is in about 55° E. long., and is west of Kara Straits, so, if a steamer cannot rely upon making that voyage, it seems useless to attempt the still more arduous task of reaching the Ob or the Yenisei. It is thought that the currents and the E. wind combined had swept down an unusual amount of ice from Nova Zemlya and the Kara Sea, completely blocking the approach to the Petchora. After re-coaling, the steamer will make a fresh attempt to reach the mouth and ascend the river.

A marine and fresh-water observatory has been established at Lochbuie, Isle of Mull, a station which promises to yield useful results in connection with the movements of the Salmonidæ and herrings. The establishment is under the direction of the National Fish Culture Association.

Two or three examples of the transmission of energy by means of electricity are to be seen in Switzerland, where there are plenty of waterfalls supplying the requisite motive power; but a company is now being formed which in many ways will be a model for others. It will have its headquarters at Montreux, will work an electric tramway between Vevey, Montreux, and Chillon, and will supply current for all purposes to the public. The company has a concession of certain rights for fifty years, and as it will get its motive power for nothing, will probably be a profitable undertaking. The population of the district is not large; but there are thousands of tourists during the summer who are sure to patronise the tramway, and the current is to be supplied to private consumers at such a rate that a lamp of fourteen candle power will cost about a farthing an hour.

MM. Klein and Berg have communicated to the Société Chimique de Paris, a note in which they state that the internal corrosion of steam-boilers is greatly increased by the presence of organic matters in the waters employed. This is not exactly news; but organic matters are frequently placed in boilers to prevent incrustation, and it is necessary to discriminate between those which are injurious and those which are harmless. MM. Klein and Berg have discovered that sugars of all kinds intensify the action (they do that in ships), while glycerine and mannite have no effect.

In Cleckheaton gas is being manufactured from shale oil and steam by the Avery system, and it is stated that the Cleckheaton and Liversedge Local Boards contemplate the adoption of the new gas, which can be manufactured for about 6d. per thousand cubic feet, for the public lamps.

Mushrooms are attracting attention in the daily papers, and the dimensions of some remarkable specimens are duly chronicled. Mushrooms 3ft. or more in circumference are doubtless useful; but the statement that a grower for market has derived a profit of 120 per cent. from the cultivation of the tasty fungi should attract attention, as there are plenty of people who would be satisfied with much less than that. There certainly seems no reason why we should import mushrooms, when they can be grown readily in this country.

Eight new military aërostatical stations are to be established in France—at Belfort, Toul,

Verdun, Epinal, Grenoble, Montpelier, Arras, and Versailles, and within a short time every army corps is to be provided with a complete ballooning outfit and staff.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

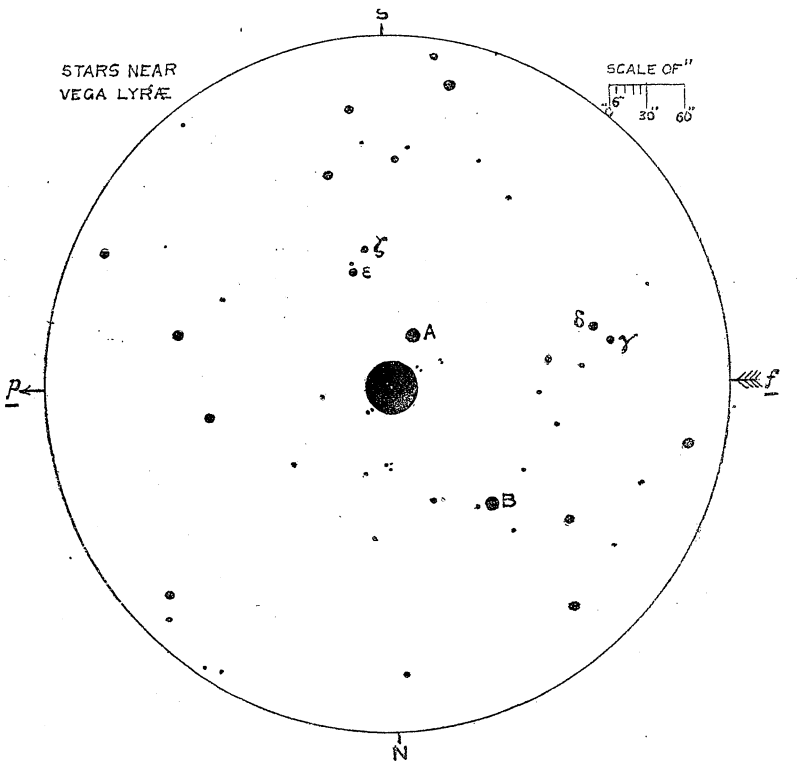
All Cheques and Post-office Orders to be made payable to PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

STARS NEAR VEGA ON ONE OF MM. HENRY'S PHOTOGRAPHS.

[26177.]—OWING to the unfavourable weather during the last few weeks, I have not, as yet, received any observations of the magnitudes of the stars near Vega. I inclose, however, a tracing of the photograph mentioned in letter 25971, page 437, showing Vega, its two bright *comites*, and fifty other stars within a radius of 4¾′ from Vega. The stars selected are those which appear brightest on the photograph, with the exception of two or three near Vega itself. The star marked A is the well-known *comes* at 155·5°, 48·6″ (1879·5.) Dawes found that the magnitude of this star when α Lyræ was in the field appeared about 11·2 in Struve's scale, but when the bright star was excluded by his eye-piece the magnitude of the small star immediately rose to 9·7 mag. Σ. B is the distant companion at about 40″ : 125″; this is No. 556 of Gore's Suspected Variables. I should imagine that the little pairs lettered γ and δ and ε and ζ should be seen with a 5in. or 6in. refractor; ε and ζ are brighter than γ or δ on the print, ε having a small star 5″ or 6″ south of it. In a note on the *comites* of Vega in the ENGLISH MECHANIC for October 19th, 1883 (Vol. XXXVIII. p. 147) I suggested that the principal star of the little pair H IV. 59 was possibly identical with Arg (+ 38°) 3235. This star is not included in the photograph in question; but I find that it is shown on another in my possession, and has a bright companion at precisely the same angle and distance as H.'s is, according to Mr. Burnham's measures. The place of H IV. 59 in Sir J. Herschel's synoptical catalogue in Vol. XXXV. of the *Memoirs* of the R.A.S. is, therefore, slightly in error. According to *Argelander* the principal star of H IV. 59 was in 1855 about 14·1sec. *p.* Vega and 5·2′ south; the place in Vol. XXXV. of the *Memoirs* being about 6·8sec. *p.* and 2·2′ south. I shall be glad to hear of observations of the magnitudes of the stars on the diagram, and of any others not shown thereon within 4′ 45″ of Vega. I presume that bad weather has prevented observations of those near ε Lyræ, shown in letter 25882, August 23rd. **H. Sadler.**



THE LAST OF COMET FABRY.

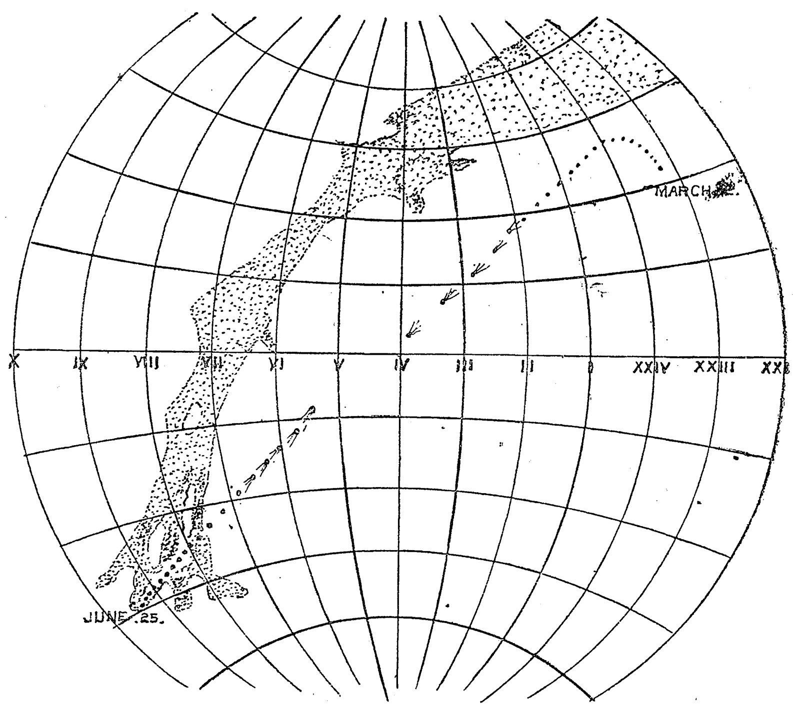
[26178.]—THE last observations of comet Fabry gave the following approximate readings:—

	R.A.	S. Dec.
June 18	9 7 10	42·3
19	9 8 20	42·7
21	9 11 30	42·30
25	9 17 20	43·1

After a week of unfavourable weather several evenings were spent in vain searching, so that I do not expect to see any more of it.

The southern path of the comet has been apparently a pretty straight line until these last four readings, which show a slight curve round λ Argûs. I inclose sketch of its whole indicated path, the northern portion being copied from your maps in "E. M." March 12th and 26th, and the southern from my notes. Its parallelism with the Galaxy is apparent.

Thames, N.Z., July 17th. **John Grigg.**



STELLAR PHOTOGRAPHY.

[26179.]—ADMIRAL MOUCHEZ has addressed a letter to the President of the Liverpool Astronomical Society calling attention to a remark made by Mr. Isaac Roberts in that capacity, and which he thinks is likely to cause a misapprehension as to the duration of exposure necessary to photograph small stars at the Paris Observatory. In a paper on stellar photography, read before the R.A.S. last January, Mr. Roberts is reported to have said: "The suggestion of Admiral Mouchez to allow an exposure of from one to three hours, would make the progress of the work extremely slow. Fifteen minutes exposure in a clear sky can often be obtained; but an exposure of three hours' duration would rarely be possible. Stars of small magnitude can be photographed by my reflector in 15 minutes; but it would be misleading to name photographic magnitudes by the side of those which have been determined by eye-observations until comparisons have been made between a large number of stars." This might be understood to signify that a star which takes an hour at the Paris Observatory can be photographed by Mr. Roberts in 15 minutes, though, of course, everything depends upon the meaning of the term "stars of small magnitude." If stars of the 8th or 9th magnitude are meant, they are photographed at the Paris Observatory in from 3 to 8 seconds.

The following table of the times of exposure which have been found necessary to obtain a photograph of stars according to their magnitudes, has been prepared by MM. Henry from the result of their long and varied experience in stellar photography. The time is understood to be only sufficient to obtain a distinct image upon the sensitive plate. If it is required to reproduce the image upon paper, the exposure would have to be from two to three times as long, according to atmospheric conditions.

METEOR.

[26180.]—WHILST observing the sun yesterday, about one p.m., I thought that I saw a meteor pass

near the sun's limb. After watching awhile my suspicions were confirmed, for I was able to follow one to a considerable distance with the telescope. Before long they were coming in two's and three's, then in showers. The majority appeared as bright as Venus does in the telescope in the daytime, and moved comparatively slow, so that they would be easily followed with the telescope. Occasionally some very large ones shot past with very great speed. The shower continued until sunset, the meteors seeming to move from south-east to north-west. This morning they were again visible whenever the sky was clear, and they continue whilst I am writing, coming as fast as ever, but in all directions. The shower surpasses any I ever saw at night, and if it lasts a few hours more will add an additional interest to the Solar Eclipse.

G. W. Middleton.

Mexborough, August 29th.

PLANETARY NEBULA G. C. 4373 (37 H IV. DRACONIS).

[26181.]—I HAVE been greatly interested reading Mr. Sadler's letter (26050, p. 504, Vol. XLIII.) giving results of observations by many astronomers on the remarkable planetary nebula H IV. 37 = General Catalogue 4373. I have observed this object many times with my 16in. refractor, and always with the result that the central star (if indeed it be a star) was well and constantly seen. The following notice of it, which escaped the search of Mr. Sadler, is by the late Prof. O. M. Mitchell, to be found in "Mitchell's Burritt's Geography of the Heavens," page 133, as seen by the 11in. refractor of the Cincinnati Observatory.

"This singular object is described in the 'Bedford Catalogue,' without any mention of a remarkably bright but small nucleus which occupies its centre. This point was detected by myself, July, 1847. When the eye and attention are attentively fixed on the central point, the nebula *fades from the view*, and the moment the attention is withdrawn from the nucleus, and a casual glance is directed to the nebula, the star fades, and the nebula brightens up in a most beautiful manner. This curious phenomenon was noticed by many persons in my company. No one can doubt the connection between this nebulous mass and the round central point of light. It is unlike a star, as it is round and clear, with a minute disc, and no radiance. I have discussed but one other object like it. Here is the connecting link between planetary nebulæ and nebulous stars; at least, such would be the opinion of those who still adhere to the nebulous theory."

My principal object in calling the attention of the readers of the "E. M." to this subject is the singular fact that in the same field (diameter 32′) is a new nebula, heretofore overlooked, discovered by me May 27, 1886. A single equatorial pointing gave its position for 1885·0, R.A. 17h. 59m. 45s. Dec. + 66° 35′ 25″, and "described as exceedingly faint, small, little, elongated, in field with H. 37, IV."

In whatever light this planetary nebula may be viewed, it is a marvellous object, the whole heavens affording but few examples of H, class IV., of equal interest. I am more interested, however, in H, IV., 73 = G.C. 4514, R.A., 1860, 19h. 41m. 8s., Dec. + 50° 10′ 18″, which has also a central star, and bears magnifying well. "G. C." calls it pretty large. I call it small. No person can look at this object with a large telescope without considering it equal in interest, if indeed it does not surpass its prototype in Draco.

Lewis Swift.

Warner Observatory, Rochester, N.Y., Aug. 18.

LIVERPOOL ASTRONOMICAL SOCIETY: CIRCULAR NO. 7.

[26182.]—(1) THE observations of 10 Sagittæ on 60 nights since 1885, Nov. 28, give P = 8·32134°. Epoch max.: July, 17·56. The following are the times of maxima and minima during September:—

Maxima.	Minima.
1886, Sept., 5·5	1886, Sept., 1·6
13·8	9·9
22·1	18·2
30·4	26·5

(2) The star D.M. + 17°, No. 3,940, announced as variable in the *M. N.*, Vol. XLVI., p. 293, was observed as 9·5 on April 26 last. From this date it increased, and on June 13 it was 8·3. Latterly it has diminished, and on August 20 it was 8·7. Vogel gives the spectrum as III. *b*! Dunér as III. *a*!! The star's place for 1885 is R.A. XIX. 16·33 + 17° 26·4.

T. E. Espin,
Observer to the Society.

Wolsingham, Aug. 26.

ASTRONOMICAL—A SUGGESTION.

[26183.]—SINCE there is just the probability that the temporary brilliant stars which appeared in the regions of the heavens between Cepheus and Cassiopeia in the years 945, 1264, and 1572, may be one and the same star, reappearing after an interval of about 315 years, I would suggest that careful photographs be at once taken of these regions, so that in the event of a reappearance about 1887, it might at once be ascertained whether the new star was really a new star, or an old small magnitude star, suddenly blazing forth with increased light.

H. P. Slade.

NOTES ON THE CHAMBER ORGAN.

[26184.]—IN my brief reply to the letter by "Organist," written while from home, and published in last week's issue, I allude to the specification of a "Chamber Organ," comprising about fifty speaking stops. The instrument was built as a "*Chamber Organ*" by one of our leading firms for an enthusiastic lover of the organ, in Yorkshire; and I think "Organist" will agree with me that it is a still more important specimen of organ-building than the one he kindly brought before the readers of the ENGLISH MECHANIC in his letter (26114). The specification is as follows:—

GREAT ORGAN CC TO a^3. 58 NOTES.
3IN. WIND.

1.	Double Dulciana.........	16ft.	58	pipes.
2.	Bourdon	16ft. tone.	58	„
3.	Large Open Diapason...	8	58	„
4.	Small Open Diapason...	8	58	„
5.	Salcional	8	58	„
6.	Höhl Flöte	8	58	„
7.	Stopped Diapason	8ft. tone.	58	„
8.	Harmonic Flute	4	58	„
9.	Octave	4	58	„
10.	Octave Quint	$2\frac{2}{3}$	58	„
11.	Super Octave	2	58	„
12.	Mixture	III. Ranks.	174	„
13.	Full Mixture	V. Ranks.	290	„
14.	Double Trumpet.........	16ft.	58	„
15.	Tromba	8	58	„
16.	Posaune	8	58	„
17.	Trumpet	8	58	„
18.	Clarion	4	58	„

SWELL ORGAN. CC TO a^3. 58 NOTES.
3IN. WIND.

1.	Double Diapason.........	16ft.	58	pipes.
2.	Geigen Principal.........	8	58	„
3.	Violin e Cello	8	58	„
4.	Voix Célestes	8	58	„
5.	Octave	4	58	„
6.	Wald Flute	4	58	„
7.	Piccolo	2	58	„
8.	Sharp Mixture............	III. Ranks.	174	„
9.	Contra Oboe..............	16ft.	58	„
10.	Oboe	8	58	„
11.	Horn	8	58	„
12.	Clarion	4	58	„

CHOIR ORGAN. CC TO a^3. 58 NOTES.
$2\frac{1}{2}$IN. WIND.

1.	Lieblich Bourdon	16ft. tone.	58	pipes.
2.	Cone Gamba..............	8ft.	58	„
3.	Dulciana	8	58	„
4.	Pierced Gamba	8	58	„
5.	Dolce	8	58	„
6.	Flauto Traverso	8	58	„
7.	Röhr Flöte	8	46	„
8.	Lieblich Gedact	8ft. tone	58	„
9.	Gemshorn	4ft.	58	„
10.	Lieblich Flöte	4ft. tone	58	„

ECHO ORGAN. CC TO a^3. 58 NOTES.
$1\frac{1}{2}$IN. WIND.

1.	Vox Angelica.............	8ft.	58	pipes.
2.	Still Gedact	8ft. tone	58	„
3.	Echo Oboe	8ft.	58	„
4.	Flauto Dolce	4	58	„
5.	Flauto Traverso	4	58	„
6.	Harmonia Piccolo	2	58	„
7.	Orchestral Oboe	8	46	„
8.	Clarinet and Bassoon ...	8	58	„

PEDAL ORGAN. CCC TO F. 30 NOTES.
4IN. WIND.

1.	Sub Bass	32ft. tone	30	pipes.
2.	Open Bass	16	30	„
3.	Violone	16	30	„
4.	Bourdon	16ft. tone	30	„
5.	Flute Bass	8ft. tone	30	„
6.	Violoncello	8ft.	30	„
7.	Super Octave	4	30	„
8.	Full Mixture	IV Ranks	120	„
9.	Trombone	16ft.	30	„
10.	Clarion	8	30	„

COUPLERS.

1. Swell to Great.
2. Swell to Choir.
3. Choir to Great.
4. Echo to Choir.
5. Great to Pedal.
6. Swell to Pedal.
7. Choir to Pedal.
8. Echo to Pedal.

Four Composition pedals to Great and Pedal organs, three Composition pedals to Swell. The pneumatic lever is applied to the Great, Swell, and Pedal organs, and to the manual couplers.

SUMMARY.

Great organ	18 stops	1,392	pipes
Swell organ	12 „	812	„
Choir organ	10 „	568	„
Echo organ	8 „	452	„
Pedal organ	10 „	390	„

Speaking stops 58. Total pipes 3,614

There can be no question as to the dignity and importance of the instrument above described, but, if we consider the manner in which such an immense organ has to be disposed in a *dwelling-house*, and the volume of sound it is capable of yielding—out of all reason in a room of common dimensions—we must hesitate to accept it as a *Chamber Organ*. I understand it has recently been transferred to a church, certainly a more appropriate place for it. Large Chamber Organs are huge mistakes, and this is generally discovered to be the fact sooner or later, judging by the proportion of them which find their ultimate resting places in churches or public concert-rooms.

G. A. Audsley

Devon Nook, Chiswick, W.

NOTES ON THE CHAMBER ORGAN.

[26185.]—I FEEL highly honoured that Mr. Audsley, p. 570, Vol. XLIII., should have noticed the few words I had to say on the above subject, and at the same time I apologise for having presumed to instruct him as to the merits of organ builders.

The organ I gave a specification of is a chamber organ, pure and simple, and "simply perfect," not on account of its size, nor of the accessories which are really necessaries, but on account of its structure and fascinating tone, which last is maintained throughout, even when the full organ is played.

The instrument is erected in a gentleman's drawing-room in Holland Park, but the exact dimensions of the organ and room I cannot at present call to mind. However, I will endeavour to obtain all the information required, from Mr. Gern, together with the details of another chamber organ not quite so large, but very effective both in variation and beauty of tone, and forward them to the Editor for the next issue, if possible.

Organist.

CHAMBER ORGANS.

[26186.]—MR. G. A. AUDSLEY, in his "Notes on the Chamber Organ," condemns the good old organs as "unworthy of notice." Surely he must be joking. If a chamber (?) organ is to have two manuals and pedals, and dear old Snetzler's one manual set aside, where are we artisans to get a 2 or 3 manual organ from, and when we have it, where are we to put it? Are we to hire them?—for I'm sure we cannot raise £400 for an instrument such as he suggests. For my own playing I have a 7-stop "Snetzler," and I wish every man could have one who has a taste for the beautiful tone of his organs; there is nothing to equal them now. He built "singing organs"; now we get "screamers," with a vengeance. It is my firm belief that thirty years hence the pure organ tone, such as the old builders gave us, will be forgotten, and the noisy instruments of our day, and those of future builders, will make as big a row as the Falls of Niagara.

Musicus.

THE SIZE OF THE LARGEST ORGAN.

[26187.]—REFERRING to the letters on the above subject, I think they are a waste of space, as little or no benefit will arise from them. The gentleman who formulated the query 60018 ought to have stated in what way he required to know the largest organ, whether in number of stops, or pipes, or the area it took up, for all these would most probably alter the answer. I certainly agree with "C." that a GG organ is larger both in area, weight, and number of pipes, than a CC organ. A CC open will contain, in ordinary, 56 pipes, from CC to G, or, if carried up to C, 61 pipes. A GG open will contain 61 pipes from GG to G, or, if carried up to C, 66 pipes.

Now will not, according to this, a GG to C open contain more pipes, be a greater weight, and require a larger area than a CC to G open.

Considered as so many pipes and weight of material, the GG organ must be the largest, stop for stop.

Taking a large GG organ, there is sufficient material in the five odd pipes at the bottom, GG to BB, to make a decent-sized instrument, then leave the original capable of performing any written organ music.

I question if anyone can say for a certainty which is actually the largest organ, certainly only a builder, as there are so many points to take into consideration. Lastly, the scaling of an organ makes a considerable difference. A Diapason of 7in. scale will be larger than one of 6in. scale, and this proportion carried throughout a large organ

THE SAFETY GOVERNOR.

[MACFARLANE'S PATENT.]

WITH THROTTLE VALVE AND STOP VALVE COMBINED.

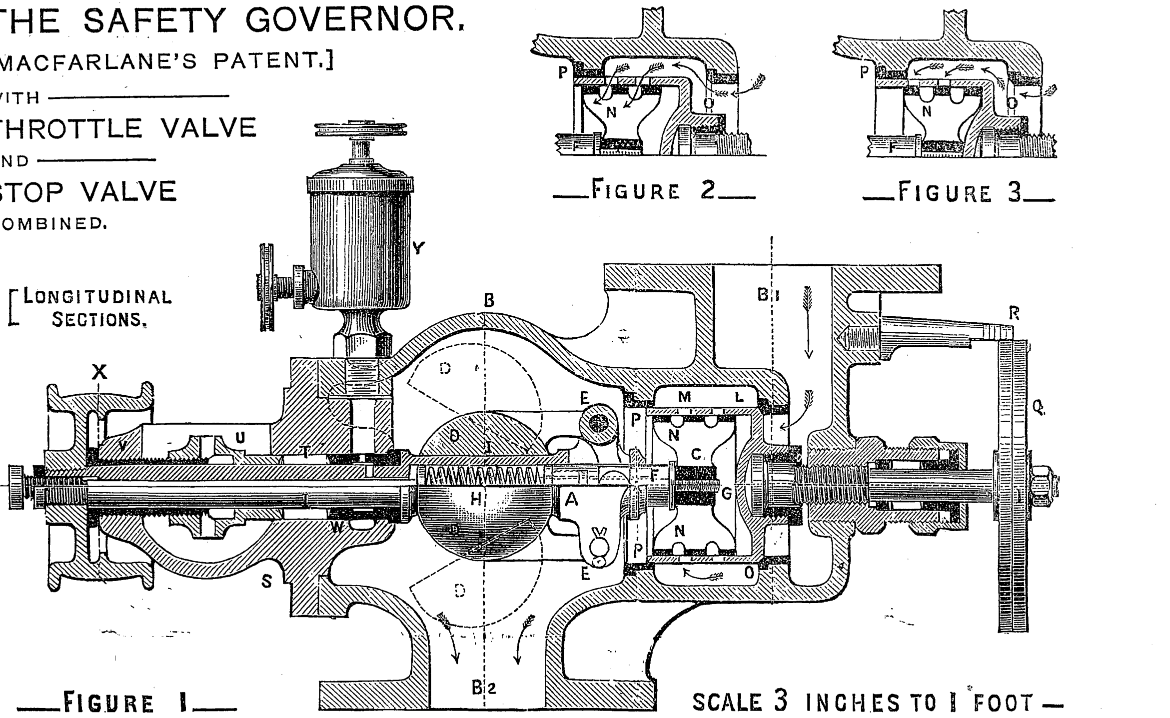

FIGURE 1 FIGURE 2 FIGURE 3

SCALE 3 INCHES TO 1 FOOT

makes a much greater difference than the majority would think.

Without taking all these points into consideration, any further discussion of this subject is worthless, and a waste of valuable space.

I noticed "Country Solicitor's" remark in one of his letters a number or two back, and I will answer him as soon as I can; but I am, and have been, so very busy, that I have had no time to write.

Uranium.

[26188.]—IN the letter 26165 please read in the thirteenth line from the top of the middle column of the page "CC," not "CCC."

In the ninth line from the top of the right-hand column, read "second-slides," not "seconds, slides, &c."

In the twenty-fifth line from the top of the same column, read "CC," not "C."

Some accident has befallen the setting up of the concluding sentence, the first part of which ought to read—"Granted the lower notes are superfluous, still there they are; and the pipes occupy space not required by a CC, and yield tones not forthcoming from a CC either."

C.

GOVERNORS.

[26189.]—SOME time ago a few letters on steam-engine governors appeared in your columns under the numbers 59581 and 25926. Under the latter number your correspondent, "W. J. R.," says: "When some other correspondents, who write so ably in the 'E.M.' on mechanical matters, have had their say (if they care to discuss the matter), I may venture to make a few more remarks upon this interesting subject." As none have thought it worth while to continue the discussion (and it looks as if the matter were to be allowed to drop), I take the liberty of sending you a few particulars regarding my patent governor, No. 7544/85, trusting it may be the means of bringing forth some valuable information on the subject of governors generally from your correspondent "W. J. R." and others.

Fig. 1 is a vertical section of governor on longitudinal centre line. The centrifugal part A is placed inside a casing or steam-chest B, and is connected direct to the throttle-valve C. A pair of hemispherical pendulums D working on centres E move a sliding piece F, with spindle G attached to the throttle-valve C. To balance the centrifugal force of the pendulums D, a helical spring H is placed in a chamber of governor spindle I, and is capable of adjustment by means of spindle J passing through the centre of the driving spindle I. The stop-valve K has a cylindrical part L cast on back of it, which forms an adjustable seat or sleeve for throttle-valve C, and is provided with two circumferential rows of portholes M, which correspond with two circumferential ports N in the throttle-valve. The stop-valve shuts against a conical seat O, and slides through a cylindrical guide-ring P, and is provided with the usual screw-spindle, stuffing box, and hand-wheel Q, which is divided on periphery, and shows by means of pointer R the amount of the opening of stop-valve. The driving spindle I is carried by the cover S of the steam chest B, which is provided with stuffing-box T, having a stuffing gland U with guide liners V and W. The outer end of driving spindle I has fixed to it the belt-pulley X. On top of governor casing B is fitted a lubricator Y for oiling the internal parts of governor, and also for lubricating the steam cylinders of the engine. Steam enters by the flanged branch B and leaves by B2 in direction of the arrows.

Fig. 2 is a section of stop and throttle-valves, showing their usual relative positions when working.

Fig. 3 is a section of stop and throttle-valves, showing their positions when the belt breaks or slips off.

In the designing of this governor three very important considerations were always kept in view—viz., safety, sensitiveness, and simplicity, and I shall endeavour in a few words to show how far these points have been, in this case, attained.

1. Safety. When the engine is working with the stop-valve full open, should the belt break or slip off, the throttle-valve would shut the ports the backward way and stop the engine, instead of, as in the ordinary governor, allowing it to run away and do damage. It will be observed that no extra attention is required to set this safety arrangement in gear, the mere fact of turning on the steam being sufficient, and that this important advantage is obtained without extra complication.

2. Sensitiveness. The centrifugal part of the governor being placed in the steam, it acts directly on the throttle valve, and without the variable friction due to stuffing boxes, joints, &c., and with a minimum of slackness of joints, &c., to be taken up before the effect of the centrifugal force is felt by the throttle valve. The elimination of these important defects enables the governor pendulums to be made considerably smaller for the work to be done—a circumstance which makes it very suitable for high speeds. In the construction of this governor the centres of the pendulum levers are so arranged relatively to the centres of gravity that the load on the spring due to the centrifugal force increases directly as the travel of the throttle valve, and as the compression of a helical spring increases directly as the loads it follows that the governor can be made practically isochronous, or, in other words, to have all the advantage that can be derived from the parabolic governor and with the simplest form of pendulums.

3. Simplicity. In the governor here illustrated, and which is suitable for a 2½in. steam pipe, the actual number of separate pieces (including even the bolts, split pins, &c.), is not more than 42—a number which I venture to think will be found to be less by 25 per cent. than any other governor of the same class presently in use. The parts are all easily to be got at, and, even in the smallest sizes, are sufficiently large to be easily made or repaired by the tools in use in any engineering works. In addition to the considerations above, the following advantages may be mentioned, viz.: The centrifugal part is entirely inclosed and kept free from dirt; the oil required for lubricating the governor passes afterwards to the steam cylinders, and, in fact, the whole of the lubrication required for the engine cylinders may be made to pass through the governor, keeping it practically running in oil. The speed of the engine may be varied within certain limits by the stop-valve when the engine is working.

J. W. Macfarlane.

EFFECT OF TIME ON CHANCES.

[26190.]—THIS is a table of the kind suggested by "J. M." in the reply 59842 (p. 582, Vol. XLIII.), and perhaps might serve to familiarise those who guess at chances with the effect of multiplied time, or "number of throws," in changing improbability into probability. The second column arises from merely squaring the fraction that expresses the "odds" in column 1. Thus the fraction two-thirds becomes four-ninths, the former being "2 to 1," the latter only 4 to 5 or ·8 to 1. The third column is the quotient on dividing logarithm of 2 by logarithm of the reciprocal of the first fraction; and column 4 is the quotient of 1 (the logarithm of 10) by the said logarithm.

If the odds *against* a thing happening to-day are	The chance of its not happening in 2 days is	Time in which the chances become even.	Time in which they become 9 to 1 *for* it.	Time in which they become 20 to 1,

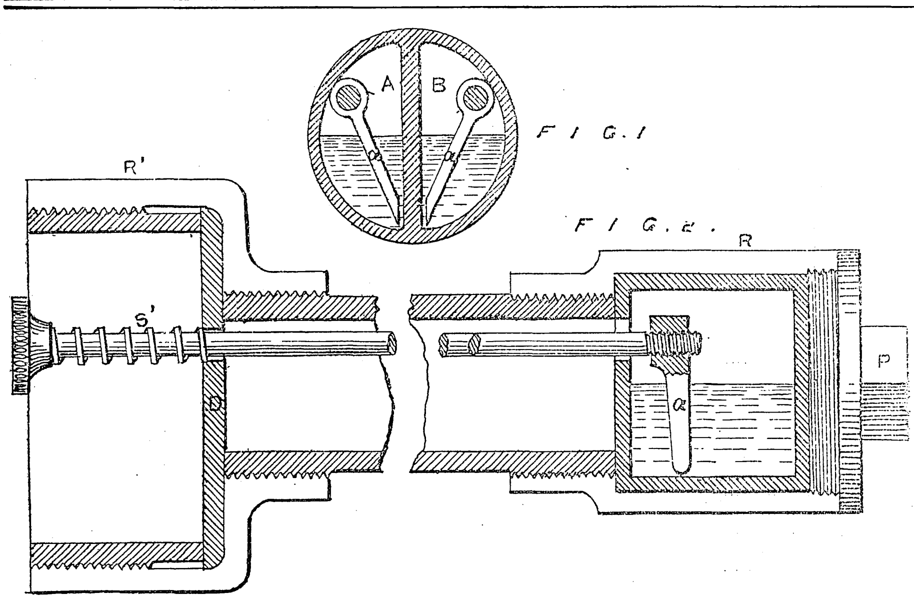
Aug. 28. **E. L. G.**

FLUTE PLAYING.

[26191.]—DOUBTLESS, like myself, some of my brother amateurs who occasionally take up the flute find the instrument hard to blow and give it a drink of water; oil is better, but is apt to spoil the buffing of the keys. The best lubricant I have found is a spoonful of golden syrup; this at once awakens the silvery tone, the sound becomes easily clear, smooth, brilliant, and, of course, sweet.

E. B. Fennessy.



PYROMETER—MAX. AND MIN.

[26192.]—I HAVE much pleasure in bringing the following adaptation of the well-known fusing point of alloys under the notice of your readers. Some time since, being then in charge of the char-burning plant of a sugar-refinery abroad, I found the want of a simple and reliable pyrometer to be used by the furnace men a great drawback to the working of the kilns. I have, indeed, two pyrometers at my hands—one a mercurial one, and the other having a clay tube inclosed inside an iron pipe, both differing from one another in a most erratic manner, and when removed from the furnaces would never return to zero. What I required was a pyrometer indicating a minimum of 500° Fahr., and a maximum of 550° Fahr., or thereabouts, to be used by the men at intervals, as occasion might require. Procuring a piece of inch gas-piping 5ft. long, I screwed on one extremity a reducing coupling $1\frac{1}{4}$in. to 1in., and on the other end a reducing coupling $2\frac{1}{4}$inch to 1in. I next prepared a cylindrical box, divided in the centre into two compartments A and B (Fig. 1). A longitudinal section of this box is shown in Fig. 2, where it is shown in its proper position inside the small reducing coupling R; the pluck P holding it securely in its position. An alloy of tin and lead, the melting point of which lies at 500° F., is placed in compartment A, and a similar alloy, whose melting point lies at 550° F. in B. The agitators, *a a*, having eyes tapped to receive the ends of two wires, $\frac{3}{16}$in. diameter, are also placed in their respective compartments, in such a position that the tapped eyes are opposite two holes left in the end of box; the larger reducing coupling R 1 had a guide or division plate, D, fitted as shown in Fig. 2, and secured by piece of $2\frac{1}{4}$in. pipe, cut off flush with the outside of coupling. Two rods of $\frac{3}{16}$in. wire protruding through holes left in this plate, terminated into polished steel knobs, having 500° and 550° stamped thereon. A brass spring, S, between plate and knobs pushed the rods out whenever the alloy was sufficiently melted to allow the agitators to move. A second box, having alloys of 470° and 500°, as well as an extra knob with 470° marked thereon, completed the pyrometer. When about to ascertain the temperature of the kilns, the smaller of the couplings is thrust into the heated spot, both pushes having, when last used, remained right up to the plate by reason of a lead weight which acted as a lid, the instrument standing upright when allowed to cool. The springs being in compression, push out the spindles whenever the inscribed degrees of heat are reached. Those interested in this instrument will see that by interchanging of different capsules and knobs, this pyrometer, as a maximum and minimum indicator, is complete, moreover having no delicate moving parts, and is otherwise so simple that any mechanic can repair it. I am of opinion that it supplied a want felt, perhaps, by others.

Liverpool. **P. F. Otto.**

A PSYCHOLOGICAL PROBLEM.

[26193.]—"GARRISON GUNNER" seems to me to have conceived a very important truth; but he has, I think, stated it imperfectly in his interesting letter, p. 557, Vol. XLIII. He says:—"When the imaginative faculty is partly dissociated from the control of the will, it may co-exist with the reasoning faculty, which latter may not have escaped from the will, its ruler."

It appears to me that in the process of imagination the will is, to a given extent, metamorphosed. But the reason remains inherent all the while. How in such a case can the will be said to be the *ruler* of the reason?

Now, the reason is ratiocinative, and therefore it may be said to be coincident with the *operation* of the will.

In some respects both the reason and the understanding are, so to speak, superior to the will. By one of our English Philosophers the reason has been well called the "natural revelation."

The phenomena of dreaming cannot properly be explained apart from the full consideration of the function of sleep.

In regard to this subject I propose to submit certain remarks on some future occasion. It is quite possible "F.R.A.S." merely dreamt about the act of pinching. I once vividly imagined in my sleep that I had cut my fingers with a razor.

What of the interpretations of the dream-books? My small experience of them goes to show that there is some amount of method in their madness.

H. W.

[26194.]—IN reply to 26167, "An Inquirer after Truth," I beg to say that he will most likely alter his opinion after perusal of the appendix to "Mental Physiology," by the late Dr. Carpenter, or the notable works by Drs. Braid and Tuke on "Hypnotism." Much reliable information on mesmeric phenomena can be seen in the magazine called *Health*, where several articles on "Sleep-walking" are contributed by Dr. Andrew Wilson; the latest and most reliable information can be seen in the works of the Society for Psychical Research—viz., "Proceedings," part 5, price 2s. 6d. (Trübner and Co., Ludgate-hill); "Third Report of the Committee on Mesmerism," by Prof. W. F. Barrett, M.R.I.A.; E. Gurney, M.A.; R. Hodson, B.A.; A. T. Meyers, M.D.; F. W. H. Meyers, M.A.; H. N. Ridley, M.A., F.L.S.; W. H. Stone, M.A., M.B.; George Wyld, M.D.; C. Lockhart Robinson, M.D.; and F. Rodmore, M.A., hon. sec.

Joseph W. Hayes.

[26195.]—I WILL try to answer the queries of "An Inquirer after Truth" as briefly as possible (p. 579, Vol. XLIII.). First of all, public exhibitions are not places to study mesmerism at. Some of them may be mere second-class conjuring tricks, others real use of the mesmeric power to produce useless and, I fear in many cases, injurious effects. It is a power which I firmly believe should never be used save for some worthy purpose, such as curing a nervous disease, or as an anæsthetic in surgery.

As to the question about signing a cheque, the answer is simple. Most probably I should not be able to mesmerise the querist; but if once he were thrown into the mesmeric trance by me, I could undoubtedly make him sign a cheque in my favour for his whole fortune.

As to the use of mesmerism for surgical operations, there was a certain Dr. Esdaile in India, during the Governorship of Lord Dalhousie, who used no other anæsthetic. He employed a staff of native operators to mesmerise, and, to use the words of his report to the Government, "Out of 261 operations, 215 of which were extirpations of tumours of all sizes, varying in weight from 10lb. to 103lb., not one patient had died from the direct effects of the operation," &c. Lord Dalhousie made Dr. Esdaile Presidency surgeon. Mesmerism has been used again and again as an anæsthetic, with satisfactory results, but the fact is that doctors have no time to employ it. Chloroform is much handier and quicker. The only experiment I ever tried in this direction was when a lady, whom I had the power of mesmerising, cut a large vein in her hand by accident, and it was a question how to stop the hæmorrhage. By a few passes down the arm and hand they became stiff and rigid, and the circulation entirely ceased (doubtless by the contraction of the blood vessels owing to nervous action upon them). It was then easy to bind up the wound so that the bleeding would not recur when the circulation was restored. As there was no pulse at the wrist, I presume a wounded artery might have been dealt with in like manner.

As a short and concise book on the subject, I would recommend "Mesmerism, with Hints for Beginners," by John James, published by W. Harrison, 38, Great Russell-street, London, price about 3s. 6d. But I would strongly recommend "An Inquirer after Truth" to have nothing to do with the subject personally, unless to use it as a curative power. He will probably repent it if he does. Constant mesmerism of one person gives the mesmeriser a most undesirable power over the mind of the patient.

I believe the power of clairvoyance, by which I understand the faculty of the mesmerised person to see what is going on in places entirely out of the ken of the ordinary senses, to be rather rare, but undoubtedly to exist. Also, though here I am aware I am asking my readers to believe what no man can be expected to credit on any authority but his own eyesight, I have proved by experiment that it is possible to mesmerise from a distance (well understood that the subject must be a very good one, and have been frequently mesmerised before by the operator). However, I do not care to go into the subject further, nor am I at all anxious to set the readers of the ENGLISH MECHANIC investigating for themselves, any more than I should give a man who had not studied electricity a powerful induction coil and a battery to experiment with. The result in either case might be dangerous. Mesmerism is a powerful agent, and most imperfectly understood; but it is a *fact* that it exists—people might as well disbelieve in electricity as in it.

Garrison Gunner.

[26196.]—"AN Inquirer after Truth" (p. 579) asks the name of a book fully treating of the subject of mesmerism as an anæsthetic in surgical operations. There is a whole literature on this questionable subject; but should the inquirer be willing to invest any money in the purchase of such a volume—a thing I do not recommend—he will find what he wants in "Natural and Mesmeric Clairvoyance," by Esdaile, published by Hippolyte Bailliere, Regent-street, 1852—to say nothing of the "Dictionnaire Infernal" and other delightful gospels by the same publisher. Dr. Esdaile, it appears, was a presidency surgeon at Calcutta, and no doubt was able to "animal-magnetise" Hindoos and others and produce astonishing results. For the action of a resolute and fearless organisation on an inferior panic-stricken one is assuredly one of the commonest facts, and has been at all times known and turned to account, both in a legitimate manner and as part of the stock-in-trade of impostors. Why this action should be called "Magnetism," as if it had anything to do with one of the properties of iron ore, or why it should be the centre of such an enormous mass of lies, empiricism, and foolish literature are mysteries which perhaps are hardly worth solving. There is a legitimate, because metaphorical, use of the word magnetism in relation to humanity, as when Emerson speaks of the "Magnetism which all original action exerts." Carlyle in his "Latter Day Pamphlets," 1850, speaks in words well worth weighing of a certain notability whom he found in gaol: "I had seen him about a year before, by involuntary accident, and much to my disgust, 'magnetising' a silly young person; and had noted well the unlovely voracious look of him, his thick oily skin, his heavy dull-burning eyes, his greedy mouth, the dusky potent insatiable *animalism* that looked out of every feature of him: a fellow adequate to animal-magnetise most things, I did suppose—and here was the post I now found him arrived at." Here we see something of the nature of this influence, namely that it is intimately related with the lower part of man's being, not at all with the higher spiritual aad intellectual part. The healthy virile intellect will have none of such hysterics. Imagine—if you can—a person endeavouring to animal-magnetise the famous Dr. Johnson, and the kind of success he would have met with. On the other hand, given a patient of the weak-kneed, horribly-apprehensive, pseudo-intellectual sort, it is difficult to fix the limits of his delusions, or to say what surgical operation could not be performed on him whilst his poor mind is wholly comatose through fear. The horrible painless fascination which animals of prey can exercise, the epidemic delusions in assemblies, what are they but the turning of persons into "things," as Carlyle, with true instinct, writes it?

It is remarkable and highly significant that the manifestations of Mesmer—what would have been called in the phraseology of an older date, "Satan's Invisible World Displayed"—were contemporary with a rotten state of society, in which men, having no religion, eagerly sought after wonders and got them. The demand being great the supply was

kept up, and hence our "literature of spiritualism," &c. Gas lamps are known to give more light than planets, and are more wonderful to some people.

As regards making people sign cheques, or what amounts to the same thing, obtaining money under false pretences, the records of the Old Bailey would furnish the inquirer with valuable information. I was present at the trial of a famous spiritualist some years ago, who had by chicanery obtained a large sum of money from a dupe, and I had the chance of seeing what can never be gathered from printed reports—the demeanour of the principal actors in the drama. Though the prisoner was hopelessly beaten by the production of the facts of the case, and was palpably an accomplished swindler, a remarkable thing took place. A long string of witnesses *as to good character* came forward—witnesses of honesty and good social position. But the judge, endowed with even more of that shrewd antiseptic common-sense, which is the characteristic of English judges, at once saw through the business. *These also were dupes.* By a few questions, apparently harmless, but really suggested by a deep insight into human nature, he destroyed the value of their testimony.

After this, and knowing as I do the predatory nature of a hawk among sparrows, I could not doubt that there was such a thing as animal-magnetism.

E. W.

EGYPTOLOGY.

[26197.]—IN reference to the letter on "Egyptology" (26168), I wish to refer Mr. Smith to the works published by the Egyptian Exploration Fund, of which Miss Amelia B. Edwards, The Larches, Westbury-on-Trym, is an hon. sec. Much information may also be had from Prof. Maspero's official report on the Mummy, No. 5,233, also from Reginald Stewart Poole, Esq., LL.D., Keeper of the Coins in the British Museum. In a reported lecture of his on "Pithom," the following passage occurs:—"Very massive store-chambers, which must have been founded by Rameses II. about 1400 B.C. This identification of the Great Oppressor, who built those cities early in his reign, led to the conclusion that his successor, Manephtah, was the Pharaoh of the Exodus xxx., which would place the Exodus about 1320 B.C." The *Times* of June 18, 1886, has a good article on this subject. The explorer, Naville, who discovered Pithom, in the Wady Tumelat, identified his "find" as "one of the two treasured cities built by the Children of Israel for Pharaoh" (Ex., 1, 2, 3), which was proved to be Rameses II., as the temple, forts, and city were found to have his name inscribed upon them. In Brugsch Bey's "History of Ancient Egypt" the following lines occur in reference to the Shepherd Kings: "In the Hyksos Dynasty, supposed to be the *Twelfth*, King Amen-em-hat built a Pyramid called Ka-nofer."

It is impossible as yet to be quite accurate as to the time these kings reigned, for, as Principal Dawson says, the lists are "muddled," many of the "kings" mentioned by historians being merely "heads of local tribes"; however, with the aid of the mummies and inscriptions, a fairly authentic record may soon be expected. It is interesting to note that the king called "Sesostris," we are told by Herodotus in his book "Euterpe," "compelled his captives to make vast and numerous canals and other works" around the neighbourhood of the Pelusian Daphne, none other than the present Tel-Defenneh (the Tahpanhes of the Bible), where Jeremiah prophesied (Jer. 37 to 47). A good deal of information on the early Egyptian kings may be seen in Piazzi Smyth's "Our Inheritance in the Great Pyramid," especially on p. 449, chap. 21, headed "Hierologists and Chronologists"; but by far the most important information may be had in "Flavius Josephus against Apion," Book I. Josephus claims the Hyksos, or Shepherd Kings, as the ancestors of the Jews, and gives the testimony of Manetho and others to prove it—viz., Book I., Sec. 14: "This whole nation was styled Hyksos." "These people kept possession of Egypt 511 years." After several interesting circumstances about them, Josephus sums up thus: "It is evident that these shepherds (our forefathers) were delivered out of Egypt, and came thence and inhabited this country 393 years before Danaus came to Argos, or preceding the siege of Troy almost 1,000 years." This departure of the "Shepherd Kings" is supposed to have taken place "about 37 years before Abraham came out of Haran."—(C. Whiston).

Joseph W. Hayes.

LIST OF EYEPIECE POWERS FOR ASTRONOMICAL TELESCOPES RANGING FROM 1 TO 20½ FEET FOCAL LENGTH.

[26198.]—BEING very frequently asked to calculate the power for various eyepieces of varying lengths of focus, I have just thought it would not be a bad idea to publish in the "E. M." a table giving the power of an eyepiece at a glance with a given focus of object-glass or speculum. Such a list has never been before published in any astronomical work that I am aware of, either on the practical or the theoretical side. So here it is.

FOCUS OF SPECULUM OR OBJECT-GLASS IN FEET.

Focus of Eyepieces in Inches and parts of Ditto.	1	1½	2	2½	3	3½	4	4½	5	5½	6	6½	7	7½	8	8½	9	9½	10	10½

⅜ "	352	368	384	400	416	432	448	464	480	496	512	528	544	560	576	592	608	657	640	689
¼ "	528	552	576	600	624	648	672	694	720	744	768	792	808	840	864	888	912	936	960	984

Supposing the focus of a speculum is 10ft. say, and focus of the eyepiece is ¼in, look along the top column for 10ft., then look down the left-hand side of table for ¼in. focus; then run the eye along even with the top column, and under 10ft. you will find 480 marked as the power of the eyepiece.

Again, if you should require to know the focal length of any eyepiece marked, say, for 2½ft. focus of object-glass, powers 60 and 120, look under the column for 2½ft. until you come to 60, where you will find marked on the left-hand side ½in. focus; look still further down until you come to 120; on the left you will see ¼in., and so on.

G. W. Valentine.

156, High-street, Southampton.

THE TARAWERA ERUPTION.

[26199.]—THE following is a description of the recent eruption, received from a lady friend of ours who resides not far from the district. Divested of a few details, which are private, the information the letter conveys is as follows:—

"Tauranga, N.Z., 14th July, 1886.

"We all retired as usual on Wednesday, June 10th. I usually wake at one o'clock, not being a first-rate sleeper. I woke up as usual, feeling as if I had been shaken; but passed this over. Presently I felt the bed shake lengthwise to and fro, and heard the windows rattle; I was getting surprised. In a minute there was another shake; in half a minute another shaking. I roused everybody. We then had a much stronger shock of earthquake than previously. Some impulse moved us to go and look out towards the Hot Lakes district in S.E. direction, some thirty miles as the crow flies, and there was an extraordinary spectacle before us. Every star was shooting forth a lightning of its own, which made the sky look like a gigantic kaleidoscope. Presently vivid flashes of lightning over the whole sky were added, and then we heard a tremendous thundering boom, and a huge ball of fire, looking as big as the sun, rose up in the S.E. and burst. Then a frightful, though grand, spectacle, began. For about two miles apparently, on either side of the ball of fire flames appeared looking like a gigantic bush fire, and at the place where the ball of fire burst forth we could see immense pieces of red-hot rock and stones being thrown up and frightful forked lightning coming out of the fire, and occasionally a loud boom. The shocks of earthquake continued the whole time, and were more or less severe. It was really awful; but, strange to say, none of us were frightened exactly, but were excited and interested. The first earthquake we felt was about one o'clock; these shocks continued till about three; then the eruption came, and earthquakes lessened slightly. At four the eruption nearly stopped. We then retired; but the shocks became so frequent that we could not sleep. At 4.30 a tremendous shock, which turned us out again. It lasted a minute—we thought the house would come down. We dressed, and lit the fire, as it was of no use trying to sleep. The house creaked and the doors swung; it was like a ship at sea. Shortly a couple of friends arrived from a short distance up the road; they being rather lonely, and thinking there was safety in numbers. We went outside again to look what was doing, and during the flashes of lightning, which kept up the whole time, we could see a heavy pall of what appeared to be smoke stretching to the east for about 50 miles. We waited, and about 5.30 we had fourteen friends more who were afraid to stay in their own houses any longer. At about six the day dawned, and for about ten minutes we had a little light. Suddenly the wind changed, and blew from the S.E., and in a second almost the whole place was in darkness, and a suffocating smell of sulphur came. We shut the doors immediately, and went to the back of the house to look out, and there mud was raining hard on us, and after that fine volcanic ash came down. This continued falling until 11.30—five hours; utter darkness the whole time. We now began to feel frightened, as we did not know what was coming next, and in the darkness and the suffocating dust if anything happened, we could not have left the shelter of the house. From nine till ten a frightful thunderstorm raged; but no one seemed to heed it. There were 26 of us in the house, and we had to prepare breakfast for all. Luckily we had oatmeal and plenty of milk, but no sugar. At 11.30, after the ashes had stopped, it began to get light. A light ash fell all day and part of the next. Our cousin rode to the township, and brought back news that it was the Mount Tarawera and seven other smaller hills had become eruptive, and where a lake was there is now a new volcanic mountain. The ashes are 4in. deep on our land, and every scrap of feed is covered. It looks miserable—everything dressed in grey. Just a month after the eventful night we were at a friend's house for the evening, and at 9.30 we were startled by a big shock. It sobered us for a moment; but we are getting used to them now. Several others occurred—this evening a big one. They are having shocks all over the south island. In the direction of Tarawera now there is always an immense column of steam like a huge white cloud, and about 600ft. high.

"We are already getting irreverent, and call the earthquakes 'wobblers,' and the volcanoes 'puffing Billy,' or 'spouting Billy.'

"There is a variety of opinion as to whether the land will ultimately be spoilt or enriched. At present we are bound to keep two cows for our own use, for milk and butter, and also the horses. There is no grass; we have to feed them with hay and carrots. Food for stock is at famine prices. We all think the grass will grow through the deposit."

Other parts of the letter I have omitted as not bearing much on the subject.

A. W. Lambert.

THE COMPOUND NON-CONDENSING ENGINE FOR YACHTS AND LAUNCHES.

[26200.]—"INGENIERO" (letter 26132, p. 556) is in error in supposing that I claim greater economy for the compound non-condensing against the compound surface condensing engine; in fact, if he will refer to my letter he will find that I make no mention of the latter. I advocate the compound non-condensing engine in yachts and launches for this reason, that it possesses the advantages of a high rate of expansion, though in a lesser degree, than in the compound surface condensing engine, whilst the condenser, air, and circulating pumps are dispensed with; it can therefore be taken as a medium between the high-press. and compound surface condensing engines. I do not think I am far wrong in stating that the consumption of coal in the compound non-condensing is as two to three against the high-press.

As a theoretical illustration, suppose we have a

double-cylinder high-pressure engine: diameter of cylinders, 5in. by 6in. stroke; steam press., 80lb.; number of revolutions, 200 per minute; cutting off steam, say $\frac{1}{2}$ stroke; this will give an average mean-pressure of 67lb., and a total mean load on one piston of 1273lb.; cubic feet of steam used per hour = $\cdot125 \times \cdot25 \times 2 \times 200 \times 60 = 750$ in one cylinder = 1,500 used in both cylinders.

Let us take a compound engine having cylinders 6in. diameter and 12in. diameter by 7in. stroke with the same steam pressure and number of revolutions as the high-press. engine. The average press. in the h.p. cylinder to equal the load on the high-press. engine piston will be about 46lb., and in l.p. cylinder $11\frac{1}{2}$lb.; cubic feet of steam used per hour = $\cdot16 \times \cdot2 \times 2 \times 200 \times 60 = 768$ against 1,500 in the high-press. engine. In this case steam is cut off in the h.p. cylinder at $\frac{1}{4}$ stroke; but in practice a later cut-off would be required to develop the same power as in the high-press. engine, which would bring the ratio of coal consumption as two to three; that is, if the high-pressure engine use 3lb. of coal per H.P., the compound non-condensing would use 2lb., and do the same amount of work. Surely this is worthy of consideration, even in small boats. I am of opinion that the compound non-condensing type will be much used in launches eventually. I quite agree with the remarks of Mr. Seaton (letter 26162, p. 579) on the compound surface condensing engine: it is undoubtedly the best, as is proved in the mercantile marine, but it is likely to have a rival in the triple expansion engine. In reply to "R. N.," I have not yet been to the Exhibition, but intend doing so, when I shall no doubt be better able to reply to him on the engine referred to—viz., the single-crank compound. At the same time you will admit that it is not so handy in starting as the double-crank engine, which is a vital point in launch engines. Is not the condenser in danger of getting damaged by being placed outside? The ratio of cylinders appears to be very large; although there is no necessity to divide the work equally in the single crank, at the same time I think it is better to do so. The coal consumption of 20lb. per hour is very low—is this taken from actual work? Also at what speed did the engine drive the boat?

Engineering Manchester.

LOCOMOTIVES, &c.

[26201.]—I RESERVED my reply to Mr. W. J. Grey, as he had referred to Mr. Stretton to decide the question about the data he requires. I am much obliged to Mr. Duncan for his letter, and trust that this confirmation of my opinion on the subject will satisfy Mr. Grey. As to repeating the dimensions of the G.N. engines, I still fail to see the necessity of so doing, especially as Mr. Grey complains in the "E. M." of March 5, 1886, p. 18, of being "fairly deluged with dimensions." I may add that Mr. Stroudley made a number of very interesting experiments on the Brighton line with his express engine, Gladstone, of which I have full particulars. If these would be of any interest to Mr. Grey, I will with pleasure lend them to him if he will give me his address.

I am very glad to see, from Mr. Thompson's letter, that the M.R. 900 class are being rebuilt. Can he say what cylinders and boilers they are to have?

I certainly agree with "G." in thinking the Great Britain class very economical engines, and as far as I can judge they seem quite powerful enough. I returned with one from Swindon a few weeks ago with an exceptionally heavy train, and the speed never fell below 60 miles per hour till nearing London. The G.W. engines, especially the single expresses, are very economical engines, and reflect great credit on their superintendent.

In reply to "Gorton" *re* the Crewe compounds, I fail to see that I credited "P." with an *unduly* high appreciation of the Webb engine. I intended my remark to convey the idea that "P." thought better of them than most people. I do not think it possible for anyone who knows them (even a little) to *appreciate* them. Especially should I be surprised if "P." does, as he says he lays great stress on economy. With their enormous first cost, their amazing coal and oil consumption, their peculiar tendency to lose time, and their habitual breakdowns, they have the unenviable reputation of being the most expensive engines running. As an instance of their losing time, I may mention the following amusing incident:—On asking a friend how the Compound had done with the 10.15 into Euston, he replied, "We were 15 minutes late at Warrington, and we have lost time all the way." "P." evidently is *disposed* to think well of them; but I can assure him they will not improve on acquaintance. The Precedents are much better engines; they do as hard, if not harder, work on less coal and oil, and keep time much better, and I should say cost but little more than half the cost of a Dreadnought to build. It is curious to note that two of our best loco. superintendents are quite decided against compounding—they are Messrs. Stroudley and Stirling. Indeed, Mr. Stirling has said he would as soon think of compounding with his creditors as he would of compounding his engines. And can anyone say—much less prove—that these two gentlemen are wrong? I think not. The most successful application of the compound system to non-condensing engines has, I think, been seen in the portable engine, in which it has been adopted with considerable success according to experimental trials. But as yet we have no experience in actual work to confirm this. However, if we examine the compound portable engine of a leading maker, we find a great many reasons why it should be very economical. The piston speed is low as compared with an express engine going 60 miles per hour, the number of revolutions being 90—135 according to the power of the engine, the stroke varying from 18in. to 24in. The boiler pressure is 140lb. to the square inch, and an efficient automatic expansion gear, controlled by a high-speed governor, is fitted to the h.p. cylinder and last, but by no means least, some of England's best engineers are making them a speciality. The apparently good results obtained from these engines lead me to believe that a compound goods-engine stands a fair chance of success, and I have before now advanced this opinion. Two papers on "Compound Locomotives" have been read before the Mechanical Engineers, from which it appears that compounding locomotives working goods and mixed trains has been attended with some success. I hope the engineering press will freely criticise these papers. It would be interesting also to hear how the Webb bogie-engine, ordered by the Paulista Railway, Brazil, is doing. Perhaps "Gorton" can enlighten us.

G. D. Seaton.

RAILWAY RETURNS.

[26202.]—THE accompanying table is compiled from the reports for the half-year ending June, 1886. The train mileage includes work over foreign lines:—

	No. of Engines.	Miles worked.	Train mileage.	Net receipts.
Great Eastern	685	1,104	7,425,711	£749,963
Great Northern	775	919	8,696,616	730,009
Great Western	1,597	2,610	14,523,817	1,793,223
L. and N.W.	2,323	2,554	18,230,304	2,261,897
L. and S.W.	541	837	5,515,411	587,919
Midland	1,750	1,855	16,316,459	1,614,639
North Eastern	1,506	1,707	11,101,289	1,249,218

G.

BRAKE TRIALS.

[26203.]—YOUR readers may like to know that there have just been some brake trials at Burlington, U.S.A. The brakes tried were the (1) American; (2) Eames; (3) Rote; (4) Westinghouse; and (5) Widdifield. Some of the trains consisted of fifty goods or freight cars, and experiments were made with these very long trains on severe inclines. The results show that the Westinghouse brake was perfectly successful on fifty vehicles; but not one of the other systems could efficiently work upon this length of train. The Westinghouse train consisted of fifty freight cars, of 20 tons each, running full speed down a bank of 1 in 95, and was stopped and regulated with the greatest ease.

U. S. A.

BRAKE BLOCKS.

[26204.]—IN reply to a letter from our worthy friend, Mr. Ghilleasbuig McTomae (26161), regarding "Brake Blocks," I may say that his statements are entirely wrong as regards the Caledonian Railway Company working the vacuum brake on their stock. They do nothing of the sort; they work the Westinghouse throughout all their railway district. That is, from Carlisle to Aberdeen both the Westinghouse and vacuum brake are fitted on the West Coast carriages, which run from Euston to the North by Caledonian Railway route, only for the accommodation of the L. and N.W. Railway Company, which have adopted that brake (the vacuum).

Several of the Caledonian vehicles are fitted with the Westinghouse and vacuum brake for the purpose of giving the use of such to either company which works the different brakes. Had both companies adopted one of the brakes, it would have been the means of a considerable deal less expense to the companies concerned.

I am inclined to think Mr. Ghilleasbuig McTomae has not travelled across the Border, or the smallest boy porter could have given him the correct information he so much requires.

But for the Stranraer carriage, it is a joint-stock carriage, and has both vacuum and Westinghouse brakes.

Caly. Ry.

BRAKES.

[26205.] — YOUR correspondent, Ghilleasbuig McTomae, p. 578, is in error with reference to the brakes used on the Caledonian Railway. This Company, some years ago, adopted the Westinghouse Automatic Brake, and it has been fitted to nearly all the rolling stock. Some vehicles have been fitted with the vacuum apparatus in addition, for use when required to run south of Carlisle over the London and North-Western Railway.

The West Coast Joint Stock, and some North-Western vehicles, are also fitted with double system for exchange at Carlisle.

Clement E. Stretton,
Consulting Engineer Amalgamated Society of Railway Servants.
306 City-road, London, E.C.

MIXED TRAINS.

[26206.]—FOR several years past the Amalgamated Society of Railway Servants has strongly condemned the running of mixed passenger and goods trains, and has urged that if such trains are run the passenger carriages should at least be placed in the safest place near the engine and in front of the waggons; and at the last meeting of the committee, held at this office in July, it was resolved:

"That this Committee condemns the working of mixed passenger and goods trains, as fraught with danger through the breaking of axles or couplings, and interference with the working of a continuous brake on the passenger portions of such trains. Also on account of the difficulty experienced by drivers and guards in stopping the carriages at the platforms of stations where passengers have to alight. It was further resolved that a copy of this resolution be sent to the Board of Trade."

Several accidents have recently occurred to mixed trains, and it is very satisfactory to find that the following circular has just been issued upon the subject:—

R. 4,163. [COPY.]

"Board of Trade Railway Department,
London, S.W., 25th August, 1886.

"SIR,—The attention of the Board of Trade has been specially directed by some of the reports which have recently been received from their inspecting officers to the practice of running mixed trains in which passenger carriages have been attached to goods waggons. The facts brought to their notice in these reports have borne out the opinions expressed in previous reports as to the dangers arising from the running of mixed trains, especially when goods or other waggons are placed between the engine and the passenger carriages. The inspecting officers report that the risk of so placing the passenger carriages outweighs the advantages which may in some cases of accident to the front of the train have resulted from the waggons taking the worst of the shock. In these circumstances the Board of Trade wish to call the attention of the directors of the ——— Railway Company to the desirability of avoiding as far as may be such a practice. If the running of mixed trains is not altogether avoidable care should be taken that any waggons attached to such trains are specially constructed for the purpose, and fitted with such appliances as are generally adopted in the case of passenger carriages. The Board of Trade trust that, when the condition of the traffic necessitates the running of mixed trains, the passenger carriages will, as far as possible, be placed in front and not to the rear of goods waggons, and that all other precautions will be taken to lessen the risk of conducting traffic on such a system.—I am, Sir, your obedient servant, COURTENAY BOYLE.

"To the Secretary of the ———
Railway Company."

We can only hope that the railway companies will give the subject immediate attention and alter the dangerous system of working, but unfortunately so many circulars and requests have been disregarded in past years that probably little will be done until Mr. Channing's Railway Bill becomes law.

Clement E. Stretton.
Consulting Engineer Amalgamated Society of Railway Servants.
306, City-road, London, E.C., 27th August.

RAILWAY SIGNALS.

[26207.]—IF "Libra" will be good enough to refer again to my letter (p. 529) he will find that the quotation from Major Marindin's report states that the committee on signals is formed by the "Associated Companies." If he applies to the association, probably he will obtain the list of the various representatives.

In reply to the second question, in cases where there are four lines, the signals for the two lines in each direction can conveniently be placed side by side upon the "proper" or left hand of the railway. In some instances girders over the line are used to carry the signals, which can then with advantage be placed over the left hand of the line to which they refer.

I am unable to agree with "Libra" that cost has nothing to do with the question. An efficient system is more expensive than an inefficient one, and in the course of interviews and communica-

tions with railway officials, I am constantly reminded of the *cost* of improved systems and appliances. During the past twelve or fourteen years I have examined a very large number of signals, and I find that in every case which has come under my notice of a driver mistaking a signal, the signal itself has been found to be badly placed or fixed on the wrong side. **Clement E. Stretton.**

Consulting Engineer Amalgamated Society of Railway Servants.

Glen Magna, August 28th.

MIDLAND EXPRESSES.

[26208.]—I HAVE found that the principal cause of main line trains on the Midland failing to keep time is the numerous excursions.

Twice in one month I travelled by the Scotch express due at St. Pancras at 8.30 a.m. On each occasion we had an excursion in front of us, the result being that we were blocked at several stations, and arrived more than 30 minutes late. Surely this should not be. I travel a great deal on the Midland, and when away from the excursion traffic, find the time kept as nearly perfect as can be expected. **E. G. H.**

AUTOMATIC ACTION.

[26209.]—I NOTE that "Libra" says at the end of letter 26146, p. 577, that the Government Inspectors have set their faces against anything "automatic." There must be an error here. All signals are weighted so as to automatically fly to danger. The Board of Trade will not allow a non-automatic signal. Then, again, look at brakes. Does not the Board of Trade keep trying for automatic action? **Anti Vac.**

EARLY PRIMROSES.

[26210.]—IT may, perhaps, be worth noting that the common primrose (Primula vulgaris) has been in bloom in my garden here since August 16th, and that at the time of writing 17 flowers are fully out and numerous buds are in a forward state. The roots were transplanted from Kent at the end of November, 1885, most of them at the time being in flower and continuing to produce blooms through the winter until April. All appear to be in a very healthy condition. They are growing along the border of a narrow bed in front of the house, facing due south, and thus receive the whole of what sunshine there is to be had, as well as the reflection from the red brick wall. Soil, clay. (The political atmosphere of the district is strongly Conservative.) **R. T. Lewis, F.R.M.S.**

Ealing, W., August 27th.

THE WONDERFUL LAMP.

[26211.]—I MUST again disclaim all interest in this lamp. There is evidently an idea that I am "pushing" the sale of some particular lamp, so that while, on the one hand, Messrs. Bowron, Caplatzi, and Mag. est Ver, try to pooh-pooh the existence of such a lamp, Messrs. Paul Ward and Cherrill now say there is nothing wonderful in its performance.

Granted; I never said there was. All I said (and my statement has been abundantly verified by Mr. Carter, Prof. Cheshire, and others) was, that with two cells of a *chromic acid* battery, exposing 32 square inches of negative surface, I was able to light well a certain 5c.p. lamp.

My knowledge of the difference between the cold and hot resistance of lamps has nothing to do with the question; as a matter of fact, in the article which I quoted, special mention is made of the "hot resistance" of the lamp.

As we were discussing 5c.p. lamps only, I was quite correct in making the watts consumed the measure of "efficiency." In conclusion, may I be allowed to congratulate the readers of "Ours" on the appearance of a letter from Mr. Nelson K. Cherrill in its pages? In all matters connected with photography this gentleman is *facile princeps*, and will, I am sure, be of great benefit to all in need of information. **S. Bottone.**

ENGLISH VERSUS FOREIGN MICROSCOPES.

[26212.]—AS an Italian (and consequently without national bias), I may, perhaps, be permitted to say a few words on this subject. There can be no doubt that the English lens-makers are capable of making as good (if not better) objectives as any made by their Continental brethren. But owing to the enormous disparity in the price of labour and of food, the English maker cannot compete with his Continental rivals in point of price.

Having had occasion to deal pretty extensively in microscopes and their accessories, I have had considerable experience on this subject, and I find that the price charged by the English workman for the delicate and accurate brasswork of a microscope is generally equal to the entire charge for the complete instrument abroad.

Owing to this disparity in the prices of labour and food here and on the Continent, we may safely say that for a given sum one can at present obtain a better microscope from certain German and French firms than from the English ones. And on the other hand, if one be content to pay the tip-top prices of the best English makers, he may be sure to obtain an instrument which will fear no rival. **S. Bottone.**

[26213.]—IN reply to your correspondent, "Briton," p. 580, Vol. XLIII., I do not know much about the microscopes in use in medical schools, but I am an enthusiastic worker with that instrument myself, and if your correspondent is correct that foreign microscopes are largely recommended by science teachers in preference to English instruments, I think it is a matter that is worth the attention of anyone interested in this instrument, and that the superiority which I have always considered as appertaining to English instruments should not be allowed to be extinguished by a lack of sufficient demand to stimulate the enterprise of our English opticians. I would, therefore, suggest that some recognised authority should take the matter in hand—say our Royal Microscopical Society. Perhaps Mr. Crisp, the energetic secretary, might be induced to give the movement his aid, and at one of their winter meetings the whole of the opticians in London be invited to show the special forms of instruments they consider most useful to students. It would then give anyone who cared to have it the opportunity of seeing what English manufacturers can do; and I for one have sufficient faith in my countrymen to believe that when they come to be compared, it would be detrimental to the foreign instruments.

I shall be very interested to hear that something of the sort might be arranged, and that the greater number of London microscope-makers would worthily represent themselves at the meeting. **Another Briton.**

[26214.]—IT is a pleasure to many, besides myself, to find your correspondent, "Briton," taking up the cudgel on behalf of English mechanics. It is simply discreditable to all concerned to supply foreign brass, glass, or steel goods to our institutions. Every English workman who takes the trouble to examine those samples that fall into his hands knows that *none* of the foreign productions excel English in quality, very few equal them, and as to price—well, I should indeed be sorry to find *our* workers producing some of the horrible work that finds its way here at any price. Undoubtedly such trash is palmed off wherever there is an opportunity, and there are certainly very great chances for a certain class of buyers to get a series of "tips" out of foreign makers and their agents, which not only hide the bad places in the work, but really glazes defects so cleverly as to make almost advantages out of them. Your "industrious foreigner" and his agents can get off their hands such work as no English maker would pass; indeed, I have, in my own experience, seen a large quantity of different classes of optical goods of foreign make, and I can truly say if an apprentice under my instructions for six months, dared to bring me such work as is constantly sold, I would put the work under the hammer, and make every effort to get the apprentice to change his vocation. One great evil is growing out of this *free* trade. A few years ago many makers of small *good* goods could live in this country; whereas now his place is taken up by the "industrious" and his agents, who have thus the field, and dispose of heaps of small *bad* goods. Of course they can do this to pay, simply because common stuff is cheaply produced, and, after a succession of "tips" and profits, can be sold at a cheaper rate than good work, whether English or foreign. I have always found that the *best class* instruments of foreign make are certainly a long way behind ours for "fit" and "finish"; taking the difference of cost in most cases, you are scarcely getting 9d. worth for your 1s. when you buy a foreign instrument. With such makers in our midst as Ross and Co., Powell and Lealand, Beck and Beck, Crouch, Swift, and the host of English makers besides, the first being in the van of the micro. army of the world, both in glass and metal-work, it is an insult to common sense to attempt an apology for the presence of a foreign instrument of that sort. The same may be said of surgical, mathematical, and musical instruments.

This part of the subject shows the English mechanic a wily, although an open, foe, by comparison with the English makers (?). Who brands with a good old English name the foreign trash he buys and sells? Who has an empty workshop and a full wareroom? Whose very existence means the starvation of x families of the artisan class? Whose practical knowledge of the trade is only that which is learned behind the counter? How *we* thank *these* thousands of destroyers of the "back-bone," the "sinews" of the country, the British artisan. Would that the time-honoured request, "buy of the maker," retained its old truth and efficacy. **Prismatique.**

LIMITED EXPRESSION OF CHAMBER ORGANS.

[26215.]—REFERRING to the articles on chamber organs, by Mr. Audsley, I find him, in speaking of the limited power of expression possessed by organs, saying that "every expedient that can be devised to increase the flexibility of the instrument in this direction will be of the highest value from a musical point of view." Seeing that in all his subsequent remarks he gets no further than the "balanced" swell pedal, I wish to point out to him that the power of "swelling" is now at perfect command of the player without requiring either feet or hands to produce it, by means of a contrivance invented by Mr. Jno. Morland, organist of Waterford Cathedral. In this the weight of the player on the stool is so utilised that whilst he has *both feet* engaged in pedalling and *both hands* occupied in the manuals, he can with ease and certainty open the swell to any extent and keep it open as long as he wishes at any particular point; indeed, that power of expression, or gradual swelling, or diminishing of the tone is now to be had at *constant command* of the player, and thus for the first time in the history of the organ a player can indulge in accent or emphasis as freely or as sparingly as the character of the piece being performed may require, and all this without any discomfort or inconvenience to his manual or pedal playing.

I cannot help thinking that this will prove a great boon to all organ-players, whether professional or amateur, and hence my desire to acquaint Mr. Audsley of it, and your numerous readers, who must, like myself, find his articles so exceedingly interesting and useful. **Charles Melross.**

CURATIVE POWER OF MAGNETS.

[26216.]—THOUGH Mr. E. Willmore protest against my leaps, I do not see that at present his views on this subject differ very much from mine. From his admissions the *suggestions* I make follow quite rationally. His simile of his Mansion House proves more in my favour than in his. The connection between clairvoyance and mesmerism on the one side, and the magnetic plate of the body on the other, is beyond a doubt.

These two faculties have been proved to be the effects of *animal magnetism*, not in one, but in a whole pile of books. Surely Mr. Willmore does not deny the influence of the physical man on the intellect, and vice versâ? And if he admits it, a wide and rational bridge is at once established between the state of the body and the productions of the mind. Consider a man in danger, in terror, in ill or good health, or in love, and how these states react on each other, how they affect his mental creations, his physical achievements, and my *suggested* explanation at once loses its absurdity. I should have been glad to hear simpler and more natural ones from E. Willmore or any other psychologist, and it is with that view only that I threw out mine, and by no means because I had made up my mind that it was the right one. **A. Caplatzi.**

"BIG BEN" BEATEN.

[26217.]—THE writer in *La Nature* (p. 579 Vol. XLIII.), evidently knows little of the subject he writes about, or he would never claim that the clock at Avignon has beaten the famous Westminster timekeeper because of its four seconds' pendulum of only 132¼lb. weight. Such pendulums are no novelty, vide "Clocks and Watches and Bells," sixth edition, p. 168, where the author states: "The fashion of extravagantly long pendulums has very properly gone out, as their inconvenience and liability to be affected by the wind overbalances any advantage from them in a moderately good clock. There were several in Yorkshire until lately as long as 56ft. or four seconds." As the total weight of "Big Ben's" pendulum is about 700lb., of which the bob alone weighs 4cwt., he may still be said to hold his own against all competitors, and a few more particulars of the escapement, variation of rate, &c., of the Avignon clock must be forthcoming before it can be even said to approach the performance of the famous production of Sir Edmund Beckett (now Lord Grimthorpe) and the Messrs. Dent. **H. D. A.**

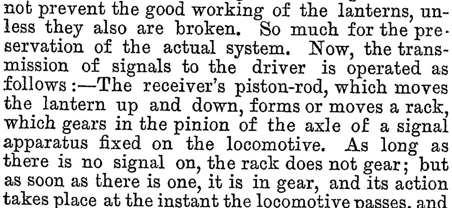
ELECTRICAL INERTIA.—Erratum.—P. 554, 3rd column, top two lines, should be: "Where the *induced* current existed for *two seconds* after the inducing current had ceased."—PAUL WARD.

THE Oak Lawn poultry ranche, of California, hatched 2,500 chickens, and has 3,000 eggs in course of hatching and 1,200 more to begin. The incubators, hatching houses, brooding houses and runways have a capacity to keep 5,000 eggs in process of hatching all the time. The superintendent has invented and built an incubator with a capacity of 400 eggs, which has just turned out 80 per cent. of live chickens.

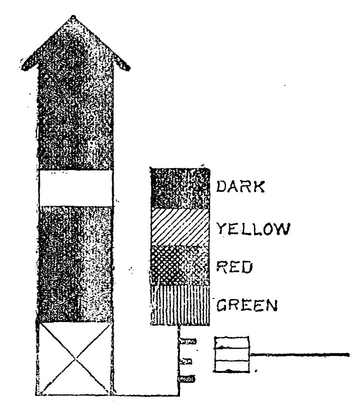
REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[59610.]—**Railway Signals.**—No. 1,116, p. 531, Errata:—Column 2, line 4. . . . Allow a *pointsman*, read a *Frenchman*. Third column, . . . that they (the signals) are not conveyed to their *distance*, read *their destinée*. By this expression I meant the driver to whom they are destined. Now for my system. I have slightly modified it in order to preserve and improve the actual sight or optical mode, as its mechanical parts may vary at the engineer's will and wish. I will not detail them, and will limit myself to the description of the principle. The system may be divided into two parts, the first one extending from the signalman's box to the signal-stand on the line as usual, and the second one from that stand to the driver's place on the locomotive. The signals are transmitted from the signalman's box to the signal-stand by hydraulic, or, rather, liquid pressure, produced by a cylinder and piston in a tube, the diameter of which may be that of a quill pen, carried in the ground to avoid accidents. Each end of the tube is terminated by a cylinder with a piston, the first one of which I call the sender, the second one the receiver. Supposing the signals to be three in number, the piston stroke is divided in three parts, each one corresponding to the sound, colour, number, and signification of the signal. I suppose the signals to be:—No. 1, "*on*," one whistling, yellow; No. 2, "*stop*," two whistlings, red; No. 3, "*back*," three whistlings, green. The piston moves are produced by a hand-lever at the signalman's command. Of course as the sender's piston is pressed down, the receiver's rises up. This effect, which can be obtained at any distance, is instantaneous. In order to avoid freezing, the liquid used in the tube is glycerine, petroleum spirit, or any other non-freezing liquid. The receiver's objects are two: (1) to move up and down a lantern in coloured glasses; (2) to command, by means of a rack, the pinion of an axle placed on the locomotive which moves the driver's signal apparatus. The signal-stand consists in an opaque box or pipe, in the centre of which there is a lighted lamp or gas-burner. The centre part of the box or pipe is glazed so as to permit, in every direction, the sight of the coloured light existing therein. This coloured light is produced by the lantern coloured glasses, which are superposed horizontally. When the sender's piston is at rest or standstill, its opaque top faces the box's glazed part, and no light is transmitted. When pressed down to No. 1, the yellow glass part of the lantern faces the box's glazed part, and a yellow light is transmitted all round, which means "on." If the piston be pressed down to No. 2, red is in sight, and means "stop." Finally, if pressed to No. 3, green is seen, and means "back." Thus far the usual optical or sight system of signal is preserved, and it is improved in this respect, that the colours are seen in every direction, and there being double glasses, as the lantern is inside of a glazed box or pipe, the chances of breaking are greatly diminished. The breaking of the box glass would not prevent the good working of the lanterns, unless they also are broken. So much for the preservation of the actual system. Now, the transmission of signals to the driver is operated as follows:—The receiver's piston-rod, which moves the lantern up and down, forms or moves a rack, which gears in the pinion of the axle of a signal apparatus fixed on the locomotive. As long as there is no signal on, the rack does not gear; but as soon as there is one, it is in gear, and its action takes place at the instant the locomotive passes, and gives accordingly the signal No. 1, 2, 3, in number, in



colour, in print, and in sound, in the following manner:—On the driver's stand there is a small apparatus consisting in a fixed flat dial on which there is an aperture; behind this dial is a rotating disc divided in three coloured sections—yellow, red, and green. Each section has a cam, and bears No. 1, 2, 3, and the words "on," "stop," "back." The cam's object is to act upon the hand of the bellows of a whistle placed behind, so that when the piston stroke is at No. 1 division, the yellow section of the disc appears before the dial's aperture showing No. 1, and the word "on," and one whistling is heard. When at No. 2 it is "stop," red, No. 2, and two whistlings, and when at No. 3, "back," green, No. 3, and three whistlings are heard. The whistlings cannot fail to call the driver's attention to the dial, the indications of which are imperative. Of course the driver obeys the order; but in the mean time the train advances, and passes the post; but, in consequence of the signal being seen all round, he has only to look back to see it. As I before said, the mechanical contrivance of the system can vary



at the engineer's pleasure. I merely indicate its principle and mode of acting. I hope, however, that what I have said is sufficient to prove to the interested that by such a system, signals infallibly and unmistakably reach the driver as well as the signal-post, and this without any trouble for him to look after it on whatever side it may be; that they are transmitted to him by sounds, colours, numbers, and meanings; that he cannot fail to hear and see them both at his stand and on the post; that all the informations now given are preserved and improved; that new ones are added; that the distance and the side of lines are of no consequence; that there is no wire, and, therefore, no breaking, contraction, or expansion to be feared; that the spectacles are safer; that the signals are seen in every direction; that the working is simple and easy, requiring but little power. Perhaps it is not useless to add that this system is not patented, and that all I claim is the paternity of my child. The same system may be applied so as to have at two stations the automatic information of the train's progress on the lines, and also to form a telegraph.—CH. RABACHE, Morchain, Somme, France, 23rd August.

[59842.] — **Mathematical Probabilities.**—TO "ALIOTH."—The table you require may be calculated in the following way:—If the odds be n to 1, divide log. $(n + 1)$ by the first three figures of M—that is, by ·434; the quotient to three figures is the number required. Take, for instance, even odds (the fraction you know to be $\frac{7}{10}$), $n = 1$ and $\frac{\log.(n + 1)}{M} = \frac{\cdot 30103}{\cdot 434} = \cdot 069$, which is very nearly $\frac{7}{10}$. In the same way the number for odds 10 to 1 is found to be 2·40. Your example can now be easily solved. Opposite to 10 to 1 in the table is 2·40; multiply this by 20 (the original odds), and the result, 48, gives the number of throws required. I did not intend my letter to be "savage," but if I have hurt your feelings in any way, I can only express my deep regret.—R. E. F.

[59854 & 60050.]—**Shot Paradox and Boxes of Spheres.**—Why "paradox," I should like to know? What is there paradoxical in n inch balls going into a closed box containing $< n$ cubic inches, seeing that a spherical inch is only ·5236 of a cubic one? And what does "E. L. G." mean by his answer (p. 583) to "J. K. P.'s" question of the closest way of packing a very great number of balls, which I had answered incidentally in the same paper in which it was asked, that the triangular and the rectangular modes of packing leave exactly the same minimum of empty space —viz., ·26 of the whole mass, if large enough to neglect the margins, which vary a little with the shapes and sizes of the piles? "E. L. G." professes to contradict that by saying that "the base must be neither like that of a honeycomb (meaning the common triangular setting), nor square, but like the alternate squares of a chessboard." He does not give the relative sizes of the balls and squares, but I suppose he means the balls to touch or their diameter to equal those of the squares, for otherwise there would clearly be not less, but more, space left empty. But if he does, that is simply the common square set pile looked at diagonally instead of directly. Again, what is the use of his confessing that his 38 was a mistake for 32 when I had shown that it involved no less than 14 mistakes, for that 14 numbers less than 38 will go into a box containing fewer cubic inches? The fact is, he had invented a formula which is evidently wrong for any kind of pile, and it naturally led him to a multitude of wrong results, as he must be well aware by this time, but seeks to cover his retreat by a display of utterly irrelevant fireworks about cubes and "oblong tubes" (as he is pleased to call my boxes, which were nearly as wide as they were long, and nobody had said anything about cubes), and "bishops and rooks moves on a checker layer" (which most people would spell chequer, but, of course, he knows better), and "cleavage directions," all in the most uncleavable direction of all—viz., right through the centres of the planes of balls; and says that "of course he was not considering a single layer." But if not, why wasn't he, seeing that it is a fundamental and à fortiori ingredient in the problem? And he certainly did not exclude it. That implies, too, that I had dealt with single layers only, whereas I had given 3 and 5, which was his own maximum for his 38 balls. Anybody may make mistakes in calculations or in inferences from them; but these methods of trying to conceal mistakes are not creditable. "E. L. G." is always writing as if his dicta were sufficient to correct anybody, whereas it is clear that they are quite as likely to be wrong as right. To be sure, "it may only be his fun," as "F.R.A.S." says about him on another subject of which he knows a hundred times as much as "E. L. G.," but it is rather poor fun, and hardly worth even laughing at. I may as well now drop the word "Another," though I cannot supply another initial without risk of confusion, and so I sign simply—G.

[59870.]—**Carnation Disease.**—The following, which I take the liberty of extracting from an article by Mr. Worthington G. Smith in the *Gardeners' Chronicle*, will throw further light on carnation diseases:—"During the last few years a destructive brown mould has been very common on carnations. In bad cases whole collections have been destroyed. The name of the fungus which causes the mischief is Helminthosporium echinulatum. The fungus was first described, with a small illustration, by the Rev. M. J. Berkeley in the *Gardeners' Chronicle* for March 19, 1870, since which time the attacks of the parasite have greatly increased both in frequency and intensity. The superficial appearance of the fungus as it grows on both sides of the leaf is very distinct, and may be immediately recognised by its correspondence with the accompanying figure. [Mr. Smith gives a drawing, which I do not copy.] The mycelium or spawn of the fungus, the threads of which are comparatively very thick, creeps in a radiating fashion inside the leaf immediately below the leaf epidermis. From the inside of the leaf the fruiting threads burst through to the outside in a series of black concentric circles like minute fairy-rings. When a fragment of one of the miniature fairy-rings is removed with the point of a lancet, and examined under a microscope with a power of 400 diameters, the fungus is seen as in the lower part of the illustration. The mycelium is very thick and lumpy, and the supporting stems of the spores are also very irregular in shape, and jointed. The spores themselves, which are borne on the top of, or at the sides of the fruiting threads, are very handsome, and are either without articulations, or have from one to five joints or septa, as illustrated. The spores are very finely and beautifully echinulate; they are slightly constricted at the joints, and each spore is furnished with a very minute but perfectly distinct footstalk, as shown. When spores are jointed, as in the examples before us, each joint is capable of reproducing the fungus on germination. As the fungus vegetates between the two membranes of the leaf it cannot be reached by any sulphuring process without destroying the leaves; the only mode of action that can be taken, therefore, against the fungus is to very carefully pick and destroy every infected leaf. Dr. Cooke has described, under the name of Helminthosporium variabile, a fungus not to be distinguished from H. echinulatum. H. echinulatum sometimes leaves carnations, sweet Williams, &c., amongst the Caryophyllaceæ, and infests Ornithogalum; when on Ornithogalum the fungus is named (for a change) Heterosporium ornithogali. Three years after Mr. Berkeley had published the plant before us under the name of Helminthosporium echinulatum, he republished it in the *Annals and Magazine of Natural History*, May, 1873, under the name of H. exasperatum! The fungus, therefore, has four names—two given by the same author, and two which must be regarded as synonyms."—SAML. RAY.

[59983.]—**Consecration.**—I do not know what I have done that such a question as this should be directed to me. At any rate, I can't answer. I don't know how a house could be "left on will for Divine worship." The proper place for divine worship is a church where all the seats are free.—LIMB O' TH' LAW.

[59985.]—**Sleeplessness.**—The best remedy for sleeplessness in those advanced in years who cannot take active exercise is mental work of a kind

that is likely to tire the brain. To many people the endeavour to reckon up how much they have spent during the day, or during the week, accounting for every item, is often a capital soporific, and so, I should think, would be the endeavour to solve some problem in electrical engineering, involving the calculation of resistances and weights of wire, &c. It is impossible to criticise the method of "Bionomist," because, like the Spanish fleet, it is not yet in sight; but there is too much mystery about it to induce a belief that it is a real remedy for insomnia.—SAML. RAY.

[59989.]—**Problem in Chances.**—The whole number of possible payments in one day is $35 \times 12 = 420$, of which 418 payments are odd and only two even; the probability, therefore, of an odd payment on any one day is $\frac{418}{420}$, of an even payment $\frac{2}{420}$, or $1 - \frac{418}{420}$. The probability of there being odd payments on 10 days is $\left(\frac{418}{420}\right)^{10}$, of even payments, on 8 days, $1 - \left(\frac{418}{420}\right)^{8}$. But the probability that two independent events will both happen is the product of their respective probabilities, and as the above events are practically independent, the probability that there will be odd payments on 10 days and even on 8 is $\left(\frac{418}{420}\right)^{10} \times 1 - \left(\frac{418}{420}\right)^{8}$, or about $\frac{65,456}{6,302,060}$, which is, roughly, one chance in a thousand. But we have next to consider the probability that the eight even payments would be divided in the manner stated in the query, viz., six payments of £2 and only two of £3, the most likely division being, of course, four payments each. The numbers are so small that the result can only be approximate; by a rather long calculation, which would occupy too much space, I find the probability to be $\frac{104}{1,000}$, say, $\frac{1}{10}$ roughly. The probability found above, being multiplied by $\frac{1}{10}$, gives a result of ·000104; that is to say, there are only 104 chances in a million, or about one in ten thousand, that the toll-keeper's return is correct. I may observe that while his veracity is a moral question, the measure of his veracity is strictly mathematical, and such questions have been treated at great length by Poisson in his great work on "The Theory of Probability." It looks very much as if the toll-keeper were rather fond of annexing the odd coppers.—R. E. F.

[59990.]—**Walnut Fittings.**—Tallow mixed with umber of a suitable colour; otherwise size.—E. G. M.

[59991.]—**Water Supply.**—This querist should procure Molesworth's Pocket-book, which will be found to contain the requisite information.—T. P.

[60003.]—**Aerated Water.**—Quite possible for animalcules to exist in aërated water. Carbonic acid will destroy all forms of life which breathe oxygen to keep them in existence; but not germs.—T. J. S.

[60014.]—**Fly for Gravity Escapement.**—Why does not "Duffer" refer to Lord Grimthorpe's book ("Clocks and Watches and Bells," by Sir E. Beckett), and discover that he has very correctly named himself?—VIDEO.

[60017.]—**Electro-Motor.**—How can anyone say whether such a motor is in existence without more particulars of that designed by "Magneto."—J. T.

[60038.]—**Dynamo.**—If the iron be soft and good, you should be able to get about 50 volts. 30 amps. out of your machine at about 1,500 revolutions. Of course you must have a laminated armature if you want to run the dynamo continuously. Put about 7lb. of No. 12 on the armature, in one length, and about 50lb. No. 18 on the fields. Connect as a shunt machine.—S. BOTTONE.

[60040.]—**Strains on Arches.**—I think I do include all, and only all, the forces acting on the structure; while "M.I.C.E." includes more than all on one side, and less than all on the other side of the point O. This seems even clearer in the case (page 582) than in the former case. Surely the whole 30 tons at B act downwards at 10ft. (in the 17th line the 10 is evidently intended to be 20) to the left of the new point (call it O^1), just as the other weights to the left of O^1 act at their respective distances from O^1, and surely no part of the weight at B can have any moment at any point between O^1 and the right abutment. The equations would then be—$P \times 27{\cdot}6 = 87\frac{1}{2} \times 160 - (30 \times 10 + 30 \times 40 + 30 \times 70 + 30 \times 100 + 27\frac{1}{2} \times 130)$, and $P \times 27{\cdot}6 = 87\frac{1}{2} \times 50 - 27\frac{1}{2} \times 20$, which give the same value for P. We cannot expect to have quite exact results, because the arm at which P acts is taken to the centre of the depth of the arch, while the line of thrust is a funicular polygon which does not coincide with the centre curve.—J. S. C.

[60050.]—**Shot Paradox.**—I have been hoping to see a methodical solution of "E. L. G.'s" problem (which he now owns is not a paradox); but his last letter, p. 583, beyond giving a few hints, does not give a solution. It is a consolation to solvers to know, as "E. L. G." tells us, that the arrangement is confined to chess-board order—i.e., the spheres standing on the red squares of a chess-board, and touching at the angular points of the squares. I had seen that the cube which contains 500 must be on this arrangement: The base must consist of ten rows of five, and there must be ten such layers. This does not sound like a cube; but anyone by drawing a figure may see that it is so, and that its dimensions are $(1 + 4{\cdot}5\sqrt{2})^3 = 399{\cdot}18$. The box to contain 501 must have its layers either all equal or differing by one. In the first case, since the total number of balls is odd, there must be an odd number of balls in each layer, and there must be an odd number of layers. Using expressions containing x to represent the number of balls in a layer, and expressions containing y to represent the number of layers, we have—

$(2x + 1)(2y + 1) = 501$ .... (i.)

In the second case, the layers are alternately odd and even, in which case there must always be an odd number of odd layers, and either an odd or an even number of even layers, or algebraically—

$(2x \pm 1)(2y \pm 1) + (2x)(2y) = 501$...... (ii.)

or—

$(2x \pm 1)(2y \pm 1) + (2x)(2y \pm 1) = 501$ (iii.)

Solving i., ii., iii. in positive integers, we obtain the following arrangements:—

(a) 9 layers of 29 and 8 layers of 30
(b) 7 layers of 39 and 6 layers of 38
(c) 5 layers of 45 and 6 layers of 46
(d) 3 layers of 71 and 4 layers of 72
(e) 3 layers of 83 and 3 layers of 84
(f) 3 layers of 167
(g) 1 layer of 501

The two last need hardly be considered, so we have now to arrange the layers so that they shall contain the above numbers thus:—

(a) 29 and 30 cannot be arranged in alternate layers except in two straight lines
(b) 39 must be in 6 rows of 4 and 5 of 3
38 „ 6 „ 3 „ 5 of 4
(c) 45 „ 3 „ 7 „ 4 of 6
46 „ 4 „ 7 „ 3 of 6
(d) 71 „ 5 „ 7 „ 6 of 6
72 „ 6 „ 7 „ 5 of 6
(e) 83 and 84 cannot be arranged in two layers except in two straight lines.

We are thus reduced to three arrangements, viz., b, the bottom layer of 6 rows of 4 and 5 of 3; the next layer of 6 rows of 3 and 5 of 4, and so on alternately for 13 layers, the upper one being the same as the lower. c and d will be seen to be the same arrangement, but turned on its side and end respectively. The dimensions of this box will be $(1 + 3\sqrt{2})\ (1 + 5\sqrt{2})\ (1 + 6\sqrt{2}) = 401{\cdot}316$, that is greater than the cube by $2{\cdot}136$, so that the arrangement is not so economical as the cube, the addition of unit volume to the contents increasing the capacity by 2·136. Without being sufficiently at home with mathematics to prove my assumption, I would venture to ask "E. L. G." whether I am right in assuming that that arrangement which is the nearest approach to a cube will be the most economical. I have worked at the problem in several different ways, but regret having mislaid my calculations; but I fancy I arrived at six or seven results, but cannot remember whether I confined myself to square order; but the results were all greater, some considerably greater than 401·36. Will "E. L. G." inform us whether there is any rule for working out such problems? The formula he gives on p. 533 will, I think, only hold for chessboard order. How can it be shown that chessboard order is the most economical?—LINKUM DODDIE.

[60073.]—**Battery.**—TO MR. E. CONRY.—Many thanks for your reply. I have, as you suggested, unsealed the top of the cell, and it appears to me to be simply a Leclanché with agglomerate plates. The pole in the centre, which I mistook for the negative, is the carbon plate cut narrow where it comes through the top; below it has solid black blocks (manganese and carbon I suppose) on each side; outside these is coarse canvas, and all kept together with rubber bands. The zinc plate quite covers the four sides of the cell, and all fit so closely together that there is not much space for the sal-ammoniac solution. The cell is made of vulcanite, or some similar material, and the copper strap is not attached to it, as I supposed, but is riveted to a strip of the zinc plate, which comes through the top. Are they in any way superior to the ordinary agglomerate Leclanchés besides their portability? Is there greater quantity of electricity from zinc plates which surround the carbon than from zinc rods?—G. D.

[60137.]—**Marking Ink—Nigrosine.**—A letter addressed to Mr. F. Carter, High-street, Carshalton, would probably elicit the desired information. This gentleman has long made these dyeing materials an object of study.—S. BOTTONE.

[60137.]—**Marking Ink.**—I fancy the marking-ink sold under the name of "Jetoline" would answer "Maschera's" purpose; it is supplied in cases with two separate bottles containing albumen in one, and (I think) some kind of aniline dye in the other. Equal quantities are to be mixed just before use, and it is very readily applied by stamps of any kind; a small quantity of the mixed ingredients being poured on a pad of indiarubber, and this covered with a piece of cambric or thin calico stretched tightly over it, and kept in place by elastic rings, forming a convenient mode of application.—GAMMA SIGMA.

[60137.]—**Marking Ink.**—In reply to "Maschera," nigrosine can be obtained of dealers in chemicals and dyestuffs under the name of aniline black. Aniline dyes are obtainable of oilmen, &c., in small packets for domestic dyeing, but the black generally turns out on examination to be simply a mixture of powdered logwood extract and green vitriol. Shirt-makers usually, I believe, employ coal-tar thinned with turpentine, though the following is much used:—Heat 9 parts Venice turpentine with 4 parts oleaine till thoroughly incorporated. Place 10 parts of soft soap on a slab and work in above mixture. Now add 6 parts ground and sifted lampblack, mix well, and finally, to improve the colour, add 1 part neutral extract indigo. Above can be used with metallic types. For an indelible cancelling ink nothing I have met with equals Richmond's, of New York). I am not aware whether this has as yet been placed on the London market, but shall have pleasure in sending the formula free to anyone desiring it.—PERCY W. STANLEY, 119, Manchester-road, Poplar, London.

[60141.]—**Differential Galvanometer.**—You require, not a differential galvanometer, but a Wheatstone bridge, and a sensitive galvanometer of ordinary make. To make this latter, get an oblong card box 2in. by 1½in. by 1½in. (such as serves to cover the small "tandstickor" matches). Cut a central slot out of the top, about $\frac{3}{16}$in. wide, to admit the pivoted needle. Now wind this neatly from one end to the other (not covering the slot) with No. 30 silk-covered copper wire. Tie the ends down neatly. Soak in melted paraffin wax. When cold, glue down to a base board 4in. by 4in. Bring out the ends of the wires to two binding screws, inserted at two corners of the board. Drive a fine needle point upwards in the centre of the slot. Now make a glass pivot from a bit of glass tubing, and fasten thereto a well-magnetised lozenge-shaped piece of steel spring, about 1¼in. long. Poise this on the needle. Glue a graduated circle, about 3in. in diameter, having a central hole punched, to admit the passage of the head of the pivot, on to the coil of wire. Now take a light, straight piece of straw, about 2½in. in length, and as thin as possible, and glue it by its centre to the top of the pivot, taking care that it remains exactly parallel with the magnetic needle below. When dry, knock the bottom out of a glass capped box (such as used by mineralogists), about 3in. diameter by 1½in. deep, and glue it over all, to serve as a cover, to protect from currents of air, &c. Full instructions for making bridge were given at p. 286, Vol. XLIII of the "E. M." See also my advertisement in Sale Column.—S. BOTTONE.

[60158.]—**Induction Coil.**—Through illness and overwork, I have not been able to comply with "Telephonist's" request, and even now can only give him a few rough hints (diagram to follow on when I have opportunity of preparing drawing). However, if he cuts his eb. tube into 6½in. lengths, that will do. The ends are secured by screwing them on to tube and the discs are all in their places, separated by distance rings before the coil is begun to be wound.—PAUL WARD.

[60159.]—**Stevenson's Thermometer Screen.**—I beg to express my best thanks to Mr. W. Marriott for the very intelligible instructions given on p. 583. I cannot comply with conditions *re* positions; it will have to be fixed either on a platform on the housetop or in a yard about 60ft. square, surrounded by buildings of various heights. To which would Mr. Marriott give the preference?—TELEPHONIST.

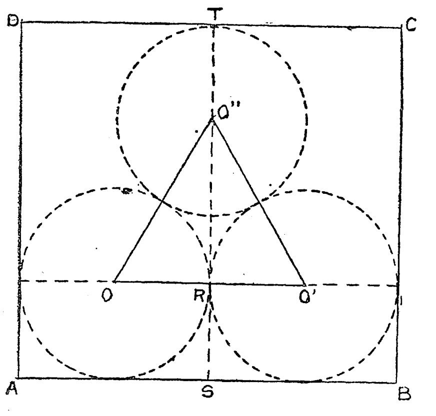
[60174.]—**Photography—Intensifying.**—Do the photographic readers let pass such an answer as that by our learned correspondent, Mr. C. E. Allen, in last week's without some deep criticism? It is by such ridiculous answers that the amateur English Mechanics are led astray and taught the wrong principles of this magnificent art-science. He proffers, I may say, a reducing agent for an intensifier. Can this be an error of unthoughtfulness or of utter ignorance? Be it as it may, but he must remember that the unique toning solution he suggests for an intensifier does in reality reduce instead of intensify. It may strike him that a print, after toning, is very much reduced in intensity

—that is, if he has any photographic knowledge. One particle of gold replaces three of silver, as is known to the merest dabbler in ceramic photos. To more fully illustrate my ideas, we have, say, a negative which we wish to transfer to porcelain, and to obtain the design we employ a gold toning bath to displace the silver particles, leaving the gold *in situ*. The intense image we have before this operation (formed of finely-divided particles of metallic silver held *in situ* by the inert gelatine) is reduced greatly in "pluck" by this replacement of minute particles; hence reduction, and not intensification. Referring to the two following replies by Mr. R. A. R. Bennett and "Citrus," hyposulphite of soda and cyanide of potash are nasty things to play with when inert ammonia stands by. They are not only difficult to eliminate from the film, but do not produce permanent results.—A. TREYER EVANS, Newport, Monmouthshire.

[60177.]—**Electric Time Ball.**—TO MR. BOTTONE.—I am obliged for your reply to my query; but you have mistaken my difficulty. I can manage to drop ball at any time; but I am in a fix how to raise it again ready to receive current. I thought of dropping ball similar to the way clocks are synchronised now—by electric current. Will you kindly send sketch how I can raise it?—W. J.

[60185.]—**L.B. & S.C. Engines.**—No. 4; name, Mickleham, D class: cylinders, 17in. by 24in.; diameter leading and driving wheels (coupled), 5ft. 6in.; trailing, 4ft. 6in.; total wheel base, 15ft.; total length engine, 31ft. 7½in.; total heating surface, 1,040 sq. ft.; firegrate area, 15 sq. ft.; number of tubes, 229; total weight, 38tons 10cwt.; total gallons in tank, 860. E class: 85, also 86 Geneva; cylinders, 17in. by 24in.; wheels—trailing, leading, driving (coupled), 4ft. 6in.; total wheel base, 15ft. 3in.; total length engine, 32ft. 4½in; heating surface, 1,037 sq. ft.; number of tubes, 229; total weight, 39tons 10cwt.; total gallons in tank, 900. Am sorry I cannot supply particulars of L.S.W.R. locos.—G.N.R.

[60186.]—**Mathematical Problem.**—Let A B C D be a section through the middle of the cube containing the spheres.



The side A D = S T

And S T = R S + R O″ + O″ T

But R S = 3 (diam. = 6)

And O″ T = 3

And $O''R = \sqrt{O O''^2 - R O^2}$

$O O° = 6$ and $R O = 3$

$O'' R = \sqrt{36 - 9} = \sqrt{2F}$

$\therefore S T = 3 + 3 + \sqrt{2F}$

$S T = 3 + 3 + 5{\cdot}2$

$S T = 11{\cdot}2$in.

—TOODLES.

[60186.]—**Mathematical.**—The reply of "T. C., Bristol," gives neither the smallest box "cubical in shape" (as "Adam" required) nor the smallest oblong box. The smallest cube to hold three—namely, that of 10·242641 (say 10¼in.)—will equally well admit a fourth ball; but as the third cannot shift from its allotted place when the box is shut, this may fulfil "Adam's" condition of "fitting." If we neglect the condition of being "cubical in shape," the smallest rectangular one is less than two-thirds of the above cube, and less than three-fourths of "T. C.'s" box—namely, one of 6 by 6 by 18—taking the three balls in one row instead of each touching every other. The smallest number to go into a cube less than their own number of cubes is 32. The fewest to go into less space than in a single row is 11 in one layer of 3 rows; and any number under 38 occupy less in one layer than in several layers.—E. L. G.

[60192.]—**Electroplating Bath.**—Silver may be recovered from an old plating solution by any one of the following methods. 1. Use a platinum anode, and deposit all the silver on a cathode of copper foil. 2. Evaporate the solution to dryness, mix the residue with an equal weight of dry sodium carbonate, and fuse on charcoal. 3. Evaporate to dryness, mix the residue with an equal weight of plumbic oxide, fuse the mixture in a clay crucible, and cupel the button of silver and lead on bone ash to remove copper and other base metals. If you wish to get pure silver nitrate the last method will be preferable, as you will only have to dissolve the silver in nitric acid, and evaporate all the free acid, to get silver nitrate crystals. From these any of the other salts may be made. If you only wish to get silver chloride, dissolve the metal obtained from either process in nitric acid, drive off all the free acid by heat, dissolve the crystals in distilled water, and add dilute muriatic acid until all the silver has been thrown down as silver chloride in the form of white curds. If these are stirred with a piece of zinc, the chlorine will leave them to combine with the zinc, and pure metallic silver will be left in the vessel in the form of a grey powder. This should be washed in dilute sulphuric acid to remove all traces of zinc before it is fused, or dissolved in nitric acid.—G. E.

[60194.]—**Strawberries.**—I would inquire of "A Lady Gardener" whether she has had her strawberries taken up each year, the roots and tops cleared of all dead vegetation, the runners cut off, and such divisions made as are natural and easy. If this has not been done, they will grow weaker each year, until they assume the appearance and power of production of wild ones. Plant on a rich high bed, with good drainage, about the end of February. Water liberally in dry weather; when the flowers begin to appear, water them once a week with guano water.—GARDENER.

[60207.]—**Disinfectants.**—In answer to "Zero," I think the most useful classification of disinfectants to give him will be into gaseous and non-gaseous ones. The chief gaseous ones are the following: Chlorine, bromine, and sulphurous acid, which comprise the most powerful disinfectants that can be found; but they have the disadvantage of destroying colours and some of the metals very readily. Among the principal non-gaseous forms are the following:—Perchloride of mercury, sulphate of iron, permanganate of potash, carbolic acid, and most essentials, besides resin and other vegetable products, including an important one—namely, freshly-burnt charcoal, which has the remarkable property of taking up and storing in a condensed form many deleterious gases. Nearly all disinfectants act either by oxidation, or by acting as a poison to organic life. The gaseous ones are the most reliable; but for certain purposes, as disinfecting excreta, carbolic acid or sulphate of iron, or, better, perchloride of mercury, are preferable, as it remains in contact. I must not omit to mention superheated steam, or heat of any kind in fact of over 300° Fahr, continued for some time, according to the size of the articles to be disinfected.—MICROTOME.

[60221.]—**Spanish.**—First, as to the "bones of words." The explanations given are respecting those letters that differ from the English pronunciation, and the examples refer to English words and letters. B, pronounced much as English V. C, pronounced as TH in "theft"; before O and U as K. CH, as in "chess." D, when following a vowel either in same or preceding word, as TH in "though"; when coming after a consonant is pronounced as in English. At the end of a word, however, D is almost mute. G, before E and I has a guttural sound, nearly resembling the aspiration of the English H; before other vowels as in English. H is silent. J has a guttural sound as G, but before *all* vowels. LL is pronounced as if written LH. N as NY in "banyan." S is always sounded S in "sing," and never as S in "muse." V, as in English. X formerly had two sounds, KS and as Spanish J; now in all words where previously employed with latter sound X is replaced by J. Y, as a consonant, rather stronger than Y in "yes." Z, as TH in "thank." A, as in "ark." E, as in "ell." I, as in "ill." O, as in "ode." U, as in "full." Y, as a vowel, as I Spanish.—F. DESPREZ.

[60227.]—**Covering Outdoor Steam Pipes.**—I can from experience recommend "Leroy's" composition, which has now stood the test of many years.—ACHELL.

[60230.]—**Ebony.**—I have been both amazed and amused at the six replies to 60230 query which appeared on p. 587. What can have possessed six estimable correspondents to air their absence of knowledge on the subject passes all comprehension. I did not notice the original query, but probably the following facts will meet the wants of the querist:—There are in commerce several well-known varieties of black ebony coming from different localities, and each having some well-known peculiarities—viz., Ceylon, Mauritius, Gaboon, Zanzibar, &c. Each produces a distinctive kind. The wood is both hard and heavy in all cases, but the various kinds differ in degree in both these qualities. The best is a dead black in colour; that of a brownish hue is not so valuable. Occasionally, but very seldom, amongst the Ceylon variety a piece is found having a number of small, orange-coloured spots intermixed; such pieces are used for making small fancy articles, such as work-boxes, paper-cases, cabinets, &c., and fetch from £30 to £40 per ton when really fine; but I have never seen a piece of this kind weighing above a few hundredweights. The ordinary black pieces range in value from, say, £5 to £15 per ton, according to size of the pieces, colour, and quality. For pianoforte keys the African sort is preferred; and though this is always found in small sizes, it is large enough for that purpose. Much is consumed for knife-handles, especially on the continent of Europe. For furniture but little ebony is employed; it is too heavy and in too small sizes to allow of its being much used; in addition to which the supply is insufficient and price too dear. *Ebonised* furniture is quite a different affair; it is made of some close-grained, fairly hard wood, and stained before being polished. Green ebony comes from the West Indies; it is very little used—occasionally for some turnery purpose, but chiefly as a dye wood. The whole importation of this kind, however, is a mere bagatelle.—WOOD BROKER.

[60245.]—**Sodic Sulphite Developer.**—No. 1 pyro solution: Boiling water, 2 fl. oz.; sodic sulphite, 2oz. When this is cold, add sulphurous acid, 2 fl. oz.; pyrogallic acid, ½oz. No. 2 potash solution: Carbonate of potash, 3oz.; sodic sulphite, 2oz.; water, 7 fl. oz. Dissolve sulphite in the water, and then add the carbonate of potash. For half-plates use a 4oz. measure, take 3 drachms No. 1, and (if plate is correctly exposed) 2 drachms No. 2, and fill up to 3oz. with water. If plate is under-exposed, use more No. 2; if over-exposed, less No. 2. Use alum bath both before and after fixing. This is called Beach's potash developer. I have developed over 100 plates this week with this developer, and it has worked admirably.—J. T. G., Leeds.

[60245.]—**Sodic Sulphite Developer.**—Formula given in Marion's book is—

Pyrogallic acid	¼oz.
Am. bromide	150 grains.
Sodic sulphite	1oz.
Citric acid	15 grains.
Water	3oz.

He gives double this quantity, but this is quite enough to make at a time. First dissolve the sodic sulphite and citric acid in 2oz. of hot water. Pour this solution over the ammonium bromide and pyro, which will dissolve immediately. Make up the solution to 3oz. with cold water. I generally add 5 drops of nitric acid, which I believe helps to keep it. Filter the solution at intervals, or a sediment is apt to settle, which causes pinholes in the negatives by settling on them while being developed. I have developed hundreds of plates with this developer, and in my opinion, and that of all my friends, it beats all the others I have tried hollow. The negatives produced by the "ordinary pyro. developer" are weak and melancholy in the extreme by the side of those produced by this developer. If "E. G. H." can't succeed with this, and will write to me, I will give him more details.—R. A. R. BENNETT, Walton Manor Lodge, Oxford.

[60245.]—**Sodic Sulphite Developer.**—"E. G. H." has undoubtedly failed owing to a bad sample of the sulphite; its instability is only too little known amongst photographers. It is oxidised to the corresponding sulphate by the absorption of oxygen from the atmosphere, although its deportment with oxygen is increased manifold by being kept in solution, than when in crystals. I have had several samples of this salt, some good and some bad, which appeared as if mixed with flour. I should put this down to its partial oxidation and conversion into sulphate. Always reject the small when not pure, and use the larger crystals. Leon Warnerke's sulphite developer is exceedingly good (at least in my hands); it has these advantages, that only two small bottles are needed, and the obnoxious fumes of ammonia are dispensed with, whilst the finished negative has the delicacy and tone of a ferrous oxalate developed plate. The formula is as follows:—

A		B	
Pyro	12 grains	Carbonate of potash	45 grains
Citric acid ...	2 "	Sodic sulphite	12 "
Sodic sulphite	24 "	Water	2 oz.
Water	2 oz.		

Equal portions of A and B are mixed together and poured over the exposed plate. For an under-exposed negative use more of B, an over-exposed use a few drops of a 10 per cent. solution of bromide of potash to restrain, whilst to produce density a greater quantity of A may be used.—A. TREYER EVANS, Newport, Monmouthshire.

[60245.]—**Sodic Sulphite Developer.**—Your querist, "E. G. H.," asks if this developer produces better negatives than the ordinary pyro (by which I presume he means the pyro ammonia)

formula. I answer, so far as amateurs are concerned, unhesitatingly in the affirmative. The slowness of its action would be a great drawback in a professional studio, where a sitter has often to wait until it is ascertained if a good negative has been produced; but for an amateur the great range of its developing power is invaluable—that is to say, it will produce a good negative, if the plate is rightly exposed, if it is under-exposed, and if it is over-exposed. Under-exposure is corrected by giving plenty of time (up to an hour in some cases), and over-exposure by an ample dilution with water. He also asks for a good formula. Their name is Legion, but underneath he will find some of the best. Beach's (President of the New York Society) developer. No. I.—Distilled warm water, 2oz.; sodic sulphite (pure), 2oz.; dissolve, filter, and add—sulphuric acid, 2oz.; pyro (avoirdupois), ½oz. No. II.—A. Distilled warm water, 4oz.; pure potassium carbonate, 3oz.; dissolve, and add—B. Sodic sulphite, 2oz.; dissolved in 3oz. distilled warm water. Combine A and B. For use, take one drachm of No. I. and ¾ of a drachm of No. II. to every ounce of developer required. Note.—There is some difficulty in dissolving the 2oz. of sulphite in 2oz. of hot water; but this is a test of its purity. Put the sulphite in a cup, pour on the hot water, immerse the cup in hot water, and stir with a glass rod. Rau's Developer (for contrast):—A. Water, 14oz.; sodic sulphite, ½oz.; potassic carbonate, 1oz. B. Water, 10oz.; sodic sulphite, 2oz.; sulphuric acid, 1 drachm; pyro, 1oz.; make up each to 16oz. For use, take one drachm of each to every ounce of water required, and 15 drops of (20grs. to oz.) solution potash bromide per oz. of developer. Allen and Rowell's (to imitate wet plates):—No. I. Distilled water, 4oz.; sulphuric acid, 24 drops; bromide of ammonium, 50 grains; pyro, 190 grains. For use, add 1 part to 20 water. No. II. Water, 4oz.; sulphite soda crystals, 240 grains; dissolve and add—bromide potassium, 180 grains; liq. ammoniæ (strong), 4 drachms. For use, add 1 part to 20 water. To make developer, use equal parts of diluted solution Nos. I. and II.; add No. II. slowly; only half of it at first, then quarter, which is usually enough. New York Society's standard:—Water, 2oz.; dry pyro, 4 grains; sodic sulphite, 22 grains; sodic carbonate, 11 grains; potassic carbonate, 11 grains; potassic yellow prussiate, 11 grains. Each of these developers has been found to suit all trade plates in general use. For my own use I have found the latter as good as any.—B.SC., Plymouth.

[60246.]—**Heating Conservatory.**—A friend of mine heats one during the winter by means of 2in. wrought pipe connected in the usual way by ⅝in. pipe to a boiler made of tin. The boiler is similar to the letter T—the top portion of the T being a dome with flat bottom connected by two ½in. tubes to stem of T—which forms the chimney of the lamp, and has an annular space round it, filled with water, into which return pipe flows, the flow pipe being taken from dome.—T. C., Bristol.

[60246.]—**Heating Small Conservatory.**—Have a hot plate in the middle of your conservatory heated by a gas flame or lamp flame applied to the under side, and have a ventilator in the topmost part of the conservatory (so formed that cold air cannot readily blow in—see chimney cowls) to allow of the hot air circulating. There should not, however, be any direct communication between the flame and the interior of conservatory, as it would vitiate the air and spoil the plants; it should be altogether outside, as underneath an iron plate forming part of the floor.—E. CONRY.

[60247.]—**New Caledonian Single Engine.**—The leading dimensions of the engine are as follows:—Cylinders, 18in. diameter, by 26in. stroke, and boiler-pressure 150lb. per square inch; driving wheels, 7ft.; trailing wheels, 4ft. 6in.; and bogie wheels, 3ft. 6in.; total wheel base, 21ft. 1in. The distributed weights, when in working order—bogie, 13·5 tons: driving wheels, 17 tons; trailing-wheels, 11·4 tons; total, 41·9 tons. The tender is six-wheeled, 4ft. diameter; wheel base, 13ft.; has a capacity of 2,850 gallons, and when loaded with coal and water, weighs 33·5 tons. Total of wheel base of engine and tender is 42ft. 6in.; and total weight when loaded 75·4 tons.—HENRY VERNON.

[60252.]—**Gravity.**—It is well known that the body would reach the Antipodes in one hour and return in another; but it is a common error to suppose it could pursue a straight line. It could only do so from a pole. Elsewhere, its eastward rotational velocity being retained, would compel it to describe an ellipse whose major axis is the earth's diameter, and its minor axis (if falling at the equator) 95ft.; and away from the equator only as much less as the cosine of latitude. Thus your well would have to be oblong, and in England some 60ft. wide, or the body would strike against its eastern side. The velocity of passing the centre is about 28 furlongs per second = that of a satellite just above the surface.—E. L. G.

[60253.]—**Vacuum Brake.**—I cannot give a full explanation; but it is, as you say, frequently difficult to obtain a vacuum for a time. I think it is probable that some of the heated air from chimney enters the pipes, and so causes the same difficulty as is experienced with injectors when they miss, and the steam blows back; it takes some time to start them again—at least, that is my experience—and a bucket of cold water is frequently a cure if thrown over an injector.—T. C., Bristol.

[60254.]—**Tricycle Driving Gear.**—Gut bands do not answer well for tricycle driving, as they stretch and deteriorate rapidly on exposure to wet. It might do very well for a tropical country where fine weather can be depended upon.—E. CONRY.

[60255.]—**Hydrostatic.**—If I understand you correctly the rod is simply kept vertical in the water and is immersed to a depth of 4ft. The c.g. of the water displaced is, therefore, 2ft. from surface, but c.g. of rod is only 1ft. from surface, and practically there is a turning movement existing, and which tends to lay the rod horizontally. In other words, it is simply a state of unstable equilibrium, there being no actual turning moment until the two c.g.'s are out of the vertical, however small in amount.—T. C., Bristol.

[60256.]—**Multitubular Boilers.**—It depends whether you go in for economy of fuel, or for quickness of heating power. The most economical boilers are those that expose the greatest amount of heating surface to the action of the hot air and gases from the firebox, without requiring artificial aid to create a draught. The quickest heating kind is a matter of opinion; but engineers seem to favour the horizontal multitubular, and these certainly get up steam with wonderful rapidity. One of these, for 40 H.P., will get up steam to 100lb. in half an hour after lighting fire, and this after standing 16 hours or so.—E. CONRY.

[60257.]—**Curative Power of Magnets.**—In answer to "Florian" I would say that it is a difficult matter to select a book among the many that treat on the subject of his query. Most that I know of are writers in French, German, or Italian, and only treat more or less fully one side of the theme. Still, here are a few:—"Animal Magnetism: Physiological Observations." Translated from the German by C. Woodbridge, with Preface by Romanes. London, 1880. Kegan Paul, 2s. 6d. Lee (Edwin's), "Animal Magnetism." 1866. Longmans, 7s. 6d. "Experiments on the Direct Power of Magnets." Airy and Stuart, 1872. "Traité Complet de Magnetism Animal." 4th éditio. 1879. Baillère, Paris. "Des Facultés Magnetiques de l'Homme, des Services, qu'on peut en attendre.' Bacot, Paris.—A. CAPLATZI.

[60258.]—**Magnetism.**—(1) Yes. (2) It is not the same; take two similar poles, of strengths 10 and 6 units respectively. Suppose, for the sake of illustration, that they are separated by unit distance, then the force exerted between them will be $\frac{10 \times 6}{1^2} = 60$ units; but, now, dividing $(10 + 6)$ units equally between them, each pole will be of strength 8 units. Now the force exerted between them will be $\frac{8 \times 8}{1^2} = 64$ units. It is only when there is great difference between the two strengths that the stronger pole induces any magnetism in the weaker. In the above case, the 10 units will induce 10 units of opposite magnetism in the 6-unit pole, so that pole will then be equivalent to one of $(-10 + 6) = -4$ units, and the force exerted between them will be $\frac{10 \times -4}{1^2} = -40$ units, so there is a loss of 20 units of force. (The $-$ sign simply shows that the force is one of attraction.) (3) It will be half the sum of their separate forces on the iron, thus: Let 10 units be the strength of each of the dissimilar poles, the force of attraction between them will be $\frac{10 \times -10}{1^2} = -100$ units. (Supposing them to be separated by unit distance.) The N. pole of 10 units will induce 10 units of opposite magnetism in the iron, therefore the force exerted on the iron equals $\frac{10 \times -10}{1^2} = -100$ units. Similarly the S. pole also exerts a force of -100 units, so that the total force equals -200 units.—MAX.

[60259.]—**Magnet "Pole-Piece."**—To get maximum efficiency, the connector of the two cores must be about the thickness of the cores.—E. CONRY.

[60260.]—**The Aneroid.**—If "X." will procure a "table of heights" from a good optician, he will see that the answer to his first query must depend on whether the readings of the barometer are high or low, and having obtained such a table, his last query will also have received an answer. I do not understand the inquiry as to "the best measure of 20ft." Does it not indicate that "X." is at sea as to the principle of a vernier? I fail also to see how a vernier can be of use, as in a good aneroid the graduations vary in size, so that it could not subdivide correctly all round the dial, unless the instrument has an extremely small range.—D.

[60261.]—**Mercurial Pressure Gauge.**—Is this exposed to the weather or to damp? If either, rainfall or condensation would probably be the cause.—T. C., Bristol.

[60268.]—**C.G.S. Unit.**—It is the French unit of force, and is equivalent to the "foot-pound" of the English scale. It means 1 gramme lifted 1 centimètre high in 1 second; but does not actually equal the foot-pound.—E. CONRY.

[60268.]—**C.G.S. Unit.**—"Centimètre-gramme-second-unit"—i.e., the unit of heat or whatever you want on the centimètre-gramme-second system of units. If it is the unit of heat that you want, it is the heat required to raise one gramme of water through one degree Centigrade.—R. A. R. BENNETT.

[60268.]—**C.G.S. Unit.**— They refer to the centimètre-gramme-second system of units, the centimètre being the unit of length, the gramme the unit of mass, and the second the unit of time. As an illustration, the C.G.S. unit of force is "that force which, acting for one second on a mass of one gramme, generates in it a velocity of one centimètre per second." For a full description of the C.G.S. units, see S. P. Thompson's "Elementary Textbook on Electricity and Magnetism."—RED LIGHT.

[60268.]—**C.G.S. Unit.**—In this system of units the centimètre is taken as unit distance, the gramme as unit weight, and the second as unit time. A C.G.S. unit of velocity is therefore a velocity of one centimètre per second. A C.G.S. unit of force is a force which, by acting on a mass of one gramme for one second, would generate in it unit velocity. It is called a dyne, and is represented by $\frac{1}{981}$ of a gramme. A C.G.S. unit of work is a force of a dyne, overcome through a distance of one centimètre, and it is called an erg. A foot-pound is equal to $1{\cdot}356 \times 10^7$ ergs; and a horse-power is $7{\cdot}46 \times 10^9$ ergs per second. In this system the prefixes mega and micro are used to denote multiplication and division by a million. Thus a megadyne is a million dynes, and the ordinary atmospheric pressure is pretty nearly a megadyne per square centimètre. Similarly, a microhm is the millionth part of an ohm.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60270.]—**Lacquering.**—Get some light lacquer from the shops; they can generally make it better than non-professional lacquerers. Then take the bedstead to pieces, slightly warm the several pieces of brass to blood warmth, dip in the lacquer, and then set to drain and dry in a tray before a stove or fire, in a rather less heat. Parts that you cannot dip may be painted with a large soft brush; but lacquering is work that cannot be learnt from any description: it requires skill of hand and practice.—E. CONRY.

[60270.]—**Lacquering.**—Prepare the article to be re-lacquered by washing off the old lacquer with a strong solution of soap lees. When this is thoroughly done, dip the article in a solution of nitric acid and water, strong enough to remove the dirt; then wash immediately in clean water, and dry well. Heat the article till it can be held in the hand without burning, and with a camel-hair brush apply the following mixture, which gives a beautiful rich gold lacquer:—1 pint spirits of wine, 3oz. shellac, ½oz. turmeric, 2drm. saffron, 2drm. annotto.—W. F. GILCRIEST.

[60271.]—**Retouching Photographs.**—Spots in photos are filled in with Indian ink. If the tint is warm, add a little carmine or crimson lake. The colours most used for painting are: For skin, chrome No. 3 and Indian red; for shadows of face, crimson lake; for shadows in dress, gum arabic; other transparent or semi-transparent colours at discretion. The photo. must be mounted, and before colouring it must be well licked over with saliva; ox. gall. sours many of the colours, and must be sparingly used; gum arabic cracks up after lapse of time, and must also be sparingly used.—B.SC., Plymouth.

[60273.]—**Effervescent Drinks.**—"Puzzled" has become so from misapprehension of the term "neutralise" as applied to the action of tartaric acid and carbonate of soda upon each other; they are not destroyed, but converted into a new substance, in the case supposed into a solution of tartrate of soda in water, the carbonic acid being set free and producing the effervescence.—GAMMA SIGMA.

[60273.]—**Effervescent Drinks.**—When bicarbonate of soda and tartaric acid are mixed with water, the following reaction takes place:—$2\,(NaHCO_3) + (C_4H_4O6)H_2 = Na_2\,(C_4H_4O_6) + 2CO_2 + 2H_2O$, sodium tartrate, carbon dioxide, and water being formed. The carbon dioxide acts as a sedative to the stomach, and the sodium tartrate is an aperient.—R. E. F.

[60273.]—**Effervescent Drinks, Seidlitz Powders, &c.**—Seidlitz powders are composed of bicarbonate of soda (not "carbonate," as it is so frequently and incorrectly termed), tartaric acid

and the acid tartrate of potash, which latter is the active ingredient, acting as a saline aperient. Bicarbonate of soda and tartaric acid mutually react on one another, setting free carbonic acid gas, and leaving tartrate of soda in solution. The gas merely renders an otherwise nauseous draught more palatable.—MAX.

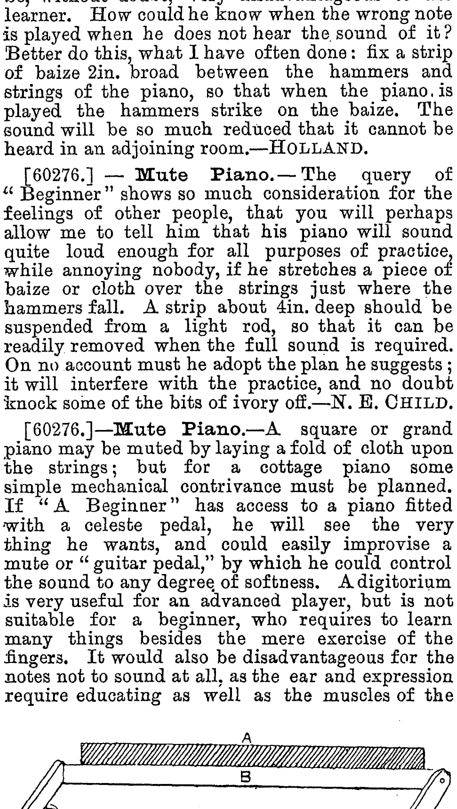
[60274.]—**Mushrooms and Salt.**—This statement is evidently intended to be taken with a good many grains of salt. That useful article has been credited with extraordinary virtues in the way of bird catching, but I have never heard of its application to mushroom culture before. If the spores are in the ground, I suspect the mushrooms will come up in spite of the salt; but, if not, all the salt in the ocean will not raise a single one.—R. E. F.

[60274.]—**Mushrooms and Salt.**—As mushrooms do not contain so much as a particle of chloride of sodium, it is difficult to give a "scientific explanation" or a "theory" (which is much the same thing) of the statement referred to by "Agaric." But inasmuch as the statement is not true, it is scarcely worth while seeking for an explanation. It seems far more likely that a meadow sown with salt in the spring would not yield even the minimum quantity of A. arvensis, and it is certain that, with suitable weather, any meadow containing spores or mycelium will produce a crop of horse-mushrooms without the aid of salt.—SAML. RAY.

[60276.]—**Mute Piano.**—Your proposal would be, without doubt, very disadvantageous to the learner. How could he know when the wrong note is played when he does not hear the sound of it? Better do this, what I have often done: fix a strip of baize 2in. broad between the hammers and strings of the piano, so that when the piano is played the hammers strike on the baize. The sound will be so much reduced that it cannot be heard in an adjoining room.—HOLLAND.

[60276.] — **Mute Piano.** — The query of "Beginner" shows so much consideration for the feelings of other people, that you will perhaps allow me to tell him that his piano will sound quite loud enough for all purposes of practice, while annoying nobody, if he stretches a piece of baize or cloth over the strings just where the hammers fall. A strip about 4in. deep should be suspended from a light rod, so that it can be readily removed when the full sound is required. On no account must he adopt the plan he suggests; it will interfere with the practice, and no doubt knock some of the bits of ivory off.—N. E. CHILD.

[60276.]—**Mute Piano.**—A square or grand piano may be muted by laying a fold of cloth upon the strings; but for a cottage piano some simple mechanical contrivance must be planned. If "A Beginner" has access to a piano fitted with a celeste pedal, he will see the very thing he wants, and could easily improvise a mute or "guitar pedal," by which he could control the sound to any degree of softness. A digitorium is very useful for an advanced player, but is not suitable for a beginner, who requires to learn many things besides the mere exercise of the fingers. It would also be disadvantageous for the notes not to sound at all, as the ear and expression require educating as well as the muscles of the



hand. It would not do at all to place a slip of wood under the projecting front of the ivory, as that would interfere with the touch, which is of great importance, and would, besides, tend to break off the ivories. A simple form of mute-pedal consists of a light slip of pine (B), called a celeste rail, about an inch in width, to which is glued a slip of thick cloth or baize (A). The slip of pine is centred to each end of the piano by two short arms, so that the rail may be raised and lowered by pedal action. When not in use the top edge of the baize rests just under the hammers; but when the soft pedal is pressed down it raises the bass end of the rocker, and the motion is communicated to the rail by the pedal rod, so that the slip of baize rises between the hammer and the strings, and regulates the quality of the tone according to the thickness of the baize. I think the best instruction book for a learner is Charles Hallé's "Practical Pianoforte School," published by Forsyth Brothers. The method of progression is very pleasant and thorough. After the first book or two the student is led into pieces of gradually increasing difficulty, and each lesson is carefully prefaced by finger exercises which are specially adapted to the technique to follow. If the exercises are carefully studied, it is quite possible for a student to attain a concert proficiency from this "school" alone.—W. H. DAVIES.

[60277.]—**Salicylic Acid.**—Tests for salicylic acid. When heated in a dry, open test tube, a crystalline sublimate forms. Ferric chloride (Fe_2Cl_6) produces a deep purple coloration; disappears on addition of alkalies. Bromine water gives a white precipitate. When heated with lime gives a smell of phenol (tar).—C. M. X.

[60279.]—**Travelling in America.**—With regard to the above, having been in America some time, (1) I should recommend "Scotsman" to go into Virginia. I found the climate as good there as anywhere; it is hot in summer, but on the whole it is very healthy. (2) As to the trade you mention, I am unable to give you any reliable information on it; but I have no doubt you stand as good a chance in such cities as Richmond, Lychburg, and Petersburg, Va., as anywhere. (3) As to travelling, either railway or steamboat is good. The latter is the least expensive, perhaps, but the former is very convenient, as you can book through from New York to Philadelphia, and thence to Baltimore and on to Washington, and from there to either of the towns mentioned above; and as to luggage, the less you can do with the better, as you can obtain most things as cheap out there as you can here; and lastly, I may add that a steady, sober man, not afraid of hard work, may get along very well there. Any other information that "Scotsman" desires I shall be pleased to answer through these pages.—F. R. LONGMORE Walthamstow.

[60279.]—**Travelling in America.**—(1) The climate generally all over the U.S. is very good; but down South it is pretty hot, and on the coast line round about Florida and below there is, I believe, considerable miasma. (2) It is very difficult to advise as to the best place there for work; but I can counsel you, on good reliable authority, to go West. Englishmen are thought a good deal of in the Western States, on account of the thoroughness of their work and their steady application; but in the great cities and Eastern states they are considered not to work quick enough. Most American manufactures partake of the quick, cheap style of work, which will not afford good, thorough, high-priced work. I should suggest going to some small agricultural town in the great farming districts (W. and Central U. S.), where there are plenty of agricultural machines (which abound in the States), and which have to be repaired on the spot. Travelling in the U.S. is very convenient. There are railways everywhere, with, on the average, far better accommodation for third-class passengers than here, and quite as cheap. The particular mode of travelling, however, depends on the locality. There is considerable depression of wages and labour in the U.S.; but I do not think it can be as bad as it is here. The excess of labour-supply arises from the incessant streams of foreign emigrants, who all make for the towns, preferring to obtain work by underbidding those already there, rather than strike out into the less crowded States and open up new lines and resources there. There is also among the U.S. employers of labour a constant "ring" to keep down the price of labour, and owing to the inefficient state of trades-union organisation, and the Republican form of government, which makes the large employer of labour ex-officio a legislator, so to speak (there being no other classes to choose legislators from), the employers have it all their own way.—E. CONRY.

[60280.]—**Water Passing through Pipe.**—To calculate the quantity of water discharged through a pipe, it is necessary to have the length as well as the diameter of the pipe. The following formula gives the number of cubic feet discharged per minute—

$$W = 4{\cdot}71 \sqrt{\frac{D^2 H}{L}}$$

W = number cubic feet discharged per minute, D = diameter of pipe in inches, L = length of pipe in feet, and H = number of feet head of water. The number of cubic feet multiplied by 6·24 will give the quantity in gallons.—W. F. GILCRIEST.

[60281.]—**Bottle Stopper.**—"Happy Jack" should put a drop or two of paraffin oil round the stopper, and let it stand for a day. If not successful, renew.—PONTO.

[60281.]—**Bottle Stopper.**—Five or six weeks since there was published a list of the usual methods of undoing these sometimes obstinate stoppers. Send to the Editor for the No.—T. C., Bristol.

[60281.]—**Bottle Stopper.**—Dip a cloth in boiling water; apply the cloth to the neck of the bottle, thus causing the neck to expand slightly, so that the stopper can easily be removed.—C. M. X.

[60281.]—**Bottle Stopper.**—Put your bottle for a short while in warm water, so as to expand just the bottle's neck, but not the stopper, and knock, after heating constantly with the back of a knife against the stopper. I believe you will thus be able to open your bottle.—HOLLAND.

[60281.] — **Bottle Stopper.** —Apply a little paraffin oil round the junction of stopper and neck, and let it have time to find its way down. By gentle side taps on the stopper it will no doubt soon yield to persuasion, and when it is out, smear a little paraffin-wax over the surface of the stopper. It will not stick again in a hurry.—SAML. RAY.

[60281.] — **Bottle Stopper, Removing.** — Unless the bottle has contained solution of potash or soda (either of which dissolve the glass and thus cement the stopper), the stopper may be removed by one or other of the following processes:—First. Pour a few drops of methylated spirits round the stopper, then placing the thumb of the left hand against the narrow side of the stopper, tap lightly on the opposite side with a wooden rod. If that does not move it, get a stout string, tie one end to firm post, pass the string once round the neck of the bottle. Hold the free extremity of the string tight in the right hand, and with the left work the bottle briskly up and down the string so that the neck becomes quite hot from friction. If that does not move it, put a few drops of olive oil round the neck of the stopper; allow it to stand all night, then plunge the neck of the bottle, held upside down, in a basin of hot water.—S. BOTTONE.

[60281.]—**Bottle Stopper.**—Take the bottle in one hand, upside down, and a knife in the other; knock the stopper of the bottle at irregular intervals, it will possibly fall out. If this doesn't do, dip a feather in some olive oil, and anoint the top of the bottle round the stopper. Leave it for a short time till the oil has soaked in, and see if the stopper will come out; if not, go through the tapping performance again, which may be more successful this time; if not, plunge the bottle, if empty, into a vessel of hot water up to the neck, which will possibly eject the stopper by the expansion of the air. If not, twist a bit of string once round the neck of the bottle where the stopper is; get someone to hold one end, and tie the other end to the knob of a chest of drawers; move the bottle as fast as you can backwards and forwards, so that the string, rapidly twisting round the bottle, heats the neck just above the stopper, which may loosen it; if it does not, *smash the bottle!*—R. A. R., BENNETT.

[60282.]—**Air Valve.**—I think it is very probable the seat of valve is too wide—have it like a dull knife-edge and grind valve in; pressure in receiver should make it tight.—T. C., Bristol.

[60286.]—**Spangled Tin.**—This effect is produced by dipping the tin plates in acid, and then washing them in abundance of water, to remove the acid. Peculiarly fine designs may be obtained by directing a blowpipe flame for a few seconds against different parts of the plates previous to immersion in the acid. The ordinary coloured spirit varnishes so often described in "Ours" serve to give the different tints.—S. BOTTONE.

[60286.]—**Spangled Tin.**—This has been answered several times in back numbers (see Vol. XXXVII., page 320) under the head of "Moire Metal." It is done by washing the surface of tin, first with alcohol to remove grease, and then with a mixture of 1 part hydrochloric acid, 1 part nitric acid, and 5 parts of water. It is coloured by being coated with coloured varnish, lacquer, &c.—R. A. R. BENNETT.

[60289.]—**St. Sampson.**—E. Dale will find a notice of St. Sampson in "Parker's Calendar of the English Church," which says he was a "bishop, and died A.D. 565. He is said to have been a native of this island, of 'royal British blood,' and a scholar of St. Dubritius, who consecrated him Bishop of York. When the Saxon invaders reached that part of the kingdom he was obliged to flee, and the saint then considered where he might be most useful, and resolved at length to attempt the conversion of Bretagne. On his way thither he stopped some time in Cornwall, converted many of the natives, and erected a church and monastery there. He fixed his residence in Bretagne at Dol, under the auspices of King Childibert, where it is said he erected a bishop's see, and converted many

thousands of the inhabitants, and died there in his 85th year. He is commemorated in the old English calendar on July 28th. The churches of Southill and Tolant in Cornwall, Cricklade, Wilts, and one in the city of York are named in his honour alone; and Milton Abbas, Dorsetshire, in the joint names of SS. Mary and Sampson."—J. PLACE.

[60293.]—**Iron Cartes, or Ink Photos.**—It is perfectly possible to produce a veritable ink picture. This was done so far back as 1842, and is described by Robert Hunt in his "Photography." You will find a fairly accurate account of the mode of procedure in last week's ENGLISH MECHANIC, page 573, second column, under the heading, "Dark Violet Black Lines upon a White Ground."—S. BOTTONE.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

60011. Model Gun, 471.

The Krotophone.—The krotophone is a new form of telephone receiver which has been patented by Mr. E. S. Spaulding, of New York, but which appears to be in reality a modified form of microphone receiver. It is well-known, and has been proved by several experimenters years ago, that the carbon, and also the metal microphone, will act as a receiver, and give out sounds, which as a transmitter it so effectually transmits. The effects as a receiver are, however, comparatively feeble. So far as we can see, the only improvement on the earlier receiving microphones constructed by the experimenters we have referred to is the use of a carbon diaphragm instead of a mica or other mechanical diaphragm. Mr. Spaulding places a pencil of carbon against the back of a carbon diaphragm surrounded by a metal ring, and the received current, after traversing the carbon pencil, enters the carbon plate and spreads to its edges, the ring forming the electrode. This arrangement, we gather from the inventor, gives a good effect. The external form of the apparatus is that of an ordinary Bell magneto telephone, the carbon plate taking the place of the ferrotype diaphragm in the mouthpiece, and the carbon pencil the place of the bar magnet in the stem.—*Engineering.*

Coal Gas.—Notwithstanding the fall in the value of what are known as "residuals," gas-making is still a very profitable business where there is a large demand to supply. Although the South Metropolitan Gas Company have reduced the price to 2s. 6d. per thousand cubic feet, they still make the handsome profit of 10s. per ton of coals, in spite of the loss of about 1s. per ton in the value of the residuals this year as compared with 1884-5. The coal cost a trifle less, and the value of the coke falls in proportion about 4d. per ton; but owing to improvements in the manufacture, either in utilising waste or in the use of more economical devices, the actual cost of manufacturing the gas has been reduced by nearly 1s. per ton of coal carbonised. Tar has fallen to less than half its value a year ago, and the other residuals also show a decline; but, notwithstanding, the profit per 1,000 cubic feet is only 1½d. less than for the year ending June 30, 1885, while for six months of the present year the price received has been 2d. per 1,000 less.

A Collection of Buttons.—Mrs. H. C. Harris, of Harlem, New York, fondly shows the work of 20 years in 8,000 buttons, collected from every quarter of the globe. The work began on a wager in Portland directly after the war, when the people believed there were not more than 999 different kinds of buttons in the world. In less than a year the 999 had been collected, and in four years 5,000 buttons, all different, many of them beautiful in design, and many brilliant and beautiful in colour. Some have come from old wars and famous battlefields, some from gold mines and poorhouses, some have been brought half around the world to the collector by sea captains, some from shipwrecks, some just from the button counter, and some are dignified old buttons that have seen life in a previous century. The collection is arranged in eight strings of 1,000 each.

QUERIES.

[60294.]—**Action of Steam.**—To "GLATTON," OR "T. C., BRISTOL."—Will you be so kind as to explain to me the action of steam in the two diagrams marked 1 and 2. Dia. No. 1—Is it the 4lb. at A that goes to 2½ at C on dia.

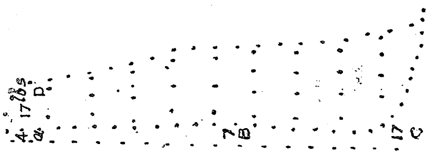

FIG. 1

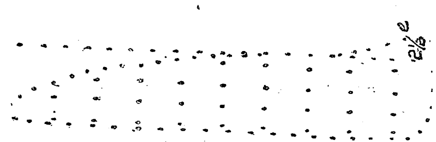

FIG. 2.

No. 2, and, if so, where does the 7lb. at B, and the 17lb. at C, and 17lb. at D on diagram No. 1 go to? They are compound engines at ¼ centre. Ought the condensing engine to cut steam off at the same time as the high-pressure cylinder does, there being no receiver, only pipes from one cylinder to the other?—YOUNG ENGINEMAN.

[60295.]—**To Mr. Bottone.**—Would a 6c.p. incandescent lamp light a room which is 14ft. by 11ft. by 8ft. high, and would a bichromate battery of six cells 7in. by 7in. by 3in. light the lamp? If so, would Mr. Bottone tell me the proportions of the acids, the amount of bichromate, &c., and the best way to cut carbons, as I have a great deal of carbon of a curved shape from a gas retort, which would cut some large plates ⅜in. thick or more? I suppose zinc would be the other plate, and the battery I intended to use would be a strong box with six divisions, each one lined with pitch.—CYCLOPS.

[60296.]—**Black Stain for Wickerwork.**—Will any correspondent tell me of a very cheap mixture of black stain, such as is suitable for the first coating of the wickerwork of perambulator bodies, and the best and cheapest method of using it? There is a stain that is used cold, and with a brush; but a cheaper article is required.—W. W.

[60297.]—**Testing for Faults.**—Will any reader of the "E. M." kindly tell me how to test for faults in dynamos and circuits with the lineman's detector, and how the detector will show a fault?—J. L.

[60298.]—**Norway and Sweden—Outfit, Cost of Living, &c.**—Can any reader oblige me by giving some information as to what outfit I should require for Norway and Sweden, between 66 and 68 degrees of latitude, cost of same, and is it best to procure outfit in England or Sweden? What is cost of living comfortably and well, what kind of food can be procured? Particulars regarding climate, temperature, seasons, route to get there, and time, &c., &c.; also names, &c., of books relating to that part.—TERRA INCOGNITA.

[60299.]—**Locomotives.**—To "CARSTAIRS," OR MR. STRETTON.—Can you oblige me with boiler dimensions of M.R. 1327 and 1740 classes? Also of N.B. express engines built by Mr. Holmes before the present class (592)? They have, I think, 17 by 26 cylinders and 7ft. coupled wheels.—G. D. SEATON.

[60300.]—**Battery for Lamp.**—Will someone kindly inform me with what solution to charge a battery composed of two pint cells, containing carbon plates, porous pot containing amalgamated zincs with mercury, zincs always to remain in solution? I want it to light a small incandescent lamp.—J. H. M.

[60301.]—**Electric Lighting.**—Will someone kindly assist me by giving me a simple method for calculating dimensions of electric light wires? I am only a learner, and not well up in algebraical formula; therefore all the books published are so much Sanskrit to me.—RULE O' THUMB.

[60302.]—**Pigmy Motor.**—Will Mr. Bottone kindly tell me the size of castings for the ring-magnet and armature of a Griscom's pigmy motor? Also the quantity and size of wire for both to make the armature revolve at the rate of 5,000 per min., running loose, with from 4 to 6 chromic acid quart cells? I should like it to be, if possible, 4in. long and about 2½in. or 3in. dia., and work well with two quart cells and full power with four or six cells.—J. H. G.

[60303.]—**Captive Balloons.** — Under the above heading, I noticed a paragraph by Eric S. Bruce (25657, April 30th), in which he says that a huge captive signalling balloon was to be exhibited at the Crystal Palace during the whole of the summer season, commencing from July 1st, and that it should be illuminated at night with the electric light by means of his patent apparatus. I should like to know why the balloon is not let up, because, as far as I know, it only ascended twice, the first being on July 6th, and then not up to the proposed height? I am not sure that the telephonic communication he spoke of was established, but the electric light was not used either times. I am told that it proved to be a failure; and, if so, will Mr. E. S. Bruce kindly inform me of the cause of the failure?—PALACE.

[60304.]—**Circular Valves.**—Will someone kindly give dimensioned sketch of a circular valve and ports for a 20in. cylinder?—TRIANGLE.

[60305.] — **Bending Thin Weldless Steel Tubing.**—Will some brother reader be good enough to instruct me how to do this without flattening the tube, as I am making a tricycle, and cannot manage the bending without spoiling the looks of the tube?—GRATEFUL.

[60306.]—**Photographic Engraving.**—A descriptive appendix on this process, invented by Hy. Fox Talbot, is added to Thomson's "Handbook of Photography." I have carefully followed out every instruction, but the results are not satisfactory. I shall be glad to know of any reasons for my failure. Also if there are any other processes of producing the photographic image upon copper and of etching it wholly by mechanical means?—C. B. ROPER.

[60307.] — **Quantitative Analysis of Silver Alloy.**—I wish to take a wet assay of some electro-plated copper small goods. A fire assay of the goods shows a deposit of silver varying from 1·50 to 3·00 per cent. As there is always a loss of silver in assaying by this method, I wish to check the loss by means of a qualitative analysis of the goods. I have tried the following method: Dissolve 100 grains in nitric acid, evaporate until the solution crystallises on cooling, dissolve in distilled water; heat this solution, and add from a burette a quantity of decinormal solution of sodium chloride. 1. I fail in rendering the mixture of nitrate of copper and of silver neutral to litmus paper. When this solution is evaporated to dryness to dispel the acid, the copper salts will not dissolve in distilled water. If I add a solution of sodium carbonate to neutralise the acid, a pale blue precipitate is thrown down. 2. I fail in throwing down all the silver from the solution of copper nitrate and silver nitrate. Even after a large excess of sodium chloride solution is added, the chromate of potassium indicator shows a quantity of silver left in solution. Will Mr. W. J. Grey, or some other competent analyst, oblige me with advice calculated to lead to success? If so, please give weights and measures in grains.—G. E.

[60308.]—**Sound Proof Doors.**—Wanted, the best means to prevent sound passing through folding doors from room to room without bricking up.—BETA.

[60309.]—**Legal.**—Some years ago, I advanced a widow £100 on the security of her contingent life interest in her dwelling house, shop, and garden, the property being of a long leasehold tenure, with no head rent. The contingency referred to is that by the terms of her late husband's will, under which she holds the property, should she marry again, the property goes to her daughter. Now the daughter has married an unprincipled man, and he has written to me offering £30 if I will relinquish my charge on house, &c., which they want to sell, threatening, if I refuse, that his mother-in-law will go through form of marriage with some penniless object, whom he will suborn with £5. His excuse for this audacious proposal is that the interest paid has more than equalled the sum advanced. Would such an arrangement destroy my claim? If I could prove (by securing the good offices of the "penniless object" aforesaid) no consummation to the marriage, could I get it annulled? Could I institute proceedings for conspiracy to defraud? Supposing I got the "penniless object" to agree to bringing a suit to annul the marriage, could he do so on the grounds of no consummation, and, if successful, would this reinstate my security? How long a time must elapse after a marriage to bar proceedings for its annulment on any of the foregoing grounds? Would my not being able to personally serve the mortgagor with any proceedings make any difference, as she intends going abroad directly after the form of marriage; her friends to follow directly after settling the business?—SHYLOCK.

[60310.]—**Field Tubes.**—I should be pleased to hear from some reader who has tried the above in small launch boilers—what results they give, and their disadvantages, if any. I have never seen any at work, although I have had plenty of experience with other types of boilers, and I am told they are very easy to fix, the ends having a slight taper, and being simply driven into the tube plate or furnace crown. Also that the circulation is so good that salt and dirty water may be used without their stopping up. If this is so, why are they not more often used? Launch engines, as usually made, look squat and snug, low down in a boat; but it seems to be forgotten that an inch of leverage on the crank is worth several sq. inches on the piston while easing the supply of steam from the boiler and allowing easy firing. The generality of small launches cannot go full speed continuously for any number of miles with the best stoker that ever handled a shovel. As to compounding without condensing, my opinion is not worth much, but I think it is a fact, in many cases, if the big cylinder was unshackled, and the shaft turned by the high-pressure one alone, the speed would result, and perhaps a few turns more. I believe in expansion in one cylinder, and therefore advocate longer strokes, but think the loss from back pressure, friction, and radiation neutralizes any advantage from a separate cylinder, unless a vacuum pull is obtained also. For very small boats, lightness is the great desideratum, and a surface condenser, even if outside the boat, would be better dispensed with by adding a trifle more heating surface in the firebox and raising the pressure 10lb. or 12lb. Of course, when economy of coals is of any account, surface condensation is everything; but a boiler may be kept tolerably clear of salt and deposit by a frequent and judicious blowing down at an expenditure of a little extra fuel. Some years ago, I saw an account, in an American journal, I believe, of small boats having very light steam generators. Spray was pumped through a hot tube and raised into steam quickly, fresh water being a *sine qua non.* If not working in clear water, the exhaust had to be condensed and returned again and again. Does anyone know anything about these? Many would be glad to know of something light enough to be hauled on a yard when not in use. Anything with steam in it, no matter how small, must be left afloat; and in a tidal river when left to the tender mercies of bargemen and other frequenters of large rivers, leaves very much to be desired.—TUBE PLATES.

[60311.]—**Slide-rest.**—In taking light finishing cuts on metal—an iron rod, for instance,—I am often bothered by ribbed markings, which wind screw-fashion along the whole length of the work, being, in fact, a faint copy of the screw of the upper slide. Sometimes the little ribs are palpable to the touch; at other times you have to hold the work up endways to the light to see them at all. I have tried tightening and loosening the screws of the loose V in a variety of ways, but cannot hit upon anything that is quite reliable as a cure. Will some kind reader, who is up in lathe matters, tell me what is in fault, and, if possible suggest a remedy? My lathe is a 5in. Britannia Co.'s.—W. A. S.

[60312.]—**Lubricating Oil (Mineral)**.—Is there any way of discovering the presence of adulteration by chemicals (say alum) other than by chemical analysis—for instance, by spectroscope, or polariscope?—J. B. G.

[60313.]—**Ozone.**—TO MR. S. BOTTONE AND OTHERS. —Kindly inform of best way to make ozone for commercial purpose on the largest possible scale. What apparatus are required, and how much capital is wanted? I have use for ozone if it can be obtained in large quantities at a moderate price. Are there any books on manufacture and use of ozone? I may state that in experimental way I have been successful in making ozone, but can get no further.—ROSE CULTURE.

[60314.]—**Pollak's Battery.**—How is a Pollak's regenerative battery constructed, and is it of great value for lighting purposes?—HOLLAND.

[60315.]—**Salt in Steam Tubes, &c.**—The water used in a 16 H.P. engine contains some salt, which forms a hard coating, 1½in. thick, around the taps and inside the exhaust pipe for heating water. I have tried to burn it off and out of pipe, but cannot do so. Will some reader give a remedy for getting off the salt coating and for totally taking the salt out of the water.—THOMAS PLUNKETT.

[60316.]—**Electric Time Ball.**—TO E. CONRY.—Being also interested in making of time ball (for shop window), I should feel obliged for some suggestion for raising ball, either by electricity or by clock at its basis. Would like it to rise and fall every hour.—WATCHMAKER.

[60317.]—**Specimen Fish.**—Can any reader of "E. M." oblige by giving directions for preserving and stuffing fish?—NO SIG.

[60318.]—**Probability Query for "Alioth."**—If mortality tables make the yearly death-rate of boys of 12 as low as ·005, and if this low rate (which is confined to some two years) were to last for ever, what would be the age to which a boy would have the same chance of living that he has of dying within a second? Also within the minute, or within the hour?—E. L. G.

[60319.]—**Chemical Salts.**—What method is recommended for restoring deliquescent salts which have become moist from exposure to air? For example, NH_4CNS. Should this salt be dried by heat? Will it keep indefinitely in strong solution?—B. A.

[60320.]—**Fossils.**—When in Wales lately, I got some fossil ferns in one of the slate quarries there. The line of cleavage of the slate is at right angles to the bed, and I cannot understand how a complete fern can be found on a piece of thin slate, as the block cannot be split on the line of the bed as originally laid down. Perhaps some of your geological friends can enlighten me.—SPES.

[60321.]—**Mathematical.**—A ship sailing directly towards a harbour in lat. 51° 40′ N., and long. 55° 30′ W., at the rate of ten knots an hour, is found by observation after 12 hours sailing to be in lat. 50° N., long. 57° 49′ W. The estimated place is in lat. 49° 43′ N., long. 52° 15′ W. Find the direction and rate of the current which has acted on it during this time. Also, supposing the same current still to act, find the course she should now steer to reach the harbour, and the time in which she will reach it. What book do you recommend on "Spherical Trigonometry" for a sailor's use?—H. B.

[60322.]—**S.E.R.**—Can any of your readers inform me what brake is used by the S.E.R. on their Granville express, there being only a single hose pipe between the carriages? I am almost sure it is not Smith's vacuum. For what purpose is this brake used? I believe it is only fitted to two of their old single-wheel locos.—viz., Nos. 83 and 85. Are they fitting this brake to any more of their trains besides the Granville express?—G.N.R.

[60323.]—**G.W.R. Engines.**—Can anyone inform me for what purpose the eccentrics are placed outside on G.W.R. loco. No. 9? Is this the only one built, and are any more going to be built?—G.N.R.

[60324.]—**Terrestrial Telescope.**—TO "GARRISON GUNNER," OR OTHERS.—I use a telescope principally for making out flag signals on ships, and should be grateful for any advice as to the most powerful glass for the purpose that would be portable. I use at present a glass 2⅛in. clear aperture, and 42in. long when focussed (not including sunshade). I don't know the power. It is rather unwieldy, on account of its length; but is superior to most cost-guard glasses I have tried. I think the above-named officer once said he had a 3in. glass with a power of 50 or 55. Would he kindly say what length it is when open? I presume 3in. is the largest size that would be portable. Assuming my glass to be a good one, can I do better? Should I gain much by an additional ⅞in. of aperture? About what would be the cost of a good 3in. glass for my purpose?—D. G.

[60325.]—**Polishing Celluloid.**—Artificial ivory, or celluloid, is now extensively used for piano keys. I bought a piano two years ago, the keys of which, though quite white when new, are now quite yellow. I find that if I scrape and glass paper them I remove this yellow stain, leaving them a pure white, equal to when new; but I cannot restore the polish. All the usual means, as used for ivory, have failed. Will some of "ours" kindly help me?—LIFE BOAT.

[60326.]—**Weak Ankle.**—I should be obliged if any gentleman can assist me in the following: A girl, 13 years of age, of rather delicate constitution, has so weak an ankle that the sole of her left foot turns outwards when she walks. I have noticed it coming on for about three months.—J. H. A.

[60327.]—**Electro-Motor.**—Would Mr. Bottone kindly assist me with the following? I wish to construct an electro-motor of 2 H.P., of the Gramme type? What size of forgings shall I require for the fields and armature? Also, what size and quantity of wire, and what current will be required?—J. G.

[60328.]—**Spirit Level.**—Will some of "ours" say how to adjust a spirit level accurately in passing in a new tube?—H. H.

[60329.]—**Fire without Smoke.**—I should be pleased to know if there is any correspondent who can tell me of any article by which I can get a blaze without presence of smoke—that is, a blaze that smoke will not blacken any article I might put before it?—X. Y. Z.

[60330.]—**Engine Filling.**—Can any of "ours" give me information as to the filling used by the painters? Engines from the Glasgow and other loco. works appear to be filled with a mixture of glue and whiting, and I think gold size. I have tried this, and also with dry white lead; but find it blister in rubbing down with water. I wish to know what it is made of, quantities in proportion, manner of using and rubbing down, and any other useful information connected.—COACH PAINTER.

[60331.]—**Signals by Means of Electric Currents of High Potential.**—Would some of your readers kindly inform me if it is possible to communicate by telegraph or telephone through a conductor charged with, say, 100 ampères, at a potential of 250 volts, and, if so, what protection could be employed?—E. C. Y.

[60332.]—**Ferments.**—I want to study the action of ferments. Can any of your readers give the name of some good works on this subject, and also what power of a microscope would be needed and the probable cost?—IGNORAMUS.

[60333.]—**Electro-Motor.**—TO MR. S. BOTTONE.—I am making an electro-motor of about ¼ horse-power to drive a fan. I wish to know the size of wire for magnets and armature. Also the quantity to suit about 2 amperes and 55 volts?—PUZZLED.

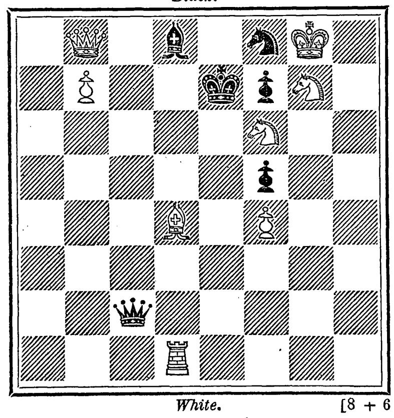
[60334.]—**Falling Bodies.**—At what angle to the horizon do bodies begin to fall, and, in the latitude of London, what is their motion in the first thousandth of a second? How far down, and how far eastward?—E. L. G.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MVII.—BY G. J. SLATER.

Black.



White. [8 + 6

White to play and mate in two moves.

SOLUTION TO 1005.

White.	*Black.*
1. P-K R 5.	1. K-Q 5.
2. Q-B 3 (ch).	2. K takes Q.
3. Kt-Q 5 mate.	

This problem has other solutions, which, the author informs us, can be avoided by removing W B to Q R 6, and the P which is at K R 4 to K R 5; thus making the first move 1. B-Kt 5.

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,004, by J. Mackenzie, M. Blackmore, F. W. S., G. T. Stringfellow; to 1,005, W. Rayner, (5), A. Dean, J. Mackenzie, G. A. A., Walker (8), I. M. Brown (2), J. A. M., A. Beginner (2).

C. J. B. (Blackheath).—If in 1,005 1. $\frac{\text{Q-Kt 2}}{\text{Kt-K 6 (ch)}}$

A. DEAN.—If 1. $\frac{\text{Kt-Q 5 (ch)}}{\text{P-B 3}}$, and how does Black mate in two?

J. M.—Your second letter respecting 1,002 came too late.

G. A. A. WALKER.—Thanks for your letter and for slip. We have referred to the solutions to 995, and find you are correct; scoring accordingly.

F. W. S.—How do you mate in 1,004 if 1. $\frac{}{\text{Q checks at B 5,}}$ or Kt 6?

W. R.—Thanks for your letter; a true bill, and something more!

MR. ALFRED E. FLETCHER states, in his latest report as chief inspector under the Alkali, &c., Works Regulation Act, that in one establishment where lead rich in gold and silver is treated, he found, on testing the fume escaping from the chimney, that the value of the metals passing away in this form in a year was £3,000. The larger portion of this escape is now saved by arrangements for causing the fume to settle. In a lead smelting works in Wales, a flue or culvert three miles long has been erected to give the fume an opportunity of settling, yet a considerable quantity finally passes from the top of the chimney into the air. Metallic fumes from copper, zinc, arsenic, and other works also escape. Much of this can now be prevented by electrical means, as explained by Dr. Lodge.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

BACK NUMBERS.

WE receive so many queries asking for directions how to make many instruments and appliances which have been fully described in back volumes, that we have compiled a list, which we shall insert in this column at intervals, of those most frequently sent, and as the numbers are still in stock, new subscribers should consult the list before sending their questions.

Bookbinding: No. 613.
Electric machines: Nos. 1,009, 1,025.
Electro-magnets: Nos. 772.
Lacquers: No. 866.
Pattern Making: Nos. 938, 941, 943, 945, 948, 950, 952, 954, 955, 956, 958, 959, 962, 963, 969, 974, 978, 986, 989, 993, 995, 998, 1,000, 1,001, 1,003, 1,004, 1,008, 1,009, 1,010.
Silver-plating: Nos. 1,009, 1,010.
Varnishes: Nos. 478, 619, 675, 723, 775.

The following are the initials, &c., of letters to hand up to Wednesday evening, Sept. 1, and unacknowledged elsewhere:—

E. P. ALEXANDER.—W. H. P. Scourfield.—Lt.-Col. O'Hara. —Rev. J. Lamont.—King, Mendham, and Co.—Sphere. —Hyperborean.—M. Isader.—J. Low.—Brass.—Inquisitive.—T. Wilson.—A. Craggs.—Pharmacist.—R.—North-Western.—A Fellow of the Royal Astronomical Society. —R. L. Readdie.—B.Sc., Plymouth.—H. D. Taylor.—Triple Valve.

APPRENTICE. (See indices. An ink is made from logwood and sulphate of iron; but it is usual to add some galls. The other ink mentioned has, we believe, bichromate of potash in its composition.)—PIPE-MENDER. (Ordinary pins or the spelter sold at the shops. See indices.)—LONDONER. (If the matter is "perfectly clear and simple," procure the forms at any law stationer's, and fill them up. There is no "red tape" about it. The "Rules" published at the Patent Office, price sixpence, contain all necessary information.)—RELIEF SIGNALMAN. (Langdon's "Application of Electricity to Railway Working," Macmillan and Co., is a work that will probably suit.)—H. B. (See indices.)—BRASS. (Fully explained recently. See No. 1,079, p. 267, or any elementary textbook. It is incorrect to speak of a "current of 6 volts.")—SUFFERER. (It is a matter for personal experiment.)—F. A. (What is known as 21oz. glass will do.)—J. T. S. (For Sundials, see No. 1,058 (p. 394), 924 (p. 316), 933 (p. 525). If you have a dial, and mean only "mount," then you must give details of its construction.)—IGNORANT. (We described and illustrated it on p. 429, as mentioned in the article referred to. It is in No. 1,112, and is there entitled "Maquay's Battery.")—M. D. EWELL, Chicago. (Chambers's "Descriptive Astronomy" is published by the Oxford Press, price 28s. Chambers's "Astronomy" is published by the firm of Chambers, Paternoster-row, or Edinburgh. We do not know price. 2. Latimer Clarke's "Treatise on the Transit Instrument" is published by Spons, who have an establishment in Murray-street, New York. The price here is 5s. He has also a "Manual of the Transit Instrument," published at 1s.) —GEO. H. HEAVEN. (If you cannot refer to back volumes, watch for replies to query 60246, p. 587.)—FRIGA. (The colours for working drawings have been frequently given; but Maxton's "Manual of Engineering Drawing," Lockwood and Co., will suit you.)—BACK PRESSURE. (There are Reynolds's books published by Crosby Lockwood and Co., and Sinclair's "Locomotive Running and Management," an American work, published here by Trübner. See the catalogue of scientific and technical books, which has been compiled by G. Philip and Son, 32, Fleet-street. We do not think, however, that you will find such information as you require.)—TERRA INCOGNITA. (Unsuitable. See a little book entitled "Weather Warnings for Watchers," Houlston and Sons.)—W. SANTO CRIMP. (There is a recipe for dead black in No. 1086, p. 401; but you do not state whether the lacquer is wanted for outside work.)—DIRTY FINGERS. (Take the greasy marks out with benzoline, a bit of blotting-paper, and a warm flat-iron.) —F. C. S. (You want much more than your ten boxwood bobbins, which, in reality are not wanted at all. See the indices.)—H. V. S. AN ENQUIRER. (We do not know how to make a cell of those dimensions; but see No. 1,016, p. 28. Nor do we know how to make a "Lynden jar battery strong enough to drive a small machine." We do suggest a perusal of back numbers or a study of some elementary textbook.)—GWENT. (Perhaps there was a "crush of copy" then. At any rate, the answer was sufficient. The first number of the ENGLISH MECHANIC appeared on March 31, 1865. Vol. XLIII. is just completed.)—ICE (Do not know it under that name; but the ammonia ice-making machine was illustrated in No. 323.)—A. COLLINS. (The ingredients will vary with the district; but ground flint, potter's clay, and

borax are the principal components. Common work is often coated with a glaze made of white lead 53 parts, ground flint 36, flint glass 4, and Cornish stone 16 parts. These are ground up with water, and the glazing is accomplished by heat. To do the best work, it is necessary to make a frit—that is, fuse the ingredients together first, and then grind them up to make the glaze or enamel. See the indices.)—N. W. SMITH. (See No. 958, p. 510, and the indices, but there is no thoroughly effectual remedy.)—CONSTANT READER. (It must be made on a former, using the same materials and in the same manner as for the ordinary bellows work; but of course the materials must be cut taper.)—ELECTRICIAN. (You must line a glass jar with tinfoil outside and in to about two-thirds of the height. The directions have been recently given)—G. H. B. (Say what you mean by indiarubber; pure, vulcanised, or hard? 2. Speeding pulleys has been recently answered.)—LONDON. (No works of the kind yet—that is, none suitable for answering examination questions. Guthrie's "Electricity and Magnetism" (Collins) will suit for the ordinary exam.)—X. (See one of the elementary text-books. Cardew's voltmeter was described in No. 1,016, p. 31. 2. No room for such questions as that about borax, which are fully answered in the cyclopædias. 3, Goodeve's "Mechanics," Molesworth's "Pocketbook," Templeton's "Workshop Companion." See previous answer.)—CARBON PLATE. (How strange you have never seen an answer during all that time! See reply on p. 585 last week, and apply to Mr. G. G. Blackwell, Chapel-street, Liverpool, for his catalogue; it contains much useful information about the Leclanché or manganese cell.)—ANGLO-GRECIAN. (Certainly not easy. Hours longer; wages much less than in this country.) —G. H. T. (Kindly look up the back numbers.)—RELIEF SIGNALMAN. (Not of sufficient interest. Can you not see copies of the returns?)—C. C. T. (Nigrosine is obtainable from dealers in dye-stuffs, and all who sell the aniline dyes. The coloured bottle is to prevent the action of light.)—BLACKING. (It does not become mouldy when properly made.)—ASTRO. (Apply to the hon sec., Mr. W. H. Davies, Irvine-street, Liverpool.)—THOMAS TURNER. (Procure a handbook published by Mr. Eldridge, 54, Murray-street, Hoxton, at 1s. 6d. or 2s.) —ROMAN. (No risk at that temperature.)—IGNORANT GEORDY. (If it is a silver ink it can be done with cyanide. 2. Same manure as is used for onions, and plenty of it.)—SOLAR SYSTEM. (It seems to have been a sort of orrery, but no one can guess how it was arranged without further details. Look up the word "orrery" in a cyclopædia.)—TELEGRAPHIST. (We are not aware that any such posts are open to outsiders. They are usually filled up by the appointment of men who have served in the Royal Engineers. You can, however, apply to the War Office.)—A. THOMPSON. (A number of recipes have been given for japans and varnishes; but it is cheaper to buy than to make, unless they are wanted in large quantities.)—A. Z. (Electric alarms, or alarums, have been frequently described. You may find some useful hints in Vol. XXXVIII. pp. 478, 538; but see the indices generally.)—APPRENTICE. (Try carbolic acid; but it is difficult to suggest a remedy without knowing how the ants come through the floor.)—S. N. D. (How can anyone say what to add, without knowing what the ingredients already are? There are plenty of recipes for harness polish in back numbers. Perhaps you want something which has not yet been invented. 2. What do you mean by "tin polish"? You can but abrade the surface by any of the usual methods—whiting, say; then lacquer if you want to preserve the polish.)—G. L. WATKINSON. (Inadmissible; you are welcome, or anyone else, to criticise Mr. Stretton's facts or statements, but not to impute motives. Whether Mr. Stretton was or was not ever employed by any railway company seems to us altogether beside the question.)—F. W. REYNOLDS, M. R., RAILWAYMAN, AJAX, LANCASHIRE DRIVER, P., KAPPA, W. B. THOMPSON, D. H. SCOURFIELD. (In type.)

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., and XLII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.)

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XI., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

The Meat Consumption of the World.—An economist of repute, Pedro S. Lamas, has summed up the total quantity of meat consumed in the world. There are, he finds, on the surface of the globe 47,500,000 head of cattle and 105,000,000 of sheep. Europe and Algeria provide 25 million of cattle and 50 million sheep; Australia, New Zealand, and the Cape, 2½ million of cattle and 20 of sheep; the United States and Canada, 9,375,000 cattle and 9,750,000 sheep; the Argentine Republic and Uruguay, 6,000,000 cattle and 24,000,000 sheep; and Central America, 4,250,000 cattle and 1,250,000 sheep. Having allowed a percentage for the reproduction of species, M. Lamas fixes the yearly consumption of beef at 7,930,000,000 kilogrammes (each kilogramme about 2 1-5lb.), and of mutton at 10,550,000,000 kilogrammes. Comparing these figures with the populations in the five great groups into which he has divided the cattle and sheep world, he finds that every inhabitant of Plata has 160 kilos of beef and 56 kilos of mutton at his disposal each year; in the United States and Canada it is 23 kilos of beef and 2 of mutton; in Europe it is 15 of beef and 2 of mutton; and in Central America it is 14 of beef and a quarter of kilo of mutton. In the Argentine Republic they eat 60 kilos a head, and export 156; in Australia a similar quantity is consumed and 56 kilos exported; while every citizen of the United States wants 7 kilos of foreign meat to augment the annual consumption of 52 kilos. The average consumption in Europe is 18 kilos per head, and 1 kilo imported. We get 180 million kilos from Australia, 250 from the United States and Canada, and 14 million from Plata. North America, it seems, oversells itself.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words, afterwards 9d. per line. Paragraph advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d.
Twenty-four words	0	3
For every succeeding Eight Words	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Good Value Offered (cash or instruments) for all kinds of sound or repairable Scientific Appliances.—CAPLATZI, Science Depot, Chenies-street, near British Museum. Established 1862.

Vertical **Engine and Boiler**, on one base, 1 H.P. nearly new, to work with gas burner or coal, Hindley, Maker.—H. CREWE, 16, Montpelier Vale, Blackheath, S.E.

Rhumkorff's Coil, new, ⅜ spark, 700 round carbons, 13 mm. by 12in. long. What offers?—PERCY HUDDLESTON, 74, Rotherhithe New-road, S.E.

Will exchange my 52in. **Bicycle**, cost fourteen guineas, for Tools, Lathe or Organ.—W. B., 20, Coleherne-road, S.W.

4½in. **Screw-cutting Lathe**, 4ft. gap bed, chucks, tools, &c., quite new, for good Tricycle or Safety Bicycle in part exchange.—E. B., 64, Park, Eccles.

Single-barrel **Breechloading Gun**, choke bore, rebound lock, central fire, 12 bore. Will exchange for 2 man-power Engine and Boiler if good, or £3 10s. cash.—F. FOWLER, Haslemere, Surrey.

Wanted, **Lathe** with slide-rest, about 5in. centre—Full particulars of lathe to H. MILLER, 51, Manchester-street, Manchester-square, W., London.

Set of **Carpenter's Planes**, &c. Offers in exchange.—H. B., care of Mrs. WEBBER, Fore-street, Bodmin.

Wanted, "**Spons' Workshop Recipes,**" cheap, good condition.—HODSON, 24, Upper Walhouse-street, Walsall.

Corn Grinder, cost 35s. Will exchange to value of Cloth in plain face cloth. Offers.—Address, H. CULPIN, Hemply House, Marsden, Yorkshire.

Chemical Apparatus, Reagents, and Works on Chemistry, "Knowledge," 204 Nos.; "Science Gossip," 62 parts; "Metal World," 52. What offers?—S. RICE, Harrow, Middlesex.

24 2s. 6d. monthly parts "**Working Drawings** AND DESIGNS OF MECHANICAL ENGINEERING AND MACHINE MAKING," all perfectly clean. What offers?—PORTEOUS, 22, Junction-street, Leith.

Microscopic.—Will exchange first-class Mounts of Whole Insects, select Diatomaceæ, &c., for good Lantern Slides.—W. WHITE, 17, York-street, Nottingham.

2 H.P. **Boiler**, externally fired. Exchange for 1 H.P. Vertical.—BATCH, Creek-road, Deptford.

I have Vols. I. to VII. of "**English Mechanic,**" bound, good condition, complete, clean, &c. Offers.—F. ROBINSON, Noble-buildings, Bridge End, Rastrick, Brighouse.

Small **Electrical Cylinder Machine**, 2 Leyden jars, and other accessories. in case. Exchange Microscope. Offers. Approval.—J. GORDON, 130, Clarendon-place, Dover.

To Brass Finishers.—Will exchange **Foot-Power**, consisting of Flywheel, Driving Wheel, Double Crank Bearings, &c., for Circular Saw, Spindle, and part cash. What offers? Must sell.—37, Bridport-place, New North-road, Hoxton.

Wimshurst Electrical Machine, 5in. spark. May be seen working any evening. Will exchange for Stock, Dies, and Taps, from ¼in., or offers.—H. HOWELL, 61, High-street, Peckham, London.

Harmonium, by Gilbert L. Bauer, one set reeds, excellent tone, good as new. Exchange for Foot Lathe, with slide-rest, or good Telescope, with cash, or what offers.—SAMUEL FERRELL, Gulval, Penzance.

Motor for driving pleasure boat. Motor, propeller, rudder combined, and powerful Battery, £5 10s., or exchange for Safety Bicycle.—H. JONES, 48, High-street, Lambeth, S.E.

Diamond Drills for china, glass, stone, &c. Diamond Turning Tools. Stamp for reply.—C. BLANCHARD, 29, Earl-street, Lisson-grove, London.

Tricycle, Coventry, 2-track, 50in. wheels, double-steerer, good condition. Offers in exchange.—FORD, 75, St. Paul's-road, Camden, N.W.

Combined **Lathe, Fretwork and Circular**, iron bed on iron standards, with chucks, turning tools, 2 circular saws on spindles, adjustable table for inlaid work. What offers?—TURNER, 1, Gainsboro Cottages, South Hackney.

36in. **Facile Bicycle**, ball bearings, Hancock's non-slipping tyres, dropped handle bars, Humber spring, mud guard, bell. What offers?—TURNER, 1, Gainsboro Cottages, South Hackney.

Good exchange offered for **Plate Glass**, 6ft. and 2ft., or larger (in one or two pieces).—BERNARD GREEN, 7, Mountain-view, Cockermouth.

Six good **Lantern Slides** of Lake District for disposal. What offers to value of 6s.?—BERNARD GREEN, 7, Mountain-view, Cockermouth.

"**Christison on Poisons**" (1829), in good condition. What offers to value of 5s.?—BERNARD GREEN, 7, Mountain-view, Cockermouth.

Wimshurst Influence Electrical Machine, 17in. plates, mahogany stand, 4 to 6in. sparks. Exchange Electro Motor, equal value, or offers.—Mr. DEWHURST, to be left G.P.O. Manchester.

8 complete and 10 incomplete vols. "**English Mechanic,**" and 1 Vol. of "Gardening." Exchange anything useful.—ELEKTRON, 5, Lansdowne-road, Sheffield.

Wanted, pair **Lathe Headstocks**, about 3in., cone bearings. Exchange 12ft. Fishing rod and Tackle.—SMITH, 6, Berne-terrace, Clive-vale, Hastings.

Horizontal Cylinder, brass, well finished, 1½in. diam., with guides, bearings. Will exchange for Magneto Machine.—DUNBAR, 143, Norfolk-street, Glasgow.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

New Illustrated Price List of **Screws, Bolts, and** NUTS for Model Work, drawn to actual size, sent on receipt of stamp.—MORRIS COHEN, 132, Kirkgate, Leeds.

Fretwork.—Catalogue of every requisite, with 600 illustrations, free for 6 stamps.—HARGER BROS., Settle, Yorks.

Perspective, do you understand? "Knight's Practical Guide," 1s.—SIMPKIN and MARSHALL, or of J. P. KNIGHT, Art Master, Cheltenham.

Mica or Talc.—RICHARD BAKER and CO., 9, Mincing-lane, London.

Hardy's Patent **Safety Benzoline Lamp**, self-lighting, self-extinguishing, and unspillable post free, 1s. 3d.—THISTLETON, Oakham.

Wheel-Cutting to 12 inches diameter in brass only.—CLEGG, 18, Belinda-street, Hunslet, Leeds.

Planing to 12in. by 12in. by 8in. Boring, Turning, Screw-cutting, Slide-rests, &c.—CLEGG, as above.

Tracings heliographically reproduced at from 3s. Mechanics' drawings prepared.—Patent Office, Ashcroft-buildings, Victoria-street, Liverpool.

Patents.—Provisional Protection from £2. Complete from £5.—MANAGER, Patent Office, Ashcroft-buildings, Victoria-street, Liverpool.

Injectors, certain in action, easily fixed, no trouble, suit any boiler, and give perfect satisfaction.—POWELL.

Injectors, 2, 4, and 6 H.P., from 21s. Certain in action, no trouble.—POWELL, Engineer, Tunbridge Wells.

Brass Castings of Model Engines of all classes, in sets or otherwise. These castings are the best in the trade, and have obtained the highest testimonials from amateurs and others in all parts of the United Kingdom for cleanness of moulding, ease in finishing, and correctness of detail and design; being models of engines of modern construction. Boilers supplied of every type to suit the above from stock or to order. Fittings of all kinds, feed pumps, governors, safety valves, steam gauges, water gauges, &c. Comprehensive price list, post free, two stamps.—LUCAS and DAVIES, 21, Charles-street, Hatton-garden, London.

Japanese Bamboo **Fishing Rods**, 6 and 10 joints, 1s. 3d.; 5 joints, 1s.—BRISTOW and CO., Hull.

Lathes, 3in. to 7in. centre, chucks, tools. Illustrated List, 3d.—MILLS, Tintern-street, Sunderland.

Castings, Lathe Heads, Beds, Standards, Wheels, Slide Rests, Chucks, rough or machined. Illustrated List, 3d.—MILLS, Sunderland.

Launch Boilers and Engines up to 6½in. bore. Locomotive Boilers, Engines, Castings supplied. State requirements.—MILLS.

Model Engines, Parts, Tubing, Screws, Castings, rough or bored, turned, fitted, finished. List, 3d.—MILLS, Sunderland.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, SEPTEMBER 10, 1886.

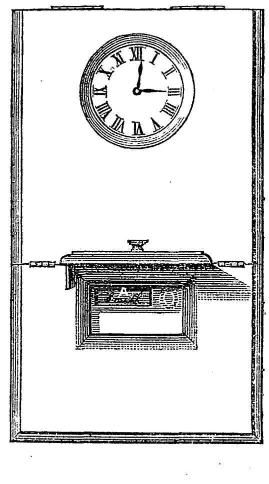
THE ART OF GLASS-BLOWING.*

ALTHOUGH some little knowledge of the art of glass-blowing is nowadays essential to the student of chemistry and physics who desires to succeed in laboratory work, there is, so far as we know, no handbook which gives clearly and with sufficient completeness the details necessary for performing some of the simple operations in producing laboratory apparatus in glass—except the little book which has just been issued by Mr. Shenstone, the lecturer on chemistry in Clifton College. The extraordinary productions of Mr. Gimingham and other skilled workers show what can be done by means of suitable material and the aid of the blowpipe, and it is not too much to say that many of the most interesting researches of the present day have been rendered possible by the glass-blower! In the majority of the textbooks such simple instructions as are required for making a capillary tube or for hermetically sealing a tube may be found; but in none of them will the student find such general instructions as will enable him so to manipulate glass as to produce any desired piece of apparatus he may require—perhaps in a hurry, at all events before he can get it from the workshop of the professional. Mr. Shenstone says that the opportunities of obtaining practical instruction in the art of glass working are so few in this country, and the advantages to be derived from an acquaintance with that art are so considerable to those who are engaged in physical and chemical experiment, that it appears to him a treatise on the subject is likely to be useful. He also says that although there are several amateurs more skilful than himself in glass-working no one has undertaken to write a book which will enable students and others to train themselves in the art, and so render them more independent in designing and constructing apparatus for research and for technical purposes. Even in a work so useful in the laboratory as Weinhold's "Experimental Physics" there is little information about glass-working, although the directions for making other apparatus are sometimes elaborate and invariably sufficient to enable an intelligent youth to prepare most of the articles he requires. Of other works dealing with experimental physics much the same may he said, for they give, if anything, less than Weinhold; while even most of the cyclopædias are silent, so far as the art of glass-blowing is concerned. The kinds of glass used in laboratory work are known commercially as soda glass, lead glass, and hard glass, but their composition varies from time to time, and is not of much importance, so long as the operator can distinguish readily between the three trade varieties. According to Mr. Shenstone, in a true glass there are at least two metallic oxides; but published analyses of different kinds of glass show that it is scarcely a definite mixture, and so far as the purposes of this work are concerned it is immaterial to the operator, for if the specimens he has are not suited to the treatment he will quickly discover the fact. It is well to purchase a considerable stock of tubes at once, and from the manufacturer, for it frequently happens that pieces from the same batch are more readily welded than pieces differing slightly in composition. The commercial apparatus is made in both soda and lead glass, mostly, perhaps, in the latter, and as repairs and additions are often necessary, it is advisable for the worker to provide himself with a supply of both kinds, for soda and lead glass are not readily joined in permanent union. Soda glass is, in some respects, easier to work than lead glass; but it is more apt to crack when cooling, and not unfrequently breaks with sudden changes of temperature. Carefully annealing will, however, remove these objections to a great extent, but not altogether, and therefore, although the cheap soda glass may be employed for most purposes without distrust, Mr. Shenstone advises those who propose to confine their operations to one kind of glass to take the small extra trouble required to learn to work lead glass. Hard glass is used only for apparatus required to withstand great heat, and is therefore difficult to work. According to Mr. Shenstone, tubes for glass-blowing should be as free as posssble from knots, air-bubbles, and stripes; should be in straight pieces of uniform thickness and cylindrical bore. When a sharp transverse scratch is made with a file, and the scratch is touched with a fine point of red hot glass of the same kind as the tube, the crack should pass round, so that the tube may be broken into two pieces with regular ends. If the crack proceeds very irregularly, and especially if it tends to extend along the tube, the glass has been imperfectly annealed, and should not be employed for glass-blowing purposes. Tube which is thin and of small diameter should not crack when suddenly brought into a flame; but large and thick tubes should be held in the warm air near the flame before being tested by actual immersion. In practice, all glass of whatever kind should be warmed up gradually, so that it has become quite hot over a considerable length or area before the flame of the blowpipe or lamp is actually applied. In his first chapter, Mr. Shenstone describes the apparatus and the working place, the latter being of much importance if the greatest measure of success is to obtained. First of all, the work-bench must be in a place perfectly free from draughts, and it must not face a window nor be in too strong a light, which renders the non-luminous flames almost invisible. Many glass-blowers, in fact, prefer to work by gaslight, sitting on a high stool so that they are well over the bench or table; but as that is rather fatiguing, when a long spell of work has to be done, Mr. Shenstone recommends sitting on a chair or low stool at a table of such a height that the elbows can be rested upon it while the hands hold the glass in the flame. As to blowpipes and bellows, the Herapath is the simplest; but we need scarcely say that the intending workers should consult Mr. Fletcher's list, which, as Mr. Shenstone observes, contains "ingenious combinations" besides the standard articles. It is, however, in connection with the practical details that Mr. Shenstone's little manual will be found so useful, for the reader there comes across information that is not generally found in the textbooks. Thus, in working with lead glass, the operator finds that when heated in the brush flame of the ordinary Herapath blowpipe, or within the point of the pointed flame, the surface becomes blackened in consequence of a portion of the lead becoming reduced to the metallic state, and the same thing will happen in bending a piece of lead glass tube if it is made too hot in a luminous flame. Consequently, when it is required to bend or draw out tubes it is advisable to remember that they may be softened sufficiently in a smoky flame; but where it is required to make joints, to form bulbs—in short, in all cases in which it is necessary to thoroughly soften the glass, that can be done without discolouring it by means of a powerful blower supplying a strong and steady blast and a blowpipe giving a clean brush flame. As in most other arts more is learned by a little practice than by any amount of reading; but Mr. Shenstone's little book will bear reading many times—until, in fact, its contents are committed to memory, for it contains just that kind of information which the beginner in glass-blowing requires. Thus he says, for instance, that beginners are apt to raise their glass to a higher temperature than is necessary, and to employ larger flames than are wanted; but the rules are:—Always employ, in the first instance, the smallest flame that is likely to do the work required; and in operations involving the blowing out of viscous glass, attempt to blow the glass at low temperatures before trying higher. Directions for making a variety of apparatus are given by Mr. Shenstone, accompanied by diagrams which render the instructions complete. He gives also a chapter on graduating and calibrating glass apparatus, which will be found very useful to the laboratory worker. In an appendix diagrams showing the chief sizes in which glass tubes are made are given with their trade numbers, so that they can be ordered from the warehouse in lead or soda glass by merely noting the number and the weight required. If Mr. Shenstone would append to these diagrams a table giving the weight per foot of the various sizes he would increase the value of this portion of his very useful work.

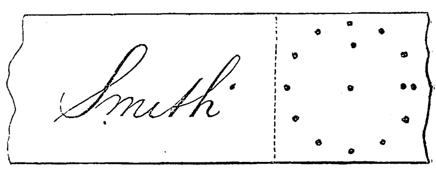
* The Methods of Glass-Blowing for the Use of Physical and Chemical Students. By W. A. SHENSTONE. London: Rivingtons.

MORRIS'S ERGOMETER (WORK-MEASURER).

MECHANICAL contrivances for checking time are no new invention; but Mr. T. Wilson Morris's ergometer, for which letters patent have just been granted, and which is now being shown by Messrs. J. Milne and Sons



at the Edinburgh Exhibition, deserves to supersede or supplement the machines that are at present in use. In every department of industry the importance of punctuality is recognised with increasing clearness, and the machine



which we are about to describe supplies a want that has been long and keenly felt.

The ergometer consists of a polished mahogany box, 17in. long, 9in. wide, and 4in. deep, showing the face of an eight-day lever clock. In front of the dial is a lid (Fig. 1).

The lid being raised a strip of paper is exposed to receive a signature or other entry, and when the lid is closed the time indicated by the dial is recorded opposite the entry (as in Fig. 2). When the lid is again raised the last entry disappears and fresh paper is automatically substituted. Should anyone, after signing, fail to

close the lid, the negligence does not go unpunished, as the time marked would be that at which the lid was next closed—an act which must be performed before paper can be obtained for another signature.

To explain the process in a few words, it will be enough to say that by a step-by-step mechanism the raising of the lid causes a strip of paper (from a roll long enough for over 1,000 entries) to be drawn past the opening A (Fig. 1).

The clock is geared by a train of wheels to a miniature counterpart fitted with steel cones indicating the hours and the extremities of the hour and minute hands. Accordingly, when the lid is closed the points on the miniature dial are impressed on the slip of paper, to the right of the entry. It will be obvious that by this arrangement no strain is put upon the clock, as the requisite power is supplied by the raising and the closing of the lid.

The invention which we have briefly described is not merely a clever piece of mechanism, but an apparatus of general utility. The following points of excellence should not pass unnoticed:—

In tne first place, every employé being required to affix his signature, opportunities for fraud are reduced to a minimum. A man whose ideas of right may be sufficiently lax to enable him to deal with medals other than his own would probably be unwilling to sign a name which did not belong to him, even supposing that he were endowed with the rare imitative faculty necessary to evade detection. Secondly, the ergometer has this important advantage over all previous contrivances—that it requires little preparation and no attention, being constantly ready for use by day or night, and only needing to be wound up once in eight days. It gives a convenient and permanent record of the time of every entry. Thirdly, the machine is compact and portable, hence in building and other trades it will be found most useful in outlying jobs where it could be readily affixed, and the expense of a timekeeper saved. The adaptability of the ergometer to railway signal boxes and to Stock Exchange purposes will be apparent to everyone. In hospitals it might be useful to indicate the due administering of medicine through the night; in the postal department to show the times at which letter boxes are cleared, and by its aid the time might be clearly and automatically printed on every telegraphic despatch.

A NEW PHOTOMETER FOR ESTIMATING PHOTOGRAPHIC EXPOSURES.

THIS instrument is the invention of Mr. H. D. Taylor, of York, and was patented last year, and introduced to the public but recently. The accompanying woodcut is one-half the real size of the instrument, and exhibits its construction. Fig 1 is a longitudinal and vertical section. The instrument consists essentially of a lamp L L L', and of an observing tube T T T'. The inventor makes use of the standard Parliamentary sperm candle as a convenient and portable source of light of sufficient constancy for the purpose in view. The candle is inclosed in the light metal lamp 4 4', and the latter is so arranged that the air feeding the candle flame finds its way into and out of the lamp by devious ways which, at the same time, prevent any exterior light penetrating into the lamp, which is thus rendered light-tight. The lamp is formed of two casings, the inner one (shown white) forming one piece with the tube holding the candle, and the outer one (shown black) forming one piece with the chimney and the short side tube or socket, K K. By grasping and twisting the candle tube the inner casing may be rotated within the outer one, and by so doing either an opening is uncovered in the side of the lamp through which to light the candle, or this opening is closed and a clear way left through which the candle light may fall upon and illuminate a disc of opal glass placed at O, within the tube K K. Provided that the candle is burning properly and the lamp held upright, it is evident that the opal disc O forms an indirect source of light of a practically constant intensity.

A metal slip, S S, perforated with a graduated series of apertures (see Fig. 4) slides through

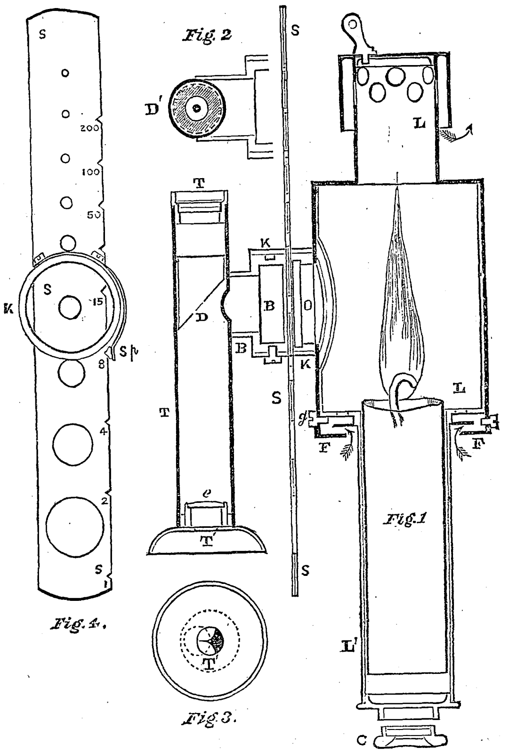


Fig. 4. Fig. 2 Fig. 3. Fig. 1

K K, just in front of the opal disc O. Its purpose is to vary or limit the area of the opal disc O which is allowed to shine into the observing tube T T'. A spring catch Sp. (Fig. 4) detains the slide S S, whenever any one of the apertures comes centrally over O, and the number corresponding to that particular aperture is read off near the point of Sp. Thus, 8 is the reading in Fig. 4.

The apertures in S S are figured or numbered in inverse ratio to their areas, the largest being No. 1, and the aperture which is $\frac{1}{30}$th of the area of No. 1 is numbered 30, and that one $\frac{1}{200}$th of the area of No. 1 is numbered 200, and so on. A hollow socket, B B, rotates stiffly within K K, in front of S S. This socket bears, fixed at right angles to it, the observing tube T T'. A thin metal diaphragm, D, is placed diagonally within T T', just where the light from O shines into T T'. This diaphragm is perforated at its centre by a small hole, and is painted white, in the form of a ring, immediately round this hole. In Fig. 2, D' shows the appearance of the diaphragm D when the white ring is illuminated by O, and viewed from the eye-end T' of the tube T T', in which end is placed a lens (*e*) to enable the eye to view the ring and hole in D with distinctness. The eye end is cupped out well to afford a shield to the eye, and keep out side light from the latter. A cap containing blue glass is screwed into the other end T of the tube T T'. Its purpose is to only allow the visible actinic rays of light to pass through the hole in D from any object to which T T' may be directed. Since T T' is connected by means of the rotating socket B with the lamp 4 4, it follows that if the lamp is held upright, then T T' can be pointed in *any* desired direction, up or down, right or left.

The object of the instrument is to enable the photographer to measure the brightness of the shadows or *darkest visible details* of his subject.

The correct exposure for any subject presenting shadows is that which is just sufficient to imprint on the photographic plate the *darkest visible details* of the subject, while any really blank shadows come out as clear glass in the resulting negative. Any exposure *less* than the above will yield an amount of blank shadow untrue to nature, while any exposure *in excess* of the above is, in most cases, superfluous, and apt to endanger the definition through the increased chance of objects moving, or to over-expose the high lights in subjects, presenting much contrast. Therefore, the proper exposure for a subject is properly determined by the brightness of the darkest visible details. Now, if the candle in the photometer is burning and the lamp held upright and the observing tube T T' is directed towards the darkest visible details of the subject, and the eye placed at the eye-end, then the hole in D will appear as a spot of blue light, more or less bright or faint. It is obvious that this spot of light is the actinic light reaching the eye of the observer from the particular darkest visible details to which T T is directed. This spot of light appears uniform in its brightness, since the lens (*e*) prevents any details being visible, as it throws them out of focus.

The spot of blue light is seen to be surrounded by the white ring illuminated by the opal disc O. Now, if S S is pushed up or down, the brightness of the white ring must vary according to the areas of O exposed by the apertures in S S. When aperture 30 is centrally over O, or, what is the same thing, when the reading of S S is 30, it is evident that the white ring on D is illuminated with just $\frac{1}{30}$th of the intensity with which it would be illuminated, were aperture No. 1 centrally over O (or were the reading of S S only 1). If, now, the white ring can always be made, by means of S S., to appear of the same brightness as the blue spot within it, then the readings of S S obviously furnish an *inverse* measure of the brightness of the blue spot of light, and therefore a *direct* measure of the exposure required to just imprint on the plate those details and that part of the shadows of the subject to which T T' is directed, and from which the spot of blue light emanates. Thus if, on a certain occasion, a photometer reading of 1 is taken from the shadows of a subject and the proper exposure is 3sec., and, on another occasion, a reading of 50 is taken of the shadows, then in this latter case the proper exposure is fifty times what was required in the former instance, or 3sec. by 50sec., or 150secs. In the latter case the details or part of the shadows observed by the photometer are only $\frac{1}{50}$th of the brightness they have in the former instance, and therefore require 50 times as much exposure. If the proper exposure is known for any particular reading of the photometer, then the proper exposures for all other readings are known, since they run in direct ratio to the readings, and the only remaining factor to be allowed for is the size of stop used in the lens used to photograph the view.

The inventor publishes a pamphlet fully describing the construction and use of the instrument, and giving full instructions, in which all calculations involved in its use in conjunction with lenses of varying apertures and stops, are reduced to a simple matter of mental multiplication. These pamphlets may be obtained from the licensee, Mr. Chas. Copeck, 100, New Bond-street, W.

It might be supposed that it would be impossible to balance and equalise the brightness of a

white ring with that of a spot of *blue* light within it; but by a very simple contrivance, not necessary to describe here, the difference of colour between them is made to almost disappear and form no obstacle to their comparison.

With the aid of this instrument, exposures may be made with the utmost confidence in the most deceptive of situations on the dullest days, or after sunset, since its readings embrace in themselves corrections for all those factors, bad light, confined situation, shaded position of shadows, time of day and nature of sky, &c., which combine together to utterly deceive even experienced judgments when unaided by any instrument. Nor can it be said that the photometer interferes in any degree with the artistic judgment of the photographer, for it is evident, that after taking an observation of his subject with it, he is quite at liberty to either under-expose or over-expose as he thinks best. If he is convinced that his picture will come out best artistically if he allows two or three times the *theoretical minimum* exposure (indicated by the photometer), he is perfectly at liberty to allow such increase, while he has the advantage of knowing what he is about; whereas, if he is unaided by the photometer, he is, as a rule, blissfully ignorant as to whether he has given too little or too much exposure, and only learns in what way he has erred—if at all—when the plate is developed and it is too late to expose another plate in case of failure. An observation with the photometer does not occupy more than two minutes after lighting the candle, after which it is immediately extinguished.

It is especially adapted for landscape work, in which the unaided judgment is so very liable to failure.

RECKENZAUN'S IMPROVEMENTS FOR REVERSING ELECTRO-MOTORS.

FIG. 1.

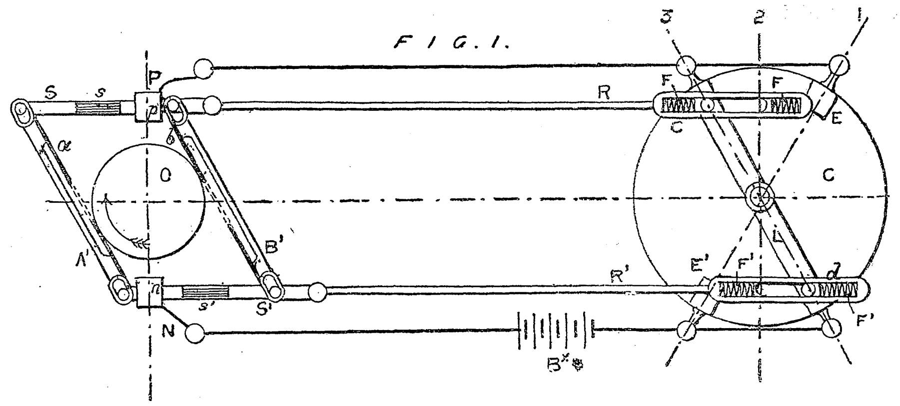

FIG. 2.

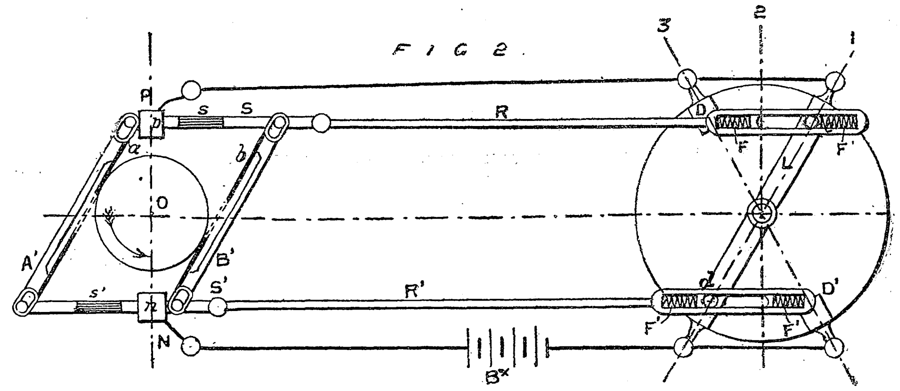


THE ingenious manner in which Mr. Reckenzaun has succeeded in effecting the reversal of an electro-motor, just at the moment when no current is passing, is shown in the annexed engraving, which represents the invention as patented. It has been well known, ever since the introduction of electric motors, that the armatures of such machines will rotate right-handed or left-handed according to the position in which the brushes are placed, relatively to the poles of the Field Magnets, and in the Specifications to Letters Patent granted to John Hopkinson, 1879, No. 2411 and No. 4653 there are described means of shifting the position of two pairs of brushes by pivoting the free ends of the same on a pin. If, however, the brushes of a motor are removed from the commutator whilst a current is flowing through the armature, two serious things will happen; firstly, an arc is formed between the receding brush and the nearest commutator segments, thereby damaging the metal surfaces; and secondly, the flow of the current from the generator being suddenly directed into the armature through different points, the currents induced by the sudden make and break have the tendency to destroy the insulation between the adjacent wires, and thus often permanently injure part or whole of the motor circuit. To avoid these objectionable features, Mr. Reckenzaun effects the reversal or the displacement of the brushes, relatively to the commutator, by means of parallel bars, capable of sliding to and fro, in or on fixed slides. Upon these bars he places the brushes, which will approach to or recede from the commutator according to the movement of the bars, which are in plan at right angles to the axis of the armature. In order to prevent the possibility of an untimely reversal, which often occurs in a hurry during excitement on board an electric boat, car, or other vehicle propelled by electricity, or on anything driven by electric motors, he connects the sliding bar or bars by suitable means with the lever of a switch which makes and breaks the main circuit between the motor and the generator. Either the switch lever is provided with an oblong hole, or the reversing bar, or some intermediate link, can be made to have sufficient backlash or freedom of movement or lost motion so that the contact on the switch is broken whilst the brushes of the motor are at rest. By moving the switch handle still further, the brushes are reversed, and finally, by putting the lever to the end of its course, contact is made in the switch to allow the current to flow when the rotation of the armature is the opposite of what it was with the switch lever in its original position. The return movement will of course bring the mechanism back to the first condition. The back lash of the mechanism and an intermediate spring or its equivalent determine the relative motion of the switch handle and the brushes. Fig. 1 shows the position of parts when the motor runs in one direction and Fig. 2 the position of parts when the motor runs in the opposite direction, as indicated by the arrow in each case on the commutator O of a motor of any suitable or usual construction. A^1 and B^1 are the brass or copper backings or holders for the brushes *a* and *b*, which latter thus virtually or electrically are only one brush each, although cut in the middle lest the commutator O should work against the brushes, which if the latter (as is usual) are made of copper wire or sheet copper would, or might, buckle or damage them. The brush holders A^1 and B^1 are, by pins working in oblong slots, jointed to parallel bars S and S^1, capable of sliding to and fro in fixed metal guides, *p* and *n*, and made in parts with insulating pieces *s* and s^1 inserted between. Continuation rods R and R^1, with intermediate springs F F^1 to give the needed elasticity, are jointed to one end of the parallel bars S and S^1 respectively, and form means of connection with the lever L of a switch of ordinary construction which makes and breaks the main circuit between the motor and the generator, there being sufficient lost motion or backlash by pins on the lever L working in oblong holes on the rods R and R^1 so that the contact on the switch is broken whilst the brushes *a* and *b* are at rest. The rods R and R^1 are insulated from the switch lever L. P and N are the terminals of the motor. The switch-disc C is fitted with contact pieces or blocks and binding screws D D^1, and E E^1 and the current from the source B^x passes through them, a circuit being made when the switch lever L is in either of the positions 1 or 3 for working the motor in one direction of revolution or the other, while in the intermediate position 2, and whilst the brushes are at rest, the contact on the switch C is broken. The current of electricity will, in series machines, pass round the field magnet coils, and enter at the binding screws P and N, thence passing to the guides *p* and *n* and through the rods S and S^1 and brushes *a* and *b* to the commutator O With shunt machines the current will pass directly from P and N into *p* and *n* and through the rods S and S^1 and brushes *a* and *b* to the commutator. The arrangement of switch lever for making and breaking the main circuit between the motor and the generator before reversing may also be employed in combination with other reversing arrangements depending on the displacement of the brushes. It will be seen that when the switch lever is moved to reverse the motor the main circuit between the motor and the generator is broken, and the defects which are liable to take place when the brushes are removed from the commutator whilst the current is flowing through are thereby obviated.

COMPOUND LOCOMOTIVES.

THOSE of our readers who are interested in the subject of compound locomotives will, when the Transactions of the Institution of Mechanical Engineers are published, have an opportunity of consulting two remarkable papers, one of which—that of Mr. Alexander Borodin, of Kieff—is almost a volume in itself. Mr. Borodin is connected with one of the Russian railways, and in 1880 altered a locomotive to the compound system adopted by that distinguished advocate of the type, M. Mallet. The cylinders were in the proportion of 1 to 2, and, practically, the locomotive would cost no more to build than one of the ordinary type. The cylinders were jacketed, and, for comparison, one of the locomotives of the usual type was also fitted with jackets. Both engines were tested with experimental trains, and were subsequently jacked up in a shed and used to drive a machine shop. All sorts of experiments seem to have been made with steam at various pressures and with different degrees of cut-off, with steam in the jackets and without. As a result of the trials, Mr. Borodin concludes that with the same expansion of steam the consumption of water and of fuel is less in a compound locomotive than in a simple engine, and as that is the gist of the whole question, it might be considered that it would be better settled by a comparison between locomotives in actual work. As to the question of jacketing, it must be remembered that a very great deal depends upon how the jacketing is done, and it seems clear that in the case of Mr. Borodin's engines the arrangements for draining the jackets were not all that could be desired. However, the following conclusions were arrived at:—When the jackets are not in use, the compound engine gives in comparison with the ordinary engine an economy of 13 per cent. in consumption of steam, and of 24 per cent. in consumption of wood. Admission of steam into the jackets does not sensibly affect the consumption of steam in the ordinary engine; whilst in the

compound engine it produces an injurious effect, and increases the consumption of fuel and water per indicated horse-power. In summing up the results of his inquiries, Mr. Borodin says that: The steam jackets on the ordinary engine, while working in the testing shed in the first and second notches, undoubtedly gave a mean economy of steam of 16 to 13 per cent. In the experimental trains the jackets did not generally give satisfactory results, except when the ordinary engine was working in the first notch; but this must be attributed partly to the losses of steam necessary for warming up the walls of the jackets each time the regulator was opened, and above all to the defective drainage of the jackets, which probably transformed them into condensers. All experience has taught makers—especially of portable engines—that unless jackets are properly drained they are worse than useless, and Mr. Borodin is probably of that opinion; indeed, he said that a better method must be sought for with regard to the compound system. He says that it undoubtedly gave an economy in water and fuel varying from 15 to 20 per cent.; an economy which, if it can be maintained in practical work, will be found of considerable importance in localities where fuel is dear and water scarce and bad. Mr. Sandiford in his paper gave an account of the working of compound locomotives in India, in the shape of data connected with two compounds of different patterns. One of these engines has two cylinders, respectively 18in. and 24in. in diameter, with a stroke of 22in., and an arrangement for admitting steam direct to the low-pressure chest; and that engine worked satisfactorily with a saving of 13½ per cent. of fuel as compared with an ordinary coupled engine having cylinders 16in. by 24in. The other locomotive has four cylinders: two of 11⅝in. outside, and two of 17in. inside, with a 24in. stroke. This pattern heads the list for economy of fuel, although the pressure of steam used (120lb.) is not sufficient in Mr. Sandiford's opinion to develop the full benefit of the compound system. M. Mallet, although he has made other designs, prefers a compound with two cylinders only when the low-pressure cylinder can be made large enough; but where that is impossible it is best in his opinion to have four cylinders. It is not unlikely that the whole question will be discussed fully on a future occasion, as from the nature of the late meeting the actual results shown by Mr. Borodin's tables could not be carefully criticised.

TRACTION AND ADHESION.*

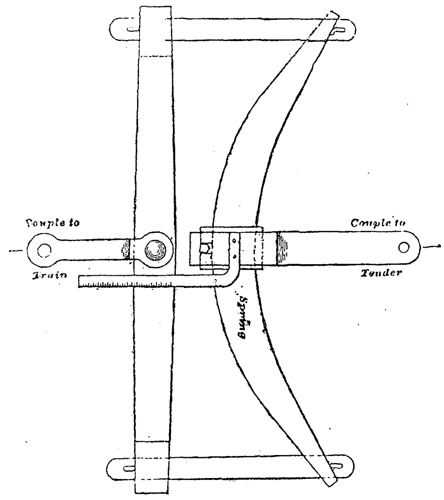
CONSIDERING the number and extent of the researches that have been made on the twin subjects which head this article, is seems strange that so much doubt should still exist as to the amount of friction between a driving wheel and a dry rail. Go into almost any roundhouse, and you may find by conversation with the runners that a large (*i.e.*, too large) proportion of the engines are "slippery," and although every day broken pins and side-rods, flat tires and worn rails swell the bills for "repairs," the same-sized cylinders are put to work on drivers bearing the same weight, and with the exception of the men who are obliged to climb hills with these engines, holding the throttle lever in one hand and sand lever in the other, no one notices this serious defect in design, or experiments with a view of remedying it.

We do, it is true, see once in a while an engine carrying around half or three-quarters of a ton of extra metal in the shape of a heavy deck-plate or cast-iron cab, and once in a while a "traction increaser" kindly relieves the tender of a portion of its load for the benefit of the engine, probably on the principle that "Whoso hath, to him shall be given." These means are all endeavours to atone for a faulty design, and could many realise how easily the proper weight for the drivers, under ordinary conditions for any given size of cylinders, could be fixed on, there would be less work for the wheel lathes.

In order to examine the subject fully, let us first see what traction is; then examine the methods of finding the power exerted on the wheels by the pressure of the steam in the cylinders. And finally I shall give some examples from actual practice that have come under my own observation, and explain a simple method by which master mechanics may, at a very slight expense, find for themselves the power exerted by their engines in hauling their trains, and proportion the loads on the drivers so that sliding and slipping will be reduced to a minimum.

First, What is the tractive power of an engine? The tractive power is its hauling power, or the power by which it is forced in a horizontal direction along the rails, and depends not only on the size of its cylinders, but also on the amount of adhesion of the driving wheels to the rails. As an engine is only as strong as its weakest part, if the wheels slip before the maximum power of the cylinders can be exerted, the excess of cylinder capacity does no more good than if it were not on the engine. Indeed, it is a great disadvantage, as the engine, when working at the longer points of cut-off, must do so on a partially closed throttle; and these points are the very ones where a full throttle opening is imperatively demanded. In the modern locomotive the pressure of the steam on the pistons is communicated by means of rods to the wheels directly. Therefore, friction aside, the work done by the steam in the cylinders must be "given out," we may say, at the circumferences of the driving wheels. As work, mechanically speaking, is the product of a resistance and the distance through which the resistance is overcome, we may ascertain the amount of work done in the cylinders of any engine during one revolution of the drivers by multiplying the pressure required to move the pistons by the distance through which the pistons move in one revolution of the wheels, or four times the length of the stroke.

This amount of work will be exerted at the circumferences of drivers on the rail, and will urge the engine in a horizontal direction along the track, if the wheels don't slip. Since, for any particular case, we wish to know not only the amount of work during one revolution, but also the tractive force which the drivers are exerting on the rail, we may ascertain the latter by remembering that the work done by the steam on the pistons is the same (friction aside) as that done by the drivers on the rail. To make this clear, we may state it in this form:



$$\left.\begin{array}{l}\text{Work done in}\\ \text{cylinders in}\\ \text{one revolution}\end{array}\right\} = \left\{\begin{array}{l}\text{Pressure on pistons by distance}\\ \text{travelled by pistons.}\end{array}\right.$$

which is always equal to

$$\left.\begin{array}{l}\text{Work done by}\\ \text{drivers in}\\ \text{one revolution}\end{array}\right\} = \left\{\begin{array}{l}\text{Resistance to motion of drivers}\\ \text{by distance travelled over by}\\ \text{driver in one revolution.}\end{array}\right.$$

This once understood, we may easily determine the resistance to motion of drivers (which, if the drivers overcome it, will be the tractive force), by dividing the work done in cylinders in one revolution by the distance moved over by drivers in one revolution. This distance is the circumference of the wheel.

Let us apply our rule: Take an engine with cylinders of 17in. bore, 24in. stroke, and drivers 62in. diameter. The area of a piston will be $17 \times 17 \times \cdot7854 = 226\cdot981$ square inches. To get the pressure on a piston, we multiply this product by the mean effective pressure in the cylinder during the stroke. If the steam admitted to the cylinder has a pressure of 135lb. per square inch, and the valve closes after the piston has moved 21in., the mean pressure in the cylinder will be about 127lb. per square inch of the piston; and since there are 226·981 square inches of surface in the face of a piston, the pressure on that face will be $226\cdot981 \times 127 = 28826\cdot587$ on an average throughout the stroke.

This force is exerted through $24 \times 4 = 96$in. during one revolution of the wheels, so the pressure by the distance through which it is exerted, or $28826\cdot587 \times 96 = 2767352\cdot352$ equals the number of inch-pounds of work done in the cylinders during one revolution of the drivers. This work is done, and also given out, during one revolution of the drivers. The circumference of a 62in. wheel equals $62 \times 3\cdot1416 = 194\cdot779$in., and the resistance to motion, or the tractive force, as we have seen, will be equal to the work done in one revolution divided by the circumference of the wheel, or $2767352\cdot352 \div 194\cdot779 = 14207\cdot652$lb.

Let us now compare this tractive power with the figures given by other experimenters for the adhesion of a driver to a dry rail.

On looking over the results of past experiments made by different authorities, we find it difficult to choose a result which we may be sure is nearly right for the use to which we would put it. We wish to load our drivers so that they will not slip when a force to overcome a resistance of 14207·652lb. at the circumference is applied, and yet we are sure that less weight is needed than would seem to be indicated as necessary by the results of some of the experiments. For instance, Poiree, a French experimenter, states that the wheels will just commence to slide at a speed of ten miles per hour if for every ton (of 2240lb.) of load on the wheels a force of 465·9lb. be applied to the circumference, while Westinghouse and Galton give as the results of their experiments under similar conditions 246·4lb. per ton as being sufficient to slip the wheels. Recent experiments conducted by the experimental department of the Pennsylvania Railroad indicate a much higher co-efficient of friction than has yet been supposed to exist, rising, in some cases, as high as 550lb. per ton of load, and, as we shall see, these figures are more nearly correct than the former ones.

I will now give a few figures from actual practice as observed while riding on engines hauling heavy trains over the Northern Pacific Railroad, and show that the figures of Poiree and Westinghouse are, for some cases at least, much too low, and then by means of experiment and comparison of results, we will try to establish a percentage of load for our drivers, which, while not excessive, will decrease the slipping.

These observations were made on the performance of an eight-wheeled engine of the "American" type. Cylinders 17in. diameter, 24in. stroke, drivers 62in. diameter. Weight of engine loaded, 77,800lb. Weight on drivers, 49,700lb. According to the figures of Poiree, which exceed those of Westinghouse, a resistance of 10,333lb. would cause the wheels to slip, whereas this engine actually took a train which, on a straight track, offered a resistance of 12,190lb. up a grade of 40ft. to the mile, and around a sharp reverse curve, with the rails wet with dew, and only slipped once—this being on the curve mentioned above, and the slipping was instantly stopped by the application of a little sand to the rails. On the curve the resistance must have increased to 15,000lb., which would give for the amount required to slip the drivers 670lb. and over per ton of load. Laying supposition aside and taking the resistance of the train on a level track, which we know to be 12,190lb., we see that the load on the drivers was 22·18 tons of 2,240lb. per ton, and that with these 22·18 tons of load the engine overcame the above resistance, therefore it must at least have required

$$\frac{12,190}{22\cdot18} = 545\text{lb.}$$

per ton of load to pull the train, and it did this easily without slipping.

At a future date, if desired, I will add the results of some experiments made with the indicator as a check on the other results; but at present I will be content with suggesting a simple form of traction dynamometer which any master mechanic can rig up for himself in odd moments (if master mechanics have any odd moments), and may find of great service and surprising accuracy, considering the simplicity of design as compared with the expensive and elaborate dynamometer cars, which are fitted up at a cost of thousands of dollars for the purpose of solving such problems as are presented here. The apparatus referred to consists of a driving or other convenient spring having attached to it a graduated metal scale. The amount of deflection of the spring can be measured on any grade and with any weight of train, and the greatest power which the cylinders can exert as well as the resistance at which the drivers begin to slip, can be noted, and the weights on the drivers regulated accordingly.

Do not, however, be content with reading this explanation of the apparatus. Make one, use it. It was from a fear that farther experiments would not be made that I have withheld figures obtained by myself. We are too likely in this age of experiment to accept results of some one's else experiments instead of troubling ourselves to add to the data. Finally, when we find the right load for our drivers, let us apply it. Not in the form of a traction increaser or a heavy sand-box cover or dome-casing, but in boiler space. It is here that so many American engines are deficient. It is here that so much fuel goes to waste by endeavouring to keep a pressure of 140lb. for cylinders that open their huge capacities to be filled with steam four times every revolution.

BRITISH ASSOCIATION.

THE ADDRESS IN MATHEMATICS AND PHYSICS.

THE address in Section A was delivered by Prof. G. H. Darwin, M.A., F.R.S., F.R.A.S., president of the section, who, after a few preliminary remarks, and a reference to the inadequacy of the denudation theory to give an accurate measure of geological time, proceeded as follows:—

But there is another theory which is precise in its estimate, and which, if acceptable from other points of view, will furnish exactly what is requisite. Mr. Croll claims to prove that great changes of climate must be brought about by astronomical events of which the dates are known or ascertainable ("Climate and Time"). The perturbation of the planets causes a secular variability in the eccentricity of the earth's orbit, and we are able confidently to compute the eccentricity of many thousands of years forward and backward from to-day, although it appears that, in the opinion of Newcomb and Adams, no great reliance can be placed on the values deduced from the formulæ at dates so remote as those of which Mr. Croll speaks. According to Mr. Croll, when the eccentricity of the earth's orbit is at its maximum, that hemisphere which has its winter in aphelion would undergo a glacial period. Now, as the date of great eccentricity is ascertainable, this would explain the great Ice Age and give us its date. The theory has met with a cordial acceptance on many sides, probably to a great extent from the charm of the complete answer it affords to one of the great riddles of geology. Adequate criticism of Mr. Croll's views is a matter of great difficulty on account of the diversity of causes which are said to co-operate in the glaciation. . . . . Now, there is one result of Mr. Croll's theory which should afford almost a crucial test of its acceptability. In consequence of the precession of the equinoxes the conditions producing glaciation in one hemisphere must be transferred to the other every 10,000 years. If there is good geological evidence that this has actually been the case, we should allow very great weight to the astronomical theory, notwithstanding the difficulties in its way.

[Prof. Darwin here alluded to the views of Wallace in "Island Life," and to suggestions made by other thinkers; but we have space only for an abstract of his interesting address.]

When looking at the astronomical theory of geological climate as a whole, one cannot but admire the symmetry and beauty of the scheme, and nourish a hope that it may be true; but the mental satisfaction derived from our survey must not blind us to the doubts and difficulties with which it is surrounded.

And now let us turn to some other theories bearing on this important point of geological time. Amongst the many transcendent services rendered to science by Sir William Thomson, it is not the least that he has turned the searching light of the theory of energy on to the science of geology. Geologists have thus been taught that the truth must lie between the cataclysms of the old geologists and the uniformitarianism of forty years ago. It is now generally believed that we must look for a greater intensity of geologic action in the remote past, and that the duration of the geologic ages, however little we may be able mentally to grasp their greatness, must bear about the same relation to the numbers which were written down in the older treatises on geology, as the life of an ordinary man does to the age of Methuselah.

The arguments which Sir William Thomson has adduced in limitation of geological time are of three kinds. I shall refer first to that which has been called the argument from tidal friction; but before stating the argument itself it will be convenient to speak of the data on which the numerical results are based. Since water is not frictionless, tidal oscillations must be subject to friction, and this is evidenced by the delay of twenty-four to thirty-six hours which is found to occur between full and change of moon and spring-tide. An inevitable result of this friction is that the diurnal rotation of the earth must be slowly retarded, and that we who accept the earth as our timekeeper must accuse the moon of a secular acceleration of her motion round the earth, which cannot be otherwise explained. It is generally admitted by astronomers that there actually is such an unexplained secular acceleration of the moon's mean motion. No passage in Thomson and Tait's "Natural Philosophy" has excited more general interest than that in which Adams is quoted as showing that, *with a certain value for the secular acceleration*, the earth must in a century fall behind a perfect chronometer, set and rated at the beginning of the century, by twenty-two seconds. Unfortunately, this passage in the first edition gave an erroneous complexion to Adams's opinion, and being quoted without a statement of the premises, has been used in popular astronomy as an authority for establishing the statement that the earth is actually a false timekeeper to the precise amount specified.

In the second edition (in the editing of which I took part) this passage has been re-written, and it is shown that Newcomb's estimate of the secular acceleration only gives about one-third of the retardation of the earth's rotation, which resulted from Adams's value. The last sentence of the paragraph here runs as follows:—"It is proper to add that Adams lays but little stress on the actual numerical values which have been used in this computation, and is of opinion that the amount of tidal retardation of the earth's rotation is quite uncertain." Thus, in the opinion of our great physical astronomer, a datum is still wanting for the determination of a limit to geological time, according to Thomson's argument.

However, subject to this uncertainty, with the values used by Adams in his computation, and with the assumption that the rate of tidal friction has remained constant, then a thousand million years ago the earth was rotating twice as fast as at present.

In an interesting discussion on subaërial denudation Croll has concluded that nearly one mile may have been worn off the equator during the past 12,000,000 years, if the rate of denudation all along the equator be equal to that of the basin of the Ganges ("Climate and Time," 1885, p. 336). Now, since the equatorial protuberance of the earth when the ellipticity is $\frac{1}{230}$ is fourteen miles greater than when it is $\frac{1}{300}$, it follows that 170,000,000 years would suffice to wear down the surface to the equilibrium figure. Now, let these numbers be halved or largely reduced, and the conclusion remains that denudation would suffice to obliterate external evidence of some early excess of ellipticity. If such external evidence be gone, we must rely on the incompatibility of the known value of the precessional constant with an ellipticity of internal strata of equal density greater than that appropriate to the actual ellipticity of the surface. Might there not be a considerable excess of internal ellipticity without our being cognisant of the fact astronomically? And, further, have we any right to feel so confident of the internal structure of the earth as to be able to allege that the earth would not through its whole mass adjust itself almost completely to the equilibrium figure? Tresca has shown in his admirable memoirs on the flow of solids that when the stresses rise above a certain value the solid becomes plastic, and is brought into what he calls the state of fluidity. I do not know, however, that he determined at what stage the flow ceases when the stresses are gradually diminished. It seems probable, at least, that flow will continue with smaller stresses than were initially necessary to start it. But if this is so, then, when the earth has come to depart both internally and externally from the equilibrium condition, a flow of solid will set in, and will continue until a near approach to the equilibrium condition is attained. When we consider the abundant geological evidence of the plasticity of rock, and of the repeated elevation and subsidence of large areas on the earth's surface, this view appears to me more probable than Sir William Thomson's. On the whole, then, I can neither feel the cogency of the argument from tidal friction itself, nor, accepting it, can I place any reliance on the limits which it assigns to geological history.

The second argument concerning geological time is derived from the secular cooling of the earth. We know in round numbers the rate of increase of temperature, or temperature gradient, in borings and mines, and the conductivity of rock. These data enable us to compute how long ago the surface must have had the temperature of melting rock, and when it must have been too hot for vegetable and animal life.

The present argument as to the date of the consolidation of the earth reposes on the hypothesis that the earth is simply a cooling globe, and there are reasons why this may not be the case. The solidification of the earth probably began from the middle and spread to the surface. Now, is it not possible, if not probable, that, after a firm crust had been formed, the upper portion still retained some degree of viscosity? If the interior be viscous, some tidal oscillations must take place in it, and, these being subject to friction, heat must be generated in the viscous portion; moreover, the diurnal rotation of the earth must be retarded. . . . . Now, if this amount of heat, or any sensible fraction of it, was actually generated within a few hundred miles of the earth's surface, the temperature gradient in the earth must be largely dne to it, instead of to the primitive heat of the mass. Such an hypothesis precludes the assumption that the earth is simply a cooling mass, and would greatly prolong the possible extension of geological time. It must be observed that this view is not acceptable unless we admit that the earth can adjust itself to the equilibrium figure adapted to its rotation.

It seems also worthy of suggestion that our data for the average gradient of temperature may be somewhat fallacious. Recent observations (*Challenger* Expedition) show that the lower stratum of the ocean is occupied by water at near freezing temperature, whilst the mean annual temperature of the earth's surface, where the borings have been made, must be at least 30° higher. It does not then seem impossible that the mean temperature gradient for the whole earth should differ sensibly from the mean gradient in the borings already made.

The foregoing remarks have not been made with a view of showing Sir William Thomson's argument from the cooling of the earth to be erroneous, but rather to maintain the scientific justice of assigning limits of uncertainty at the very least as wide as those given by him. Prof. Tait ("Recent Advances in Physical Science," 1885) cuts the limit down to 10,000,000 years; he may be right, but the uncertainties of the case are far too great to justify us in accepting such a narrowing of the conclusion.

The third line of argument by which a superior limit is sought for the age of the solar system appears by far the strongest. This argument depends on the amount of radiant energy which can have been given out by the sun. The amount of work done in the concentration of the sun from a condition of infinite dispersion may be computed with some accuracy, and we have at least a rough idea of the rate of the sun's radiation. From these data Sir William Thomson concludes (Thomson and Tait, "Natural Philosophy," Appendix E):—"It seems, therefore, on the whole most probable that the sun has not illuminated the earth for 100,000,000 years, and almost certain that he has not done so for 500,000,000 years. As for the future, we may say, with equal certainty, that inhabitants of the earth cannot continue to enjoy the light and heat essential to their life for many million years longer unless sources now unknown to us are prepared in the great storehouse of creation."

This result is based on the value assigned by Pouillet and Herschel to the sun's radiation. Langley has recently made a fresh determination, which exceeds Pouillet's in the proportion of eight to five. With Langley's value Thomson's estimate of time would have to be reduced by the factor five-eighths. It has been suggested by Croll that the primitive solar nebula may have been hot. This heat must have arisen from the collision of two or more masses; if their relative velocity before collision was that due simply to their mutual attraction, the heat so generated is already counted in the heat so generated by the concentration of the sun from a state of infinite dispersion. But if the relative velocity existed otherwise than from their mutual attraction, then the total heat in the sun might exceed that due simply to concentration. Sir William Thomson considers the hypothesis very improbable. The term improbability seems, however, almost to lose its meaning in these speculations, and at least we know by the spectroscope that actual nebulæ do consist of incandescent gases. In considering these three arguments I have adduced some reasons against the validity of the first argument, and have endeavoured to show that there are elements of uncertainty surrounding the other two; nevertheless they undoubtedly constitute a contribution of the first importance to physical geology. Whilst then we may protest against the precision with which Prof. Tait seeks to deduce results from them, we are fully justified in following Sir William Thomson, who says that "the existing state of things on the earth, life on the earth, all geological history showing continuity of life, must be limited within some such period of past time as 100,000,000 years." At present our knowledge of a definite limit to geological time has so little precision, that we should do wrong to summarily reject any theories which appear to demand longer periods of time than those which now appear allowable.

THE ADDRESS IN CHEMISTRY.

The address in Section B was delivered by Mr. W. Crookes, F.R.S., president of the section, who took for his subject the foundations of chemistry as a science, or the nature and probable origin of the elements. It was a valuable contribution to the study of an idea which has occurred to many distinguished workers, even so far back as Roger Bacon, and was supported by some account of the spectroscopic investigations which Mr. Crookes has been making. It is almost impossible to give even an abstract of this lengthy address; but the following is the summary:—

A genesis of the elements such as is here sketched out would not be confined to our little solar system, but would probably follow the same general sequence of events in every centre of energy now visible as a star. Before the birth of atoms to gravitate towards one another, no pressure could be exercised; but at the outskirts of the fire-mist sphere, within which all is *protyle* (προ, earlier than; ὕλη, the stuff of which things are made)—at the shell on which the tremendous forces involved

in the birth of a chemical element exert full sway—the fierce heat would be accompanied by gravitation sufficient to keep the newly-born elements from flying off into space. As temperature increases expansion and molecular motion increase, molecules tend to fly asunder, and their chemical affinities become deadened; but the enormous pressure of the gravitation of the mass of atomic matter outside what I may for brevity call the birth-shell would counteract this action of heat. Beyond this birth-shell would be a space in which no chemical action could take place, owing to the temperature there being above what is called the dissociation point for compounds. In this space the lion and the lamb would lie down together; phosphorus and oxygen would mix without union; hydrogen and chlorine would show no tendency to closer bonds; and even fluorine, that energetic gas which chemists have only isolated within the last month or two, would float about free and uncombined. Outside this space of free atomic matter would be another shell, in which the formed chemical elements would have cooled down to the combination-point, and the sequence of events so graphically described by Mr. Mattieu Williams in "The Fuel of the Sun" would now take place, culminating in the solid earth and the commencement of geological time. Summing up all the considerations we cannot, indeed, venture to assert positively that our so-called elements have been evolved from one primordial matter; but we may contend that the balance of evidence, I think, fairly weighs in favour of this speculation. This, then, is the intricate question which I have striven to unfold before you, a question that I especially commend to the young generation of chemists, not only as the most interesting, but the most profoundly important, in the entire compass of our science. I say deliberately and advisedly the *most interesting*. The doctrine of evolution, as you well know, has thrown a new light upon and given a new impetus to every department of biology, leading us, may we not hope, to anticipate a corresponding wakening light in the domain of chemistry? I would ask investigators not necessarily either to accept or to reject the hypothesis of chemical evolution, but to treat it as a provisional hypothesis; to keep it in view in their researches, to inquire how far it lends itself to the interpretation of the phenomena observed, and to test experimentally every line of thought which points in this direction. Of the difficulties of this investigation none can be more fully aware than myself. I sincerely hope that this my imperfect attempt may lead some minds to enter upon the study of this fundamental chemical question, and to examine closely and in detail what I, as if amidst the clouds and mists of a far distance, have striven to point out.

THE ADDRESS IN GEOLOGY.

The address in Section C was delivered by Prof. T. G. Bonney, D.Sc., F.R.S., the president of the section, who selected as his subject "The Application of Microscopic Analysis to Discovering the Physical Geography of Bygone Ages." The following is an abstract:—The ultimate aim of geological researches was to obtain answers, in the widest and fullest sense, to these two problems in the history of our globe—the evolution of life upon it, and the evolution of its physical features. In the former a host of labourers, before and since the epoch of Darwin's great book, had been employed in collecting and co-ordinating facts, and in framing hypotheses by scientific induction. In the latter the workers were fewer, but the results obtained were neither small nor unhopeful. In the past generation, men like Godwin-Austen pointed out the principles of work and gathered no small harvest, but in the present the application of the microscope to the investigation of rock structure had facilitated research by furnishing them with an instrument of precision; this, by disclosing the more minute mineral composition and structural peculiarities of rocks, enables them to recognise fragments, and sometimes even to determine the source of the smaller constituents in a composite clastic rock. The microscope, in short, enabled them to declare an identity where formerly only a likeness could be asserted, to augment largely in all cases the probabilities for or against a particular hypothesis, and to substitute in many a demonstration for a conjecture. Every rock in which the constituent particles admitted of recognition and identification might be made to bear its part in the work of deciphering the past history of the globe. Where the constituents had been derived from other rocks they obtained some clue to the nature of the earth's crust at that epoch; where the locality whence a fragment was broken could be discovered, the nature, strength, and direction of the agents of transport could be inferred—some idea as to the structure and surface contour of the earth in that district, and at that time, could be formed; and thus the petrologist, by patient and cautious induction, might in process of time build up from these scattered fragments the long-vanished features of the pre-historic earth, with a certainty hardly less than that of the palæontologist when he bid the dry bones l[illegible] and re-people land and sea with long-vanished races. The latter study was in vigorous maturity, the former still in its infancy; so much wider then was the field, so much more fascinating, to many minds, was the investigation. It was at present hardly safe to attempt to trace the exact land boundaries of the Cambrian Ocean, but the enormous masses of Archæan material entombed in the earlier Palæozoic strata of Wales and the North-West of Scotland could only be explained by the proximity of a great continental land—an extension of the present Scandinavian Peninsula, which had a general slope towards the south-east, the main watershed of which might have lain some distance to the west of the outer Hebrides. Possibly the comparatively rapid deepening of the Atlantic beyond the 100 fathom line may have had some relation to the western outline of this primæval Atlantis. But even over the more central parts of Great Britain there could not have been deep or open ocean. Great volcanic outbursts appeared to have studded the sea with volcanic islands, and to have added to the hetorogeneous materials from which the sediments were now formed. It was evident that in Silurian times the coast-line had extended southward and eastward. The old red sandstone of Scotland and Wales indicated a yet further continental extension towards the south-east. A great epoch of mountain-making in the Scotch Highlands, which had perhaps been going on at intervals from the beginning to the end of the Silurian period, had now come to an end; the southern uplands had risen up, like a Jura, to the Alps. The Palæozoic land mass continued to extend on its south-eastern flank. The Devonian period introduced them in the greater part of Great Britain to an epoch of limited and exceptional deposits, and of widely prevalent terrestrial conditions. It seemed almost certain that the old red sandstones of Scotland and Wales were of fresh-water origin. In one case, the old red sandstone of North-East Scotland, they might perhaps discern in the Great Glen some indication of the old river course. The Scottish old red sandstones were obviously the detritus of the Highland mountains—then probably a far grander and loftier chain. At this time marine conditions prevailed in the south of England. The sea appeared to have deepened towards the south. Probably the Brito-Scandinavian Peninsula curved round to the east so as to include some part of Brittany. Prof. Bonney then referred to the formation of the carboniferous limestone, and traced briefly the geological history of these islands, and he concluded by saying that the brief sketch he had given might suffice to indicate that in this search for "Atlantis through the microscope" they might find it very near at hand, and might discover analogies, as had been indicated in the president's address, between the two borders of the ocean which severed Europe from America. The facts which he had brought before them had justified, he trusted, his opening remarks as to the rich harvest which yet awaited investigations into the structure of the fragmental rocks. The land of promise stretched far away from beneath their feet, till it seemed to melt into the dim and as yet unknown distance. Not speedily would its riches be exhausted. Their hands would long have vanished, their voices would long have been still, before the work of discovery was ended, and men have reached the shore of that circumfluent ocean which, at least in this life, limits their finite powers.

THE ADDRESS IN BIOLOGY.

The address in Section D was delivered by Mr. W. Carruthers, F.R.S., F.L.S., the president of the section. The following is extracted from it:—The literature of science is of little, if any, value in tracing the history of species and in determining the modification or the persistency of characters which may be essential or accidental to them. If help could be obtained from this quarter botanical inquiry would be specially favoured, for the literature of botany is earlier, and its terms have all along been more exact than in any of her sister sciences. But even the latest descriptions, incorporating as they do the most advanced observations of science and expressed in the most exact terminology, fail to supply the data on which a minute comparison of plants can be instituted. But the means of comparison which we look for in vain in the published literature of science may be found in the collections of dried plants which botanists uave formed for several generations. The local herbaria of our own day represent not only the different species found in a country, but the various forms which occur, together with their distribution. They must supply the most certain materials for the minute comparison at any future epoch of the then existing vegetation with that of our own day. The preservation of dried plants as a help in the study of systematic botany was first employed in the middle of the 16th century. The earliest herbarium of which we have any record is that of John Falconer, an Englishman, who travelled in Italy between 1540 and 1547, and who brought with him to England a collection of dried plants fastened in a book. This was seen by William Turner, our first British botanist, who refers to it in his "Herbal," published in 1551. No collection of English plants is known to exist older than the middle of the 17th century. A volume containing some British and many exotic plants collected in the year 1647 was some years ago acquired by the British Museum. Towards the end of that century great activity was manifested in the collection of plants, not only in our own country, but in every district of the globe visited by travellers. The labours of Ray and Sloane, of Petiver and Plunkenet, are manifest, not only in the works which they published, but in the collections that they made, which were purchased by the country in 1759, when the museum of Sir Hans Sloane became the nucleus of the now extensive collections of the British Museum. The most important of these collections in regard to British plants is the herbarium of Adam Buddle, collected nearly 200 years ago, and containing an extensive series which formed the basis of a British flora that, unhappily for science, was never published, though it still exists in manuscript. Other collections of British plants of the same age, but less complete, supplement those of Buddle. These various materials are in such a state of preservation as to permit of the most careful comparison with living plants, and they show that the two centuries which have elapsed since their collection have not modified in any particular the species contained in them. The early collectors contemplated merely the preservation of a single specimen of each species; consequently the data for an exhaustive comparison of the indigenous flora of Britain at the beginning of last century with that of the present are very imperfect, as compared with those which we shall hand down to our successors for their use. The most important materials, however, for the comparison of former vegetation of a known age with that of our own day have been supplied by the specimens which have been obtained from the tombs of the ancient Egyptians. The recent exploration of unopened tombs belonging to an early period in the history of the Egyptian people has permitted the examination of the plants in a condition which could not have been anticipated. And, happily, the examination of these materials has been made by a botanist who is thoroughly acquainted with the existing flora of Egypt, for Dr. Schweinfurth has for a quarter of a century been exploring the plants of the Nile valley. The plant-remains were included within the mummy wrappings, and, being thus hermetically sealed, have been preserved with scarcely any change. By placing the plants in warm water, Dr. Schweinfurth has succeeded in preparing a series of specimens gathered 4,000 years ago, which are as satisfactory for the purposes of science as any collected at the present day. These specimens consequently supply means for the closest examination and comparison with their living representatives. The colours of the flowers are still present, even the most evanescent, such as the violet of the larkspur and knapweed, and the scarlet of the poppy; the chlorophyll remains in the leaves, and the sugar in the pulp of the raisins. Dr. Schweinfurth has determined no less than 59 species, some of which are represented by the fruits employed as offerings to the dead, others by the flowers and leaves made into garlands, and the remainder by branches on which the body was placed, and which were inclosed within the wrappings. After a further discussion of the character of these remains of the flora of Egypt, Mr. Carruthers referred to the deposits discovered at Cromer, and the remains which exist of pre-glacial flora, and came to the conclusion that the various physical conditions which necessarily affected these species in their diffusion over such large areas of the earth's surface in the course of, say, 250,000 years, should have led to the production of many varieties, but the uniform testimony of the remains of this considerable pre-glacial flora, so far as the materials admit of a comparison, is that no appreciable change has taken place.

THE ADDRESS IN GEOGRAPHY.

The address in Section E was delivered by Major-General Sir F. J. Goldsmid, president of the section, who said:—The place which geography holds among school studies is not that which it ought to hold if its uses were understood and appreciated. Primers and elementary books already published are good enough in their way, but the instruction they contain is not seriously imparted; and it may be that something fitter and more attractive to the beginner could be produced. At present all school books on geography may be said, as a rule, to be consigned to the shelf of secondary subjects; and this is not the treatment which should be reserved for a study of such real magnitude. As a matter of State or public school education the science of geography should, in truth, be elevated, not degraded. In my humble opinion, it should be placed

on a par with classics, mathematics, and history, with each and all of which it has affinity. Undoubtedly there are accomplishments which come, as it were, of themselves, or are the outcome of lightly-sown seeds in the home. These for the most part are rather mechanical than mental, though some may have advocates to claim for them intellectual honour. But a knowledge of geography is not to be so acquired; it will not come, like handwriting, with incidental practice, nor is it to be gained by mere travelling. After dwelling at some length on the deficiencies in geographical teaching in our schools and universities and reviewing the efforts for its improvement made by the Royal Geographical Society, and certain provincial societies, Sir F. Goldsmid advocated the partial fusion under one professor in our universities of the two departments of history and geography, a practice which, till recently, prevailed in France and Germany. The president then gave a long account of the work done by travellers, the particulars of which have been made known during the past year.

THE ADDRESS IN ECONOMIC SCIENCE AND STATISTICS.

The address in Section F, which was presided over by Mr. J. B. Martin, M.A., dealt mainly with political economy as a science, and with statistics in connection with town and country life. Thus Mr. Martin said: We need not despair of the future of political economy, and acquiesce in its relegation to a distant planet, because its teaching, based too often on *à priori* reasoning, and too little on the experience of history, does not always square with the actions of men, warped in their judgment of any particular problem of the day by prejudice or self-interest. May we not claim that political economy has rather taken up wider ground than, as has been said by a recent writer, that it has abandoned many of its outworks. It is no reproach to economic science to have done so, to have recognised as matters within its proper scope considerations that the older economists, concerning themselves with wealth in its narrow sense as the summum bonum, and with the desire for its acquisition as the one mainspring of human action, would have rejected as sentimental or philanthropic. Humanity is many-sided, its units do not lend themselves to grouping or combination with the precision of mathematical symbols, and the experiments of the social philosopher are subject to disturbances unknown in the laboratory of the chemist. It is at this point that the statistical method comes in as an inseparable ally of economic speculation. If the latter has had from time to time, and still has, to assert its position among the sciences, what place shall be assigned to the method, which is only too often assumed to be the mere massing and grouping of figures? It has been said—and the saying is not altogether devoid either of truth or humour—that "statisticians when they meet together devote half their time to discussing the status and dignity of their pursuit, and its precedence of, or subservience to, economics." The vulgar misuse of the word "statistics" has no doubt contributed, in many cases, to ambiguity in its use. The extreme instance need perhaps hardly be mentioned when "statistics" are used simply as equivalent to "figures"; one may read or hear even this expression, "You can prove anything by statistics." To say that you can prove anything by figures is intelligible; just so can you prove anything by a syllogism with a faulty premiss, or that might is right by the law of the stronger. But apart from cases in which false figures do not tell the truth—I do not say false statistics, for to speak of false statistics appears to me to be very nearly a contradiction in terms—there is the much more frequent class of cases in which they do not tell the whole truth.

THE ADDRESS IN MECHANICS.

The address in Section G was delivered by Sir James N. Douglass, M.Inst.C.E., the president of the section. It consisted of an historical account of the erection of lighthouses, and of the development of the use of light vessels, beacons, buoys, &c. The following is extracted from it:—Ancient lighthouses were erected on prominent parts of coasts beyond actual attack by the sea, and in many instances they were at considerable distances from navigable water, and thus, with their feeble and uncertain wood or coal fires, they were far from efficient as aids to mariners. So slow was the development in lighthouse illumination for many centuries, that, so recently as 1822, the last beacon coal fire in this country was replaced by catoptric oil light apparatus at Saint Bees Lighthouse, on the coast of Cumberland. With Winstanley's structure on the Eddystone in 1696 might be said to have commenced the modern engineering efforts "in directing the great sources of power in nature for the use and convenience of man": efforts which, followed up by Rudyerd, Smeaton, the Stevensons, and others, had since been so successful in converting hidden dangers into sources of safety, and insuring the beneficent guidance of the mariner in his trackless path. These works of modern mechanical science were now to be found around all the nautical centres of civilisation and commerce, and were very numerous. During the last century a very considerable increase had occurred in the number of lighthouses and light-vessels on the various coasts of the world, which had been required to meet the rapid growth of commerce. Only during the last twenty-five years could accurate statistical information be obtained, and it was found that in 1860 the total number of coast lights throughout the world did not exceed 1,800, whereas the present number was not much less than 4,000. Japan, which had not a single coast light in 1860, now has 57, eight of which are of the first class. The United Kingdom in 1885 had 655 lighthouses and 72 light-vessels, while the United States, which comes next in order, had 458 and 22 respectively, many light-vessels having been abolished when permanent lighthouses were erected. Concurrently with the enormous increase in the number of coast lights during the last fifty years very great improvements have been effected from time to time in their efficiency. In 1759 Smeaton's lighthouse on the Eddystone was illuminated by twenty-four tallow candles, weighing 2-5lb. each. The intensity of the light of each candle was about 2·8 candle units each; thus the aggregate intensity of radiant light from the twenty-four candles was only about 67 candle units. No optical apparatus, moreover, was used for condensing the radiant light of the candles, and directing it to the surface of the sea. The consumption of tallow was about 3·4lb. per hour; therefore the cost of the light per hour, at the current price of tallow candles, would be about 1s. 6¾d., sufficient to provide a mineral oil light, at the focus of a modern optical apparatus, to produce for the service of the mariner a beam of about 2,400 times the above-mentioned intensity. The introduction of catoptric apparatus for lighthouse illumination appeared to have been first made at Liverpool about 1763, and was the suggestion of William Hutchinson, a master mariner of that port. The invention of Argand, in 1782, of the cylindrical-wick lamp provided a more efficient focal luminary than the flat-wick lamp previously employed, and was soon generally adopted for both fixed and revolving lights. In 1825 the French lighthouse authorities effected another very important improvement in lighthouse illumination by the introduction of the dioptric system of Fresnel in conjunction with the improvements of Arago and Fresnel on the Argand lamp, by the addition of a second, third, and fourth concentric wick. Coal and wood fires, followed by tallow candles and oil, had been referred to as the early lighthouse illuminants. In 1827 coal-gas was introduced at the Troon Lighthouse, Ayrshire, and in 1847 at the Hartlepool Lighthouse, Durham, the latter for the first time in combination with a first-order Fresnel apparatus. The slow progress made with coal-gas in lighthouses, except for small harbour lights where the gas could be obtained in their vicinity, was chiefly due to the great cost incurred in the manufacture of so small a quantity as that required and at an isolated station. After some remarks on buoys, &c., Sir J. Douglass referred to the recent experiments on the use of gas, oil, and electricity for lighthouses, and concluded by asserting that now the relative merits of electricity, gas, and oil had been accurately determined, the investigations of the Trinity House Committee would, for many years to come, furnish to the lighthouse authorities of all maritime nations of the world, and their engineers, valuable data which could not fail to assist largely in the development of lighthouse illumination, and thus tend materially to the present aids to navigation, and to a consequent reduction in the loss of life and property at sea.

THE ADDRESS IN ANTHROPOLOGY.

The address in Section H was delivered by Sir George Campbell, M.P., the president of the section, who said he took for his subject practical rather than scientific anthropology—the study and cultivation of the creature man as he exists, rather than that branch of the subject which sought to inquire into his origin and development. Intensely interesting as were such inquiries, their knowledge on the subject was still very limited, and their progress slow; they had not got hold of the missing link, and scarcely knew whether the flint instruments were the work of man or of some earlier intelligent creature. They were hardly on firm ground until they came to man very much in his present form, and even already divided into the principal varieties which exist to this day. He invited them to approach the subject rather as practical agriculturists dealt with the subject of horses and cattle than as scientists who traced these animals to very ancient prehistoric types. It could hardly be doubted that, in distinguished well-marked types of humanity, the eye was perhaps, after all, the easiest and safest guide. On the other hand, when they came to nicer and more subtle distinctions, especially among the mixed races which occupy most of the world, they must confess that anthropometric science as applied to craniology, &c., gave them results only partially conclusive. So again as regarded other guides to race. It was admitted that language was not always a safe guide, but still it was a very important element in ethnological inquiries, especially among primitive races; and having paid some attention to that his impression was strong that language tests of race were to be found in the few simple elementary words and forms which any observer could easily master and examine, and not in the higher developments of the language, which were generally much intermixed with and influenced by foreign elements. There was another race-guide which required much care and some scientific accuracy, though not of what they should call a properly anthropometric character—he meant laws, customs, and habits. These were at least as persistent as, perhaps more persistent than, language. Among other habits and institutions well worthy of observation were marriage and the family descent, through the female or through the male, the forms of small self-governing communities, and the tenure of land. Animals of nearly allied species seemed to be divided by curiously sharp lines into polygamous and monogamous races, and they had yet to discover to which class man belonged before laws divided the race into two opposite camps in this matter. And what could be more important than to ascertain the effect on the race of modern urban life, of the increased use of meat, of the diminished use of milk, of the enormously increased consumption of tea, of the more constant use of the eyes and the brain, viewing these subjects in their broad general results, rather than from a merely medical point of view? It might be admitted that they were not in a position to begin confident man-culture at once. Much study was first required and much knowledge must be accumulated before they could be confident in practice. The first thing that struck them in man, as compared to all domesticated and even most widely-spread wild animals, was the extremely small variation in man all over the globe. There were differences which seemed large to them, but were extremely small from a more enlarged point of view. How enormous were the differences between different breeds of dogs, horses, and cattle! When they came to man the difference of which they made most was that of colour—a feature which they thought quite trivial in animals. Their skilled eyes recognised variations of human feature, but they were so slight that the inhabitant of another planet would see no more difference than in the countenances of a flock of sheep. In size, compared to other animals, the differences were but slight. Then, as regarded the mind, they had yet to learn that there were very wide differences of mental capacity between different races. Very likely—probably, he might say—there are considerable variations, but they are not so wide as to be apparent without careful and accurate study. With the superficial knowledge they had, no one could say that Europeans, Hindus, Chinese, were born with brains superior or inferior to the other; and even in regard to the negro he did not know that it was yet shown that with equal advantages negro babies might not grow up nearly or quite as intelligent as Europeans. Both the general knowledge they had of humans and the analogy of animals tended to show the great benefit of the crossing of breeds. Using the word English for the Teutonic inhabitants of these islands, one could hardly doubt that the English breed crossed with a dash of Celtic blood produces a better animal than either of the parent races. Witness the people of many parts of Scotland, of Ulster, and he believed he might almost say of Cornwall.

ABSTRACTS OF REPORTS PAPERS, &c.

Standards of Light.

Prof. George Forbes presented the report of the committee on standards of light. The committee had met repeatedly during last summer. It had been proposed in last year's report to carry on experiments on electrical standards in the hope of arriving at an absolute standard of light. One of the first steps was to discover a means of reproducing a definite temperature, and certain experiments were proposed for this purpose. At one of the first meetings of the committee Capt. Abney announced that he had already found a means of doing this in a different manner to that proposed in the committee's report, and depending only upon the change of resistance of the carbon filament. Under these circumstances the committee left this part of the experimental investigation to be reported upon by Capt. Abney. His further researches had, however, led him to believe that the law which he had announced to the committee did not hold with all qualities of carbon filament. He had, however, been engaged upon further experimental researches, which were almost ready for publication, and which had an important

bearing upon the labours of the committee. In last year's report attention was drawn to the value of the Pentane standard of Mr. Vernon Harcourt as a practical reproducible standard, and Mr. Rawson had been since then engaged in a further examination of that standard. Sir James Douglass had also made some experiments which were not quite complete, but had gone so far as to give great promise. Some account of the experiments in that report had been expected by the committee, but the absence of Sir James Douglass on official business had interfered with this. At one of the first meetings of the committee the secretary showed what he had done in the way of improving thermopiles such as it was hoped would be of use in the investigations recommended in last year's report, and he was instructed by the committee to proceed with the construction of the instrument, which had been completed, and was now to be placed before the section and described in a separate paper. The committee requested to be reappointed, with a grant of £25. The instrument is a combination of a thermopile and a galvanometer, and opinions were expressed by Lord Rayleigh, Lord Rosse, and Professor Fitzgerald on it in comparison with the bolometer.

The Action of Glass upon White Light.

Lord Rayleigh gave an address on "The Intensity of Reflection from Glass and Other Surfaces." He explained an apparatus which was intended to measure the amount of light reflected from glass surfaces. The amount of light reflected from a glass surface was compared with the amount transmitted by a black disc perforated with an aperture of known angular magnitude. It was found that the result depended very considerably upon the state of the glass as regards polish, the repolishing greatly aumenting the intensity of the reflected light.

Sir J. Conroy submitted "A Note on Some Observations of the Loss which White Light Suffered in Passing Through Glass." He said the experiments were made to determine the amount of light absorbed by glass, and also the amount reflected at perpendicular incidence. It was thought that by taking plates of the same kind of glass, not of different thickness, both these quantities could be calculated directly from the observations without assuming the truth of the formulæ for reflection. The amount reflected from the first surfaces would be the same, whilst that reflected from the second surfaces of the plates of glass would differ but slightly, since the amount absorbed or scattered by the glass being small, the quantity of light which reached the second surfaces would be nearly the same in all. Hence by determining the amount transmitted by two plates of the same kind of glass differing in thickness only, the amount absorbed or scattered by a thickness of glass equal to the difference between the two plates would be given to a first approximation at least. A photometer was used, and two white surfaces so placed that whilst both were visible to the observer, one only was illuminated by the light from each of the mirrors. The observations were made by determining the distance at which the movable screen had to be placed from the lamp in order that it and the fixed screen might appear equally bright when both were seen distinctly, and when one was seen directly and the other through one of the plates of glass. As the apparent brightness of a surface does not vary with its distance, no connection was needed in this case for the effect produced by the glass. Experiments were made with Messrs. Chance's "lighthouse" and with ordinary dense flint. The refractive indices of the two kinds of glass were: Messrs. Chance's glass, 1·5145; dense flint glass, 1·6330. The percentage amount of light from the first surface was for Messrs. Chance's glass 4·187, and for the flint glass 5·779. Assuming that the same percentage of light is reflected from the second surface, and neglecting the small difference produced in the amount so reflected by the absorption of the glass, of the light thrown upon the surfaces 91·80 per cent. should escape reflection with Messrs. Chance's glass and 88·77 per cent. with flint glass. The thinnest plates of the two kinds of glass transmitted respectively 91·50 and 88·83 per cent. of light, or assuming the truth of the formula and the correctness of the operations there was practically no absorption with these kinds of glass, a supposition which the decrease in the amount of transmitted light as the thickness of the plates increase manifestly contradicted. These experiments appeared to show that with Messrs. Chance's glass about 2·5 per cent. was absorbed or scattered per centimètre, and with the flint glass about 12 per cent. The determinations having been made with gaslight their value would probably be slightly different with daylight. The experiments are still in progress.

Freezing as an Aid to the Sinking of Foundations.

A paper on this subject was read by Mr. O. Reichenbach. After referring to the extended use that has been advantageously made of caissons as a means of founding the supports of bridges at great depths, especially in India over the Sutlej and Ganges, the author referred to the difficulties experienced when, adopting this method, obstructions or boulders are met with far below the surface, or where the piers are finally founded on rock of an uneven surface. Whereas piers have been founded at depths of 140ft. below water level by this method, the pneumatic method, to which preference was given in the case of the St. Louis Bridge, over the Mississippi, is limited in its application to depths of about 120ft. The method of freezing the ground in sinking foundations was patented some years ago by Mr. F. Poetsch, a well having been sunk in this manner as early as 1862. It consists in freezing the water contained in the surrounding ground; and thus providing a watertight lining, which enables the necessary excavations to be carried out without difficulty. Calculations showed that, to take an imaginary case, the freezing of the ground to sink a pier 60 mètres below water level, and 40 mètres below the river bed, and having a base 18 by 8 mètres, would occupy 2,250 hours, and require a cooling effect equivalent to 2,230 cubic mètres (or tons approximately) of ice. About 2,900 cubic mètres of ground would be frozen in the operation.

On the Laffitte Process of Welding Metals.

Mr. William Anderson, M.Inst.C.E., read a paper on this subject, in which he pointed out that in order to make a sound weld it is necessary that the surface of iron should be free from oxide, and that the usual mode of approximating to this condition is to heat to the "welding" heat—about 2,800° F. So high a temperature, however, impairs the quality of iron and, to a far greater extent, of steel. Many qualities of steel cannot be welded. In order to overcome these difficulties, powders, with borax as a basis, are generally employed. With a view to overcome the difficulties experienced in spreading these powders evenly over surfaces, often irregular and of considerable extent, M. Laffitte has invented plates, usually consisting of very pliable wire gauze, on both sides of which the flux, being vitrified, is evenly spread. Paper may also be used as a support, and in the case of small surfaces it is often sufficient to form a sheet of the flux and metal filings agglomerated together. After describing the method of preparing the plates and various modes of applying them, the author mentions that they have a very extensive use in France for all branches of metal work, including fancy ironwork, and in the arsenals, gun factories, and on the railways, &c.

Measurement of an Electric Current.

Prof. James Blyth explained a new form of current-weigher for the absolute measurement of an electric current, which he had devised. The method was by measuring in grammes the electromagnetic force between two parallel circular circuits, each carrying the same current. For convenience of calculation circles had the same radius, and were placed with their planes horizontal. The construction of the instrument was as follows:—A delicate chemical balance is provided, and the scale-pans replaced by two suspended coils of wire. Each of these is made of a single turn of insulated copper wire (No. 16 about) fixed in a groove round the edge of an annular disc of glass or brass of suitable diameter. The disc is made as thin and light as possible consistently with perfect rigidity. By means of two vertical pillars of brass this annulus is attached to a rigid cross-bar of dry wood or vulcanite, in the middle of which is placed a hook for suspending the whole from one end of the balance beam. On each side of the hook, and equally distant from it, two slender rods of brass are secured into the wooden bar, which support two small platinum cups for holding mercury or dilute acid. The position of these cups is so adjusted that when the whole hangs freely the cups are in line with the terminal knife-edge of the balance beam, and have their edges just slightly above its level. The free ends of the insulated wire surrounding the disc, after being firmly tied together for a considerable length and suitably bent, are soldered to the brass supports of the platinum cups, which thus serve as electrodes by means of which a current can be sent through the suspended coil. A precisely similar coil is suspended from the other end of the balance-beam. The speaker then went on to explain the arrangement by means of which a current was led through the suspended coils so as to interfere as little as possible with the sensibility of the balance.

A New Calorimeter.

Mr. T. J. Baker gave a description of a new calorimeter for lecture purposes. The instrument consists of two exactly similar metallic air thermometers, mounted side by side, with their U-shaped thermometer tubes adjacent, so that their indications can be easily compared with each other. The air vessel of each thermometer contains a cylindrical well, in which the substance to be experimented with is immersed. Each well is provided with a discharging tube furnished with a stopcock. The scale common to both thermometers is of milk-glass, divided into 100 equal parts, both above and below zero, and let in to the stand so as to constitute a translucent window which can be illuminated from behind. By means of this instrument many thermal problems can be demonstrated before a large audience.

Girder Bridges.

Mr. W. Shelford, C.E., and Mr. A. H. Shield, C.E., contributed a paper upon "Some Points for Consideration of English Engineers with Reference to the Design of Girder Bridges." The writers affirmed that a general comparison of English, German, and American bridges, with especial reference to the class of work adapted to newly-developed countries, afforded sufficient grounds for the examination of the English practice. This examination was limited in the paper to bridges of moderate span, which, on account of their number, were of greater economic importance. The results of a comparison of typical designs for bridges of 140ft. span were given, and it was stated that the difference between the weight of good designs of the same depth was comparatively small, while the principle that economy was obtained by increasing the depth obtained to an extent which, if recognised in theory by English engineers, had not hitherto found general expression in their practice. This was, however, partly due to external conditions, and it did not appear that there were essential national errors or prejudices in design which were likely to place English engineers at a disadvantage in colonial work. The difference between the position of the designer in America and England was investigated, with the result that, while the advantages of the English system in the interest of security were admitted, it was found to be attended with disadvantages with respect to economy, for which the publication of details of comparative cost of different methods of construction and the adoption of standard sections for rolled iron were suggested as partial remedies. The scientific and commercial interests of engineering called for the abolition of the Board of Trade rules which determined fixed limits of working stress, unless they could be brought into conformity with modern knowledge of the properties of materials and the laws of construction. The objections to their abolition, although it would open the investigation of the subject to private enterprise, were pointed out, and the construction of new rules was suggested; such rules, while preserving the freedom of the engineer in the choice of design and material, and leaving to him the estimation of all those effects of loading a structure which were capable of determination by known methods, should determine for his guidance by coefficients of safety the provision to be made separately for each of the effects which were usually understood to be covered by an arbitrary factor of safety. It was suggested that the construction of such rules would be more worthy of the professional attainments of English engineers, and would be designed to raise the standard of professional knowledge by avoiding the use of fixed coefficients of which the origin and scope were not known to the user, and to encourage good workmanship and the use of materials of a high class by varying the working stress according to the quality of the materials employed. The revival of the Royal Commission of 1847, to effect for wrought iron and steel what was then done for cast iron, was indicated as the best means of obtaining the necessary data for the construction of rules with these objects.

The Nature of Solutions.

Several papers were read having more or less reference to the nature of solutions, amongst which may be noticed the report of a committee consisting of Profs. W. L. Goodwin, and D. H. Marshall, of Queen's University, Kingston, Ontario, read by Prof. Ramsay, in which it was stated that the object of the research was to determine the condition of equilibrium assumed by molecular weights of two salts placed in separate small vessels with a weighed quantity of water. The water is attracted to the salts by the process of invaporation. The salts so far used are sodic, potassic, and lithic chlorides. The salts were carefully dried and washed out in small test tubes. The water was weighed out in a similar tube, and divided between the salts, in the case of sodic and potassic chlorides about half to each, and in the case of sodic and lithic chlorides the greater part to the latter. A little water was always left in its tube, and the three tubes were sealed up in a larger tube. After the water became quite dry the inclosing tube was opened and the three smaller tubes weighed. They were then sealed up again, and examined once more after a certain time. The examination was repeated until it was found that no change took place in the weights of the two tubes containing the salts. Three experiments were made with sodic and potassic chlorides, varying the relative

quantity of water. It was found that sodic chloride invaporates water more powerfully than potassic chloride, and that, at least with small relative quantities of water, the sodic chloride invaporates nearly all, leaving the potassic chloride almost dry. Comparing this with the state of equilibrium assumed by equivalents of caustic soda, caustic potash, and sulphuric acid in solution together, it seems that the force in the first case is of a different nature from that acting in the second. In a fourth experiment the relative quantity of sodic chloride was doubled, with the effect of hastening the completion of invaporation. The sodic chloride took all the water. Three experiments were made with sodic and lithic chlorides, varying the relative quantities of water. With small relative quantity of water the lithic quickly attracted the whole; but, with a largely relative quantity (16 molecules of water to one of each of the salts), the sodic chloride attracts part, showing that here is a limit to the quantity of water which the lithic chloride can hold against the attraction of sodic chloride. The general conclusion is that when the relative quantity of water is small it is not divided between the two salts in the ratio of their attractions for water, but this may be the case with large relative quantities of water.

Prof. Tilden read a paper on "The Nature of Solution." There were two theories held—one that solution arose from chemical combination between the solid and the liquid in which it was dissolved, and the other that it was merely a process of mechanical adhesion. He had studied the thermal phenomena with the object of seeing how far it was true that evolution of heat indicated chemical combination. The majority of solids and nearly all the salts expanded on being melted, but at what point chemical action ceased and mechanial action began he thought it was impossible to say, as the thermal changes and the volume changes were all continuous. He could not formulate a definite statement to explain why salt or sugar dissolves in water. The chief lesson he had learnt was that, practically speaking, they could not distinguish chemical combination from other forms of combination. He was inclined to believe that chemical combination differed in no respect from adhesion or cohesion, except that the atoms come together very much more closely and in a more intimate manner.

Prof. Ramsay read a paper prepared by himself and Dr. Young on "The Nature of Liquids." All liquids, dissociable or stable, showed an increase in the density of their saturated vapours above a certain pressure and temperature, differing of course for each liquid. Some liquids, known to be dissociable into simple molecules, showed an increase both on rise and fall of temperature and pressure, above and below a certain temperature and pressure peculiar to the liquid. It was known that a high temperature favoured dissociation; hence it might be expected that the increase of the density of the saturated vapour universally observed at high temperature should be explicable, not on the hypothesis that such high pressures promote combination, because the corresponding high temperature would be extremely unfavourable to combination, but on the theory that, in spite of the tendency of the high temperature to separate the molecules from each other, they were nevertheless forced into close proximity by the corresponding high pressure. On the other hand, a low temperature was known to favour stability; hence bodies consisting of molecules capable of chemical combination with each other, such as nitrogen, peroxide, and acetic acid, might be expected to give, as they did, evidence of such combination at low temperatures, in spite of the corresponding low pressures. It was impossible to conclude that the same effect should be produced under such totally opposite conditions by the same cause. The molecules of stable liquids exhibited physical attraction, not chemical attraction; the molecules of dissociable liquids exhibited, *qua* liquids, physical attraction, but they also exhibited chemical attraction, inasmuch as they tended to unite in pairs, or perhaps in simple groups.

The Glacial Formations of the Midlands.

Dr. Crosskey read a paper on "The Glacial Formations of the Birmingham District," with which he incorporated a "report on the erratic blocks of England and Wales." The object of the paper was to point out typical sections and indicate the vast problems involved in the glacial geography of the Midland district. With regard to the question as to what are the lowest beds in the Midlands of the glacial age and where is to be found at the base of the masses of clay, sand, and gravel freely scattered over the Midlands, the author mentioned that the best section of the Midland series that had been exposed was at California. At the base was a thick ice-formed clay, with striated blocks, followed by sands and gravels, and a thick upper clay with erratics dropped into it. The California lower boulder clay differed from the Wolverhampton boulder clay. At Wolverhampton Lake, blocks, Scotch granites, with a few flints had been found. It was a distinct type as containing a collection of erratics from several districts. Some of the contorted sands and clays of the district probably were deported at an early period in the glacial epoch, having been subsequently contorted. Passing on to the question of "Are there any glacial beds distinctly referable to the period of glacial subsidence?" he said that marine shells with Arctic species had been found in two localities, at Wellington and Lilleshall, supporting the theory that there must have been a Midland glacial sea. In Icknield-street, Birmingham, the rock was struck and smashed by ice laden with Welsh boulders. Owing to the subsidence of the land, blocks were floated off by the ice starting from the various points of a Birmingham land area. In consequence of the re-elevation of the land, blocks were floated off from various points in the ever-widening land area which was covered with ice during the later period. Rowley Hill, Charnwood Forest, Malvern Hills were centres of dispersion of their rocks.

The Rev. W. Tuckwell read a paper "On the Glacial Erratics of Leicestershire and Warwickshire." He referred at the outset to the evidence of a south-western dispersion of rock from Charnwood. In Stockton, a village midway between Leamington and Rugby, there was a mass of boulder clay containing abundance of Mount Sorrel granite, of so-called gneiss from Charnwood Forest, large decomposed "pockets" of red sandstone, blocks of grey sandstone highly glaciated, Bunter pebbles, flints, carboniferous limestone, and lias rock of a different texture from that native to the district. Lying loose in the village street of Stockton was a fine boulder from Mount Sorrel, glaciated, of nearly two tons weight. This had recently been inclosed and inscribed. After having described Mount Sorrel with the unmistakable character of its hornblendic granite, the author noted the extraordinary profusion of Mount Sorrel erratics as far as Leicester; at Rothley, Thurcaston, and Anstey. "Stone," or "Ston," was a suffix of nearly all the villages along the line. He further mentioned a special stone, the largest found in Leicestershire, near Humberston, estimated at twenty tons, partly imbedded in boulder clay which is filled with Bunter pebbles and rolled slate from Charnwood. Finally, he called attention to the reappearance of Charnwood stones north and south of Coventry, at Eathorpe, six miles south-west of Coventry, at Stockton, completing the evidence of a south-west stream from the Charnwood elevation throughout the two counties.

Striated Pebbles and Boulders in the Punjab Range.

Mr. A. B. Wynne, F.G.S., submitted a paper on "A Faceted and Striated Pebble from the Boulder Beds of the Olive Groups of the Punjab Salt Range." The author described this interesting specimen from the so-called glacial boulder beds of the Olive series immediately underlying and comformable with the Salt Range Eocene limestone, which was found by Dr. H. K. Warth last June, and transmitted to the writer quite recently. It consists of a reddish felsitic rock from the peninsular region of India, and it was inclosed in a group of boulder beds which contain one layer, with transported fossiliferous pebbles, inclosing *Conularia* and other fossils. The specimen, possessing twelve faceted sides, striated in different directions, must have undergone numerous changes of position, and been completely turned over in the process of grinding and polishing; and being only 2in. thick it cannot have been held with greater resistance than that afforded by the superficial 2in. of the ice mass in which it is supposed to have been imbedded or fixed from time to time.

Mr. W. T. Blandford, F.R.S., read "Notes on a Smoothed and Striated Boulder from a Pretertiary Deposit in the Punjab Salt Range," remarking that this block of stone, like that exhibited by Mr. Wynne, was obtained by Dr. Warth at Chel Hill in the Punjab Salt Range. It consists of a purplish-brown porphyry, apparently an altered felspar porphyry. The boulder is subangular, the two principal surfaces being plane, smooth, finely striated, opposite to each other, and nearly, but not quite, parallel. Each of these surfaces is bevelled off on one edge by a number of smaller facets, meeting the principal surface and each other at very obtuse angles. Besides the larger plane surface, there are on one side five smaller smoothed facets, and on the other two, but one in each case is ill-marked, the angle at which it meets the next surface being so obtuse as to be with difficulty recognised. All the smoothed surfaces on one side are striated in the same direction; those on the other side are striated similarly to each other, but diversely to those on the opposite surface of the block. Those surfaces of the block that are not smoothed are somewhat rounded.

The Cambrian Rocks of the Midlands.

Prof. C. Lapworth read a paper on this subject, remarking that about eight miles to the south of Birmingham there rises the remarkable ridge of the Lower Lickey Hills. The core of this ridge is made up of remarkable rock known to geologists as quartzite. By the earlier geologists this rock was believed to be the oldest in the district, but by Sir R. Murchison and his followers it was believed to be a metamorphic rock of Silurian age. It has been discovered, within the last few years, by Prof. Lapworth and Mr. T. Houghton, M.A., F.G.S., that this quartzite is actually of Cambrian age, rising out of the Silurian and resting upon older volcanic rocks of unknown date. The age of the quartzite is demonstrated by further discoveries, originally made by Mr. Lapworth and Mr. Harrison, among the rocks in the neighbourhood of Nuneaton. In the early survey maps of the district the quartzite of Hart's Hill, well known as the chief road metal of the Midlands, together with underlying series of shales, the Stockingford shales, were laid down as the lower part of the local carboniferous system. These observers have demonstrated that the two formations are actually of Upper Cambrian age, the shales containing in abundance the characteristic fossils of that epoch, and being underlaid, like the Lickey quartzite, by a volcanic series of much greater antiquity seen in Caldecote Hill. These fossils give us a means of fixing the exact geological age of the beds. They correspond very closely with those of the Tremadoc slates of Malvern, Wales, and Scandinavia. The carboniferous has also been proved to overlie these old rocks, and these new discoveries enable us to parallel the coal measures of East Warwickshire with those of South Staffordshire, division for division, and render it exceedingly probable that the Staffordshire thick coal is continuous under the red rocks of Sandwell and Hawkesbury. The igneous rocks of Caldecote seem to be parallel with those of the Wrekin and Charnwood. All the remarkable intrusive igneous rocks of this region are now known to be of a date long anterior to the carboniferous age. These new discoveries make it highly probable that the upper carbonian beds of Shropshire, the Wrekin, the Malverns, and Nuneaton were once continuous, and open an entirely new chapter in the history of British geology.

SOAP BUBBLES.

THE Friday evening discourse during the meeting of the British Association was delivered by Prof. Rücker, M.A., F.R.S., who took for his subject "Soap Bubbles." The lecturer commenced by stating that the curious and beautiful phenomena displayed by soap bubbles had, at all events for many centuries, attracted considerable attention. In the Museum of the Louvre in Paris there was an Etruscan vase on which was depicted a group of children blowing bubbles. We thus learned not only that the sport was of considerable antiquity, but that the graceful attitudes of the children engaged in it suggested a fitting theme for artistic treatment alike to the Etruscan potter and to the Royal Academician of to-day. It would be strange if natural phenomena which had attracted such attention should have been passed over by those whose special duty it was to attempt to interpret nature, and as a matter of fact it had not been so. Scientific men had studied bubbles carefully, but in spite of this there were many points connected with them which were too imperfectly understood. The lecturer, therefore, made no apology for the apparent triviality of his subject, and made no attempt to cover the wide ground which the title indicated. He asked the attention of his audience while he dwelt for the most part upon one, and one only, of the most interesting but least studied peculiarities of soap films. He need hardly remind them that the explanations of the colours of soap films was one of the triumphs of the theory of light. That explanation had now become one of the commonplaces of science, and applied not only to soap films, but to other phenomena, such as those to be exhibited by Professor Roberts-Austen next evening. He wished, however, to impress upon his audience at the beginning that the colours of films not only enabled us to measure their thickness, but within certain limits afforded us a very accurate measure of their thickness. The thickest soap films were so thin that it was convenient to employ a very small unit of length in measuring them. He therefore chose the millionth of a millimètre, or the twenty-five millionth part of an inch, and said he would express the magnitudes with which he would have to deal in terms of that unit. The thick soap film displayed no colours, and it might be said that the first tints were seen when its thickness was, in round numbers, two thousand millionths of a millimètre. The colours succeeded one another in regular order, but at last the film became black. According to Newton, the point at which this took place was when the thickness of the film was thirty-six millionths of a millimètre; and thereafter, however thin the film might become, no further change in colour was exhibited. A knowledge of the colours

enabled the skilled observer to study the thickness of the film to within about 1 per cent., but this power failed when the film was either too think to display any colour or so thin that it displayed nothing but the black. In this case, however, as in many others, information became specially difficult to obtain just at the point when it was specially interesting. It was by the study of extremely thin films that we might expect to learn most with regard to the molecular composition of liquids. A liquid was held together by means of attractive forces in play between the particles of which it was composed. A particle within a liquid was surrounded by others upon all sides, and was therefore attracted upwards as well as downwards, to the right as well as to the left. But the particle in the surface had neighbours on one side only, and thus the attraction exerted upon it was on the whole downwards. It followed from this that, since particles in the surface and in the interior were acted upon differently by molecular forces, they would probably be differently arranged among themselves; and since the properties of a body depended not only on its chemical composition, but also on the arrangement of its particles, we should expect that the surface of the liquid would display phenomena of which the interior showed no trace. As a matter of fact it was so, and the liquid must therefore be regarded as consisting of two parts—the interior, throughout which the properties are uniform, and a very thin surface layer, in which the properties are somewhat modified. The soap bubble, therefore, if tolerably thick, must be regarded as composed of an interior and two surface layers. If it became so thin that the interior position drained away and the two surface layers met, we might then expect that it would display some novel phenomena from which instructive information as to the nature of molecular forces might be obtained. Now there was in connection with a film which displayed the black one phenomenon which seemed to show that a limit something like this had been reached. In general the colours of a film faded gradually the one into the other, proving that the thickness changed gradually from point to point. The edge of the black, however, was nearly always a sharp line, and the colour which came next before it was often such as to prove that there was a sudden and very great change of thickness between the black portion of the film and that with which it appeared to be in contact. In some cases the black was at least 55 times thinner than the film which touched it. Bearing these facts in mind, the lecturer and Prof. Ethos Reinold some time ago undertook the study of the black portions of soap films, and the first question which they set themselves to solve was to determine, if possible, what this thickness might be. In order to measure the thickness of the black film, they began by studying the resistance which liquid films offered to the electric current. If the ordinary laws held good in the case of such films, it was to be expected that the resistance would increase in the same proportion as the thickness diminished, so that if the thickness were halved the resistance would be doubled, and so on. There were many difficulties in proving that this law held good; but the experimenters succeeded in showing that it certainly did so as long as the thickness of the film was greater than about 400 millionths of a millimètre. Below that their experiments did not enable them to speak with certainty. It was very evident that if the law held good for greater degrees of tenuity, it would enable them to measure the thickness of a black film by measuring its electrical resistance, for if that resistance were a hundred times greater than that of a film so thick that its colour enabled them to measure its thickness, they would thus know that the thickness of the black film was a hundred times less. Pursuing this method two sets of experiments were made, which gave accordant results. The mean of the first proved that the black had a thickness of 11·9 millionths of a millimètre; the mean of the second that its thickness was 11·7 millionths of a millimètre. As it was very important to make certain that the assumption was really true that the law on which this calculation was based held good for films, the experimenters devised another and an independent way of measuring the thickness of a film by means of optical observation. The mean result was in complete accord with that previously obtained, being 11·5 millionths of a millimètre. It followed, then, that any theory which was to satisfactorily account for the properties of a surface of a liquid must explain, first, the sudden change in thickness at the edge of the black; secondly, the constant thickness of the black itself; and, thirdly, the fact that the thickness of the film in contact with the black might on different occasions be very different. To explain this the lecturer discussed he properties of the surfaces of liquids. He showed in the first place that the viscosity of the surface was often very different from that of the interior, a fact which was illustrated by experiment. He then showed by other experiments the well-known fact that the surface of a liquid is in a state of tension—that is, like a blown-out bladder, which tends to contract. It had generally been supposed that if a film became so thin that all the interior liquid drained away, and the two surface layers began to intermingle, the surface tension would diminish; and many experiments had been made to attempt to obtain indications of this expected decrease in the surface tension. The result of these observations had been to prove that no such change could be detected; but as all such experiments had been made on comparatively thick films the lecturer and Prof. Reinold had recently extended them to the case of films thin enough to show the black. In doing this they had the authority of Maxwell to support the view that much might be learned by such methods as he said in his article on "Capillarity" in the "Encyclopædia Britannica," that measurements of the tension of the film, when drawn out to different degrees of thickness, might possibly lead to an estimate of the range of the molecular forces. The lecturer described the difficulties with which the investigation was beset, but stated that the final result arrived at was that if the black part of the film formed steadily, spreading quietly over the remainder of the surface, no change of surface-tension could be detected, and calculation showed that their experiments would have enabled them with certainty to detect a change of a half per cent. Sometimes, however, the black part of the film formed with great rapidity; and though it was impossible to secure that this state of things should take place at a given time, yet on the few occasions when the experimenters were able to make observations they found that the formation of the black in this way was accompanied by a change of surface-tension. They had further proved a very curious fact—that if an electric current were passed through a soap film it would apparently carry the liquid with it, so that if it was sent up the film it thickened it, and if sent down the film thinned it. By sending the current up a film which was partly black and partly coloured they found that they could obliterate the sharp edge of the black; but that when the current was removed the sharp edge in the course of a few seconds was formed again. The general result of these experiments was to show that when the film was a little thicker than the black there was an unstable thickness which could not permanently last, and that if the film were by means of the current forced to assume that thickness, it immediately on the removal of the current became thicker and thinner, and the thick and thin parts apparently were in direct contact. The forces which produced this change were certainly less than 2 per cent. of the surface-tension, probably less than a half per cent.; and the viscosity of the film permitted the effect of the complete separation of the thick and thin parts to take place in a few seconds. It remained then to explain these facts. Prof. Reinold and the lecturer came to the conclusion that they could best be explained by supposing that when the two surface layers of the film began to intermingle the first effect was—as had generally been supposed—a decrease in the surface-tension; but that this decrease was in turn replaced by an increase, so that there was a minimum of surface-tension for some particular thickness rather greater than that which displayed the black. In this view they were confirmed by Sir William Thomson, who they found had, unknown to them, expressed a similar opinion in a lecture given early in the present year. It remained, then, to explain further why this *minimum* of surface-tension existed, and here the lecturer thought that the true key was to be found in a calculation of Maxwell's given in the article of which he had spoken. Maxwell showed that the surface-tension would increase or decrease according to the relation of the thickness of the film to the distance at which the molecules repelled or attracted one another. If they attracted one another, the surface-tension would fall off as the film became thinner; if they repelled one another the surface-tension would increase. Hence in the sharp edge of the black the lecturer believed that we had experimental evidence, first of a *minimum* of surface-tension, and second of an alteration in the nature of the force in play between the molecules, which had been often assumed in physical investigations, but of which any direct proof was, he believed, wanting. The lecturer concluded by pointing out to the audience that the result to which his investigations had led seemed to afford hope that the state of tenuity might throw further light upon obscure and difficult questions connected with the nature of the forces in play between the particles of which liquids are composed.

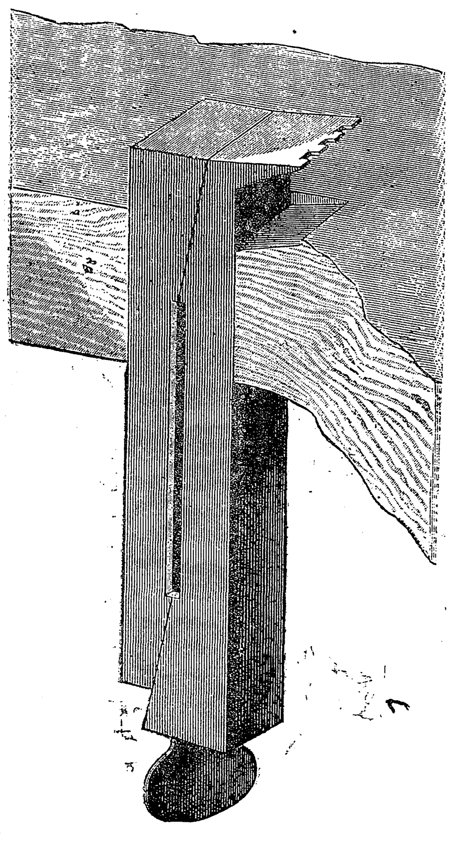
COLOURS OF METALS AND ALLOYS.

THE Saturday evening or popular lecture during the meeting of the British Association was delivered by Prof. W. C. Roberts-Austen in the Town Hall, a large number of the working classes attending. Prof. Roberts-Austen stated that under the title of the lecture he intended to include the consideration of the principal facts connected with the colours of metals and alloys, whether natural to them or produced by metallurgical art, as well as a brief examination of the kind of influence which the colours of metals appear to have exerted on the history of chemical science. With reference to the recognition of colours of metals by the ancients, he referred to the view expressed some years ago by Mr. Gladstone, "that the starting-point is absolute blindness to colour in the primitive man," and he urged that, if this be true, it is strange that in the metalwork or fabrics of savage nations the arrangement of such colours as they can obtain should be so thoroughly "understood," and the colours themselves so discriminatingly employed. Allusion was then made to the ancient belief that the seven metals known to the early chemists were specially connected, as regards colour, with the seven principal planets; to the persistence with which this belief survived, and to the fact that Sir Isaac Newton did not escape the charge of leaning toward mysticism when he stated that seven colours resulted from the decomposition of light by the prism. In relation to the influence of the colour of metals on the history of science, it was pointed out that from the 3rd to the 17th century the colour of gold appeared to haunt men, and induced the alchemists to make the strangest sacrifices, even of life itself, in the attempt to produce it. The alchemists were sustained by the knowledge that the colour of metals could be destroyed by small traces of impurity, and an appeal was made to the argument of even the "sceptical chemist," Robert Boyle, in the 17th century, that transmutation of base to precious metals is possible, because he destroyed the colour of gold, and believed that he had degraded gold to a base metal by the addition of a small quantity of a substance "given him by a stranger"; "it being," as Boyle said, "no small thing to have removed the bounds which nature has industriously set to the alteration of things." In illustration of the apparent degradation of gold by the presence of a small quantity of certain other metals, Prof. Roberts-Austen melted 200 sovereigns, added a tiny shot of lead, and proved that the bar into which the metal was cast was very brittle, and entirely different in colour from the original gold. The dependence of the colours of metals on their physical state of aggregation was then illustrated by some beautiful experiments with leaf-gold and with Faraday's finely-divided gold of bright ruby colour. The lecturer then passed to the effect of colour produced by alloying metals by melting them together. He incidentally said that he had many inducements to speak about brass—in particular he would have liked to dwell upon the beauty of such work as that of the great craftsman (William Austen) who, in 1460, made the magnificent monument in brass to Richard Beauchamp, Earl of Warwick; and he was glad to remember that the first patent for the manufacture of brass in England had been granted to W. Humphrie, an assay master of the Mint, and a predecessor in the office he was privileged to hold—but he did not intend to say much in Birmingham of the coloured alloy of zinc and copper which was its staple industry. His object was to claim the attention of the metal-workers of Birmingham to the coloured alloys of copper with which they were less familiar, and he referred at length to the alloys which had been used for centuries by Japanese Art metal-workers, the images of beautiful specimens of whose handicraft were projected on a screen. Special reference was made to a large plaque of copper inlaid with foliage, which in colour suggested the glories of a Canadian autumn, and it was stated that the addition of small quantities of gold, antimony, and cobalt to metallic copper enabled the Japanese to secure each beautiful shade of colour of purple, golden browns, and reds, for which their art metalwork is so remarkable. In illustration of the effect of various "pickling" solutions on copper, Prof. Roberts-Austen had himself prepared a trophy 7ft. high of richly-coloured leaves. Attention was then directed to the singular banded alloy known as moku-me, the manufacture of which, now almost abandoned by the Japanese, Prof. Roberts Austen is anxious to see introduced into this country; and he projected on the screen the image of a dagger-hilt of old Japanese native workmanship, in which, as a *tour de force*, the artist had reproduced the purple and brown markings of a "scarlet-runner" bean. A brief reference was made to the fact that the electro-metallurgist has at command, in the power of being able to deposit coloured alloys, an equivalent of the varied palette of the decorator; and beautiful specimens of coloured alloys, deposited by Messrs. Elkington's well-known firm, were exhibited. It was incidentally stated that one firm deposited annually six tons of silver in thin films, which, if continuous, would, it had been calculated, cover an area of 140 acres. Prof. Roberts-Austen then showed experimentally, by projection on the screen, the formation of coloured films by heating lead in air, and he claimed that the formation of a coloured calx of lead by heating the metal in air had been more frequently appealed to in support of various sets of views than any other fact in the

history of science, from the time of Geber in the 8th century to that of Priestley in the 18th. This beautiful experiment was of special interest to Birmingham, because, performed in a rougher way, it had directly led Priestley to the discovery of oxygen, and had removed his doubts as to the aërial source of the oxygen he obtained from other substances. Prof. Roberts-Austen concluded with a sentence from Mr. Ruskin's "Modern Painters," as to the right enjoyment of colour, and with a plea for the more careful study and extended adoption of coloured metals and alloys in objects intended for daily use, and for the restricted employment of gold and silver to the legitimate purpose of enriching metallic ornament.

ADJUSTABLE BENCH HOOK.

THIS device is the invention of J. B. Boyce, a practical pattern-maker, of Lockport, N.Y. It is of cheap construction, strong and durable, and



has the appearance of being a very convenient tool. It is easily attached to any wood-worker's bench, it being only necessary to cut through the top a mortise 1½in. square. No part being permanently attached to the bench, the tool is interchangeable in the mortise, and can be reversed, presenting a smooth face to the work, thus preventing marring. No second tool is needed to operate it, a half turn of the thumb-screw serving to either loosen or fasten. It may be removed from the bench and placed with other tools, securing the owner from loss by theft, as is the liability with tools for this purpose when screwed to the bench.—*American Machinist.*

Bakusine.—The patent of Herr Albert Muller (described in the *Chemiker Zeitung*) consists in mixing 100 parts of petroleum or crude naphtha and 25 parts of castor oil, or any other vegetable oil, with 60 to 70 parts of sulphuric acid at 66° B. The whole is well stirred, and is mixed with two or three times its own bulk of water. After standing for some time, the watery layer underneath is removed. The whole is let stand for some days, and is carefully neutralised with soda or potash lye. The lubricant thus produced (known as bakusine) is then packed in casks or cases.

THE late Mr. Samuel J. Tilden left between four and five million dollars for carrying on the work of free libraries in America. The sum is left in the hands of three trustees—Messrs. John Bigelow, Andrew H. Green, and G. W. Smith. After deducting the expense of establishing free public libraries in New Lebanon and Yonkers, the remaining portion of the money will, it is said, be devoted to founding a new public library in New York.

SCIENTIFIC NEWS.

SO far as attendance is concerned, this year's meeting of the British Association may be considered a success, as it may also in the number and importance of the papers read. Next year the Association will meet at Manchester on August 21, under the presidency of Sir Henry E. Roscoe, and it has been decided that Bath shall be the favoured city in 1888. With reference to the invitation from Sydney, New South Wales, that the Association should hold its meeting there in 1888, in January (on account of the difference in the seasons), it was felt that there were great difficulties in the way, but it has been so far decided to overcome them by sending a representative delegation of 40 or 50 members, who will probably meet at Sydney in January, 1888, and perhaps visit Melbourne. The council will, however, report on the matter at the Manchester meeting. The Government of New South Wales has offered to pay all expenses of 40 or 50 representatives of the British Association, and there will obviously be some difficulty in making a list which will meet with the approval of the council.

According to Dr. S. Oppenheim, of Vienna, Brooks's comet III., 1886, has a period of about nine years, but Dr. Hind calculates it at not much, if anything more, than six years and a quarter, so that the comet will return in 1892.

According to a telegram from Grenada, the observations of the corona during the last two eclipses, including that observed in Egypt, have been confirmed by the present. Captain Darwin's observations with the coronograph seem disappointing, the glare of irradiation from the body of the sun, and not the true corona, being visible on his plates. The bright lines seen in the spectra of the prominences are displaced in such a direction as to prove that there is in them a downrush of gas towards the sun. The curious prolongation of the corona observed on several previous occasions to occupy the sun's equatorial plane does not appear in any of the photographs taken, though it was visible at all the stations except Mr. Lockyer's.

The death is announced of M. Laguerre, Professor of Mathematical Physics in the College of France, at the early age of fifty-two.

Mr. Eli Whitney Blake, the inventor of the Blake stone-crusher, died at New Haven, Connecticut, on August 18th. He was born in Massachusetts, Jan. 26th, 1795. So far as we know the stone-crusher was the only successful invention of Mr. Blake; but he was one of the founders of the Connecticut Academy of Arts and Sciences, and was a frequent contributor to the *American Journal of Science*, and other scientific papers. So recently as 1882 he collected a number of his papers and published them under the title "Original Solutions of Several Problems in Aërodynamics." Mr. Blake is another instance of the effect of an active mind in promoting longevity.

From the Programme of the Finsbury Technical College of the City and Guilds Institute we learn that the entrance examination will take place on the 29th inst., and the evening classes will commence on October 4. Applications for entrance or matriculation examination of the Central Institution must be sent in not later than the 18th inst. The evening classes are under the care of competent teachers,—some of them distinguished men of science,—the fees are low, and they afford an admirable opportunity for obtaining sound and valuable information. Leonard-street, where the college is situate, is, too, within a short distance of three railway termini from which all parts of London and the suburbs are easily reached. Those who are interested in technical education, either for themselves or their sons, should send to Sir Philip Magnus, at Gresham College, for handbills and the Programme.

With reference to the article on tobacco-growing (p. 3), it may be of interest to state that Mr. Stanford, of Charing-cross, is about to issue a small work on the growth of the tobacco plant in France, containing suggestions as to its adoption here. The author, Mr. Philip Meadows Taylor, has been engaged in the cultivation of tobacco in the department of Lot et Garonne for the last forty years. He gives an account of the operations of the Régie Nationale, or tobacco monopoly in France, and full details as to the process of growth, harvesting, and drying of the plant, from the purchase of the seed from the Régie to the return to that authority of the leaves dried and ready for manufacture.

In addition to the exhibitions at Manchester and Newcastle, next year, there is to be one at Saltaire, in Yorkshire, the model industrial town founded by Sir Titus Salt.

The statement that Mr. F. Siemens, of Dresden, was experimenting with his hard glass for rails, turns out to be a mistake, the German journals having translated "sleeper" into "Schienen," which means rails, and was so translated for the English press. "Schwellen" is the term for sleepers, and it seems that Mr. Siemens has been very successful in producing these in hard cast glass.

The new Channel steamer, *Victoria*, which has already made the passage between Dover and Calais in the quickest time on record, is expected to accomplish the distance in less than an hour when a favourable opportunity occurs, and to make the trip as a regular performance in about an hour.

A tell-tale paint for hot bearings has been brought out by Mr. H. Crookes, of Westminster-chambers. When cool, or at normal temperature, it is a brilliant red; but as the temperature rises it grows darker, until at 180° Fahr. it is quite brown. As it cools it regains its original redness. This paint should be useful for high-speed machinery, especially if it will retain the remarkable property for any length of time.

Another instance of the effects of oil on waves is supplied on apparently excellent evidence. The North German Lloyd's *Werra* was recently disabled in mid-Atlantic, and was taken in tow by the *Venetian*. One morning a strong gale sprang up, and heavy seas broke over the bows of the former vessel, when the commander of the *Venetian* ordered an oil-bag to be hung over each side of his ship and dragged some distance astern. The effect was marked, as the sea became comparatively smooth, and not a drop of water broke on board the *Werra*.

At a recent session of the Academy of Sciences in Amsterdam, Prof. Forster stated that he and Dr. van Geuns had found that the comma bacillus was destroyed by heating the substance containing it to 55° C. (131° Fahr.). In their work "Les Bactéries," MM. Cornil and Babes state that the comma bacillus is destroyed by exposure to a temperature of 50° C. for a few days; also that a culture of comma bacilli can be sterilised by slowly heating it to 65° or rapidly to 75° C.

According to a telegram from Cooktown, Vice-Admiral Freiherr von Schleinitz, Governor of German New Guinea (Kaiser Wilhelm's Land), has sailed up the Kaiserin Augusta river from its mouth near Cape de La Torre, and found it navigable to the 140th degree of east longitude. A water road thus leads into the interior for more than 300 kilomètres (186 miles) in a south-westerly direction.

Births and Deaths in the United States.—The death-rate for the whole United States for the last census year was 18 per 1,000. Comparing it with the rates of some other countries for the year 1880, we find that in England and Wales the rate was 20·5; in the rural districts of England, 18·5; in Sweden, 18·1; in Belgium, 22·4; in the German Empire, 26·1; in Austria, 29·6; and in Italy, 30·5. The mean annual birth-rate of the United States is 36 per 1,000 of population, and the annual increase of population from the excess of births over deaths is nearly 2 per cent. a year, and this is exclusive of the increase from immigration. The mean annual birth-rates of some foreign countries are as follows—viz., England and Wales, 35·4; Sweden, 30·2; Denmark, 31·9; Belgium, 32: Austria, 39·1; German Empire, 39·3. The birth-rate is greater among the coloured than among the whites, but this difference is less in the rural districts than it is in the cities.

THE increase in population in New South Wales in 1885 was 59,305, being almost equal to that of Victoria, Queensland, South Australia, West Australia, Tasmania, and New Zealand combined.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

THE CITY AND GUILDS OF LONDON INSTITUTE—FINDING THE TIME WITH A SEXTANT—DETERMINING CLOCK-RATE—LUNAR LIBRATION—METEORS?—TERRESTRIAL TELESCOPE.

[26218.]—I SEE it announced that Mr. Owen Roberts, one of the Honorary Secretaries of the City and Guilds of London Institute, and a very keen and active original promoter of that somewhat dubious establishment, has resigned his secretaryship "in consequence of the pressure of other work." I wonder what this means. A little while ago Mr. Magnus, who is the director, or something of the sort, was made a knight—and Mr. Roberts wasn't; but it can hardly be the "spretæ injuria formæ" which has deprived the Institute of Mr. Roberts' services. If my memory serves me, Mr. Roberts was not too active in his opposition, when certain snobs who had been "got at" by the Brompton Ring, were instant to have the "Central Institute" located in Exhibition-road, S.W. They succeeded, and the City Guilds have had to pay through the nose accordingly. I, however, see a ray of hope in the dissolution of Mr. Roberts's connection with this charming transaction. According to the "Directory," he is clerk to the Cloth Workers' Company, who have (presumably under his guidance) been among the most munificent of the contributors to the Institute. Would it be too much to hope that if that Guild is to continue to contribute to the furtherance of technical education, it will, for the future, be advised rigidly to confine its donations to the Finsbury Technical College, which is really giving legitimate instruction to legitimate recipients in an entirely suitable locality. If, getting over their "genteel" fit, the Guilds come to realise the way in which their money has been squandered at Brompton, and have the sense and firmness to say, once for all, that they must decline to spend it in a way which brings such a wholly disproportionate return, then we may trust that the whole of the South Kensington affair will collapse, the omnivorous Commissioners of the 1851 Exhibition appropriate their palatial buildings, and a genuine system of technical education for the British workman rise out of the ruins of a detected and exploded piece of humbug.

In reply to query 60242, Vol. XLIII. p. 587, I think that I shall possibly render the method of finding the Greenwich Mean Time by the aid of a sextant more intelligible to "H. A.," if I describe it verbally, and in detail, instead of employing the trigonometrical equations which he would find in any book on Spherical and Practical Astronomy to which I could refer him, and if, further, I work out an example at full length. I shall suppose him to be in posssession of a good box sextant, an artificial horizon formed of a pail of water—or better still, a bucket of tar, a book of logarithms and the *Nautical Almanac* for the current year. I presume, in limine, that he knows how to measure the sun's altitude by bringing either of its limbs into contact with its reflection in his artificial horizon. Of course, half the resulting angle with the sun's semi-diameter applied and corrected for refraction and parallax, will be the height of the sun's centre at the instant of observation. Then, under the latitude we write the sun's declination, each with its proper sign, N. or S., marked against it. If these signs are alike, we must take their difference: if one is N. and the other S., their sum. Under this result we write the true zenith distance of the sun's centre; we take the sum and difference of these two quantities and their half sum and half difference. We add together the log. secants of the latitude and declination and the log. sines of the half sum and half difference, divide the result by 2, and the quotient will be the log. sine of half the hour angle. Turning this into time and doubling it, we shall get the *apparent* local time when the sun is west of the meridian, 24 hours—the same hour angle gives the apparent local time when the sun is east of the meridian. Apply the equation, and the true local mean time will be known; then apply the correction for longitude, and we shall get Greenwich Mean Time. Now for an example to make all this intelligible. Suppose that I was in Chester on August 1st, and that when a watch supposed to indicate Greenwich Mean time showed that it was 7h. 43m. 18s. a.m., I took a double altitude of the sun by bringing the sextant image of his lower limb *just* to touch the reflection of the same limb in perfectly still water. Suppose, further, that I found this double altitude to be 54° 33′. Then 27° 16′ 30″ is the apparent height of the sun's lower limb. But from this 1′ 51″ must be subtracted for refraction and 8″ added for parallax; this leaves 27° 14′ 47″ as the true height of the sun's lower limb, and on adding 15′ 48″ the sun's semi-diameter to this again, we finally obtain 27° 30′ 35″ as the true altitude of the sun's centre at the instant of observation. 90°—27° 30′ 35″ = 62° 29′ 25″, the sun's zenith distance, which we shall emply in the calculation which is to follow. The latitude of Chester is 53° 11′.

Latitude	53°	11′	0″	N.	
Sun's Dec.	18	2	8	N.	
	35	8	52		
Sun's Z.D.	62	29	25		
	2)97	38	17	sum	
	2)27	20	33	diff.	
Half sum	48	49	8

33	58	4·5	sin.	9·747201	
		2			
67	56	9	hour angle = 4h. 31m. 45s.		

That is to say the sun is apparently 4h. 31m. 45s. east of the Chester meridian, or it is 7h. 28m. 15s. a.m. apparent time. To this we must apply the equation 6m. 5s., and we shall get 7h. 34m. 20s. as our true local time at the instant of our observation. Finally Greenwich is 11m. 36s. east, or fast, of Chester, so that adding 11m. 36s. to 7h. 34m. 20s. we obtain 7h. 45m. 56s. as the Greenwich Mean Time at which the sun's altitude was measured. But our watch showed 7h. 43m. 18s., so that it was 2m. 38s. slow. I must ask my querist to note that, knowing our time very approximately, the sun's declination has been computed for it. Such refinement is scarcely needed in the case of the equation of time.

One of the most simple pieces of apparatus, by the aid of which "Tempus Fugit" (query 60266, Vol. XLIII. p. 588) can ascertain his clock rate, is described by Lord Grimthorpe in the introduction to his book on "Clocks, Watches, and Bells." His diagram and description were copied by some correspondent into a back volume of the ENGLISH MECHANIC without any acknowledgment of the source whence they were derived. If "Tempus Fugit" has the sharp edge of a building or chimney-stack visible from one of his windows, and will paste a piece of black paper punctured with a small hole on one of the panes (so that his eye shall always occupy identically the same position with reference to such an edge, then, as stars rise south and set 3m. 56·41s.), sooner every night, if at the instant a bright star disappears behind the building, his clock shows, say, 7h. 22m. 4s., the next evening when the star vanishes, the clock should mark 7h. 18m. 8s., and so on. The shadow of a plumb line on a meridian line will give local apparent noon too; but your querist will find plenty on this subject in your former volumes.

The rule for which "H. C. L." inquires (query 60292) on page 588 of Vol. XLIII., appears on page X. (preface) of the *Nautical Almanac* for 1867, thus:

Putting $\lambda, \beta, \alpha', \delta'$ for the Moon's Longitude, Latitude, Right Ascension, and Declination affected with parallax and

$$\triangle\lambda = \tan^2 \tfrac{1}{2} I \sin 2 (\lambda - \text{☊})$$

$$\frac{1}{\overline{a'}} = \frac{1}{\cos. (\lambda - \text{☊}) \sin. I}$$

$$\tan. B' = \sin. (\lambda - \text{☊}) \tan. I,$$

Libration in Latitude, $b' = B' - \beta$

Libration in Longitude, $\overline{l'} = l - l_o$

$$= \lambda + \triangle\lambda - \frac{b'}{\frac{1}{\overline{a'}}} - l_o$$

Angle which the meridian of the middle of the Moon's disc makes with the circle of Declination, taken positive when the northern part of the circle of Declination is to the west of the Moon's meridian.

$$\text{Sin. } C = - \sin. i \frac{(\cos. l - \text{☊} + \triangle)}{\cos. \delta}$$

$$= - \sin. i \frac{(\cos. \alpha' - \text{☊}')}{\cos. b'.}$$

See also for further details on pp. 531, et seq., of Neison's admirable work "The Moon."

Had Mr. G. W. Middleton (letter 26180, p. 10) only focussed his telescope carefully upon his "Meteors," he would have found that they were simply feathered seeds of the thistle, and the like, drifting across his field of view and becoming brilliantly illuminated as they passed near to the sun. Did your correspondent notice the direction of the wind upon the day of observation? Should he be able to obtain a sight of Vols. XI. and XII. of the R.A.S. *Monthly Notices*, in any library, public or private, he might with advantage consult p. 48 of the former, and pp. 38 and 183 of the latter of these volumes.

As "D. G." addresses his query (60324) on p. 23 to "Garrison Gunner" "or others," perhaps I, having had very considerable experience with telescopes, may venture to answer him, and say that no 3in. telescope can in any legitimate sense whatever be considered "portable." The one he has probably magnifies something between 30 and 40 diameters if it is one of the best kind. I myself always carry a telescope of $1\frac{5}{8}$ aperture, giving a linear magnifying power of 24, and find this a most useful instrument, and quite as large as can be held steadily in the hand. Of course, if you have a tripod stand, or can fix your telescope on a wall or window sill, you can employ a larger and more powerful instrument; but I am speaking of one to carry about with you. By the bye, some of these $\frac{5}{8}$in. objectives have pancratic eyepieces fitted to them.

A Fellow of the Royal Astronomical Society.

PLANETARY NEBULA ON ONE OF MM. HENRY'S PHOTOGRAPHS—MAGNITUDES OF STARS NEAR VEGA—PLANETARY NEBULA G.C. 4373 AND SUPPOSED NEW NEBULA.

[26219.]—IN giving an account of one of MM. Henry's photographs of Cygnus in letter 25881, page 370 of Vol. XLIII., I omitted to state that a small planetary nebula was visible on the photograph in question. The nebula is No. 4 of Prof. Pickering's list in the *Observatory* for October, 1882, and was discovered by him while sweeping with a direct-vision prism attached to the 15in. equatorial on November 25th, 1881. Prof. Pickering says that "except by its spectrum, it is undistinguishable from a star of the fourteenth magnitude," in, I presume, the photometric scale. Its place for 1886·0 is XXh. 6m. 39·6s. + 37° 4′ 28″. On the photograph it seems nearly two magnitudes brighter than Prof. Pickering's estimate, and it appears precisely like a star.

Since writing letter 26177 on p. 10 of the present volume, I have received estimates of the magnitudes of some of the stars near Vega from Mr. Holmes. He rates γ and ϵ of the twelfth, and δ of the thirteenth in Smyth's scale; while he says ζ is the limit of visibility with his 9in. mirror. On the photograph ϵ and ζ seem very nearly equal in magnitude, ϵ being just a shade the larger of the two. Perhaps "F.R.A.S." or some other of your correspondents would examine the field. I am much obliged to Prof. Swift (letter 26181, p. 11) for referring me to Mitchel's Burritt, which I had overlooked. The R.A.S. possesses a copy of this very rare work, and Prof. Cleveland Abbe published the double-star observations contained in it in the *Monthly Notices* for January, 1877. I think I referred to this paper in a letter to the ENGLISH MECHANIC some time in 1877. Prof. Abbe included the names of nebulæ observed by Mitchel in the paper in question; but the Editor of the *Monthly Notices* omitted to print them. Had they been printed I should probably not have forgotten to refer to Burritt, as I consulted Mitchel's *Sidereal Messenger* while preparing letter 26050. In a letter received a few weeks ago, Prof. Swift tells me that the first volume of his Observations of Nebulæ, containing 350 discovered by himself, is in the press, and will shortly be issued. From the care with which their places have been determined, as is shown by his communication to the *Sidereal Messenger*, the *Astronomische Nachrichten*, &c., his catalogue will form a very valuable contribution to this branch of the science. Is not Prof. Swift's new nebula in field with 37 . H. iv. identical with one found by d'Arrest, and entered in the supplement to the G.C. as No. 5,893? D'Arrest found it on Oct. 6, 1866, and describes it as "Debilis, longula, irregulariter terminata; classis fere tertiæ. In campo pariter cum H. iv. 37. Solutionis levis suspicio tantum." Its place for 1885·0 is XVIIIh. 0m. 13·5s. + 66° 36′ 18″. It will be observed that this place

is within three minutes of arc of that in which Prof. Swift locates his *nova*, and I cannot help thinking that his new nebula must be identical with d'Arrest's. If so, Prof. Swift's estimate of its exceeding faintness must be at fault. Of H iv. 37 d'Arrest writes: "Per amplificationem 231 nimbus confertissimi ac coarctissimi stellularum agminis faciem induit."

Erratum.—On page 10, Aug. 23 is the date appended to letter 26177, and not to letter 25882.

Sept. 6. **H. Sadler.**

LIVERPOOL ASTRONOMICAL SOCIETY. CIRCULAR NO. 8.

[26220.]—The star D.M. + 35° No. 4002 was observed with the $17\frac{1}{4}$in. equatorial on the night of June 26th last, as a very red 8·5 star. On August 29th it was again observed with the same comparison stars, and was found to barely equal 9·5. There seems, therefore, reason for suspecting it of variation. Dunér calls this star "rouge-jaune foncé, Sp. III. *b*!!" and identifies it with Pickering No. 36 (A.N. 2376), which seems improbable, as Pickering's place is 1m. 20s. P., and 0° 7′ S. The place of D.M. + 35° No. 4002 for 1885 is xxh. 6m. 3s. + 35° 36·1′.

T. E. Espin,
Wolsingham, Sept. 1. Observer to the Society.

METEORS (?)

[26221.]—Referring to Mr. Middleton's letter (26180), describing his daylight observation of showers of "meteors" near the sun, on the 28th ult., which apparently continued until sunset, and were again visible next day, the majority appearing "as bright as Venus does in the telescope in the day time," and moving comparatively slowly, so that they could easily be followed by the telescope, it would be interesting to learn whether the same were seen by any other observer. For my own part, I am inclined to question their being meteors, and to think that to some other cause these appearances must be attributed. For instance, Dr. Dick, in his "Practical Astronomer," states that in his frequent observations of Venus, to determine the nearest positions to the sun in which that planet could be seen, he frequently perceived a luminous body pass across the field of the telescope, apparently of the same size as Venus—in several instances four or five appeared to cross the field of view. He was for a considerable time at a loss to form an opinion of the nature of these bodies; but continuing his observations every clear day for a twelvemonth, he discovered that some, at least, of them were birds, the convex surfaces of which in certain positions strongly reflected the solar rays. He, however, also quotes a curious observation made by Benjamin Martin, and likewise the apparent projection of star-like objects from the sun during the progress of an eclipse, as seen in France in the year 1820—all which were doubtless attributable to atmospheric undulations.

Dr. Phipson, in his "Meteors, Aërolites, and Falling Stars," states that Arago remarks that whilst observing the sun even through the coloured glass affixed to the ocular lens, he had frequently seen luminous points passing across the field of the telescope; he believed, however, that he had seen these appearances most frequently about the autumn, when flocks of spiders' web were wafted through the air. Phipson adds that he had himself witnessed similar appearances caused by the displacement of a little dust within the telescope, and further states that an interesting article in the journal *Cosmos* (Vol. I. p. 292, 1852) shows that the "meteoroid masses" seen in the rays of the sun by Mr. Reade, were proved by the later observations of Mr. Davis to be seeds of various kinds suspended in the air, and carried along by the wind. I have myself, when observing Venus by daylight, seen birds passing as described by Dr. Dick, and have been assured by persons looking for Venus at such time, that they have seen meteors flash across the sky, which appearances I have always attributed to the transit of birds.

I would suggest to Mr. Middleton that he should carefully repeat his observations, and favour the "E. M." with the results of the same, stating size and description of telescope employed, powers of eyepieces, direction of "meteors" (if seen), and direction of the wind.

Southampton, Sept. 4. **A. H. S.**

PHOTOGRAPH OF LIGHTNING FLASH.

[26222.]—It may interest some of your readers to know that I got two beautiful photographs of two different flashes taken by Mr. Auty, 10, Froutstreet, Tynemouth, where copies, I believe, may be had. These photographs show the fainter ramifications of the spark very well, and are interesting specimens of the kind. Seeing last week's letter brought these photos. to my mind, and I thought many readers of "E. M." might be glad to know where a photo. of lightning flash can be had in England. **T. R. Clapham.**

LIMITED EXPRESSION OF CHAMBER ORGANS.

[26223.]—I have read the letter by Mr. Charles Melross (26215, p. 16) with some little amusement; for the idea of an organist literally sitting on the swell pedal and enjoying his sedentary crescendo and diminuendo is deliciously funny. Mr. Melross says, "The weight of the player on the stool is so utilised that whilst he has *both feet* engaged in pedalling and *both hands* occupied in the manuals, he can with ease and certainty open the swell to any extent and keep it open as long as he wishes at any particular point." But why does he practically stop here? It would have been most interesting to the readers of the English Mechanic if he had given details of this *seat of expression*, and drawn us a picture of the graceful swaying of the organist's body in accord with the musical impulses of his soul, for I presume some movement of the trunk is required to open and close the swell shutters. I hope he will give us full particulars of this curiosity of organ building. Mr. Melross appears to overlook the fact that the mode of operating the Swell he alludes to does not invest it with additional powers of expression, it only leaves the right foot so far disengaged. I am acquainted with the other expedients which have been resorted to to render the action of the swell independent of the feet; but no success has attended them.

I note the air of commiseration in which Mr. Melross remarks that I get "no further than the 'balanced' swell pedal." I thank him for his sympathy, while I really do not feel as if I deserved it. He quotes my remark that "every expedient that can be devised to increase the flexibility of the instrument in this direction will be of the highest value from a musical point of view." Just so; but he has not laid sufficient value on the word *instrument* in the above passage. It will be observed I allude to *every department*, and, indeed, to *every pipe* in the organ, and do not specially allude to the *one department* known as the *Swell*.

Suppose I insist on having three departments made *expressive*, how is our sedentary friend, the organist, to gracefully sit on three expression levers? He would require three stools, and we know that between two stools one is apt to come to grief. But, joking apart, I must ask Mr. Melross to wait for my subsequent articles, in which he will find my views, with reference to the means to be adopted for imparting increased powers of expression to the Chamber Organ, given at some length. **G. A. Audsley.**

CHAMBER ORGANS.

[26224.]—Whatever good may in the long run result from the articles now appearing on the Chamber Organ, it is evident they will provoke honest discussion, and bring forward many interesting and very valuable communications. In reply to "Musicus," I must assure him I never felt further from joking in my life than when I wrote, "I shall dismiss the Chamber Organ with one clavier only as unworthy of serious consideration. It is an instrument so hopelessly imperfect that it is a matter for wonder that it should ever have been introduced, or that anyone with the slightest knowledge of the organ and organ music should have tolerated it." But I must ask "Musicus" to tell me where I condemn "the good old organs as 'unworthy of notice'"? I have no objection for my words to be honestly criticised, but I have a right to expect them to be *correctly quoted*. No man admires the tones of the organs by "dear old Snetzler" and the other fathers of the art of pipe-making and voicing more than I do, and I think every word I have written on the subject of voicing is an earnest cry to have those refined tones back again in our modern organs. I should much like to hear the sweet tones of the instrument so lovingly commented on by "Musicus." To listen to one of Snetzler's "singing organs" is a rare treat to the musical ear; and its lovely voice, indeed, makes one sigh over the degeneration in the art of organ pipe voicing which has so long obtained. It would be extremely interesting to have full particulars of the seven-stop Snetzler in the possession of "Musicus"; may I venture to hope he will give them in these pages?

To return to the more important question in his letter. It is certainly not my fault that a properly schemed and appointed Chamber Organ is beyond the reach of "artisans"; but that melancholy consideration does not alter the fact that a one manual organ (without pedals) is a "hopelessly imperfect" affair. The following passage, which I quote from a letter I have to-day received from a Doctor of Music and an organist of high repute, very strongly supports my own opinion. The writer says: "Your vigorous hits at that *one manual* abomination, whether Church or Chamber, are well calculated to consign it to the land of dusty curiosities, and in the interests of the true soul of music—living expression—I fervently hope oblivion will soon be its fate."

If "Musicus" is an "artisan," as he implies, surely he can see an easier way of procuring a decent Chamber Organ than by paying a large sum of money for it. If I was in his place I should convert the Snetzler into *one department* of an organ of more useful form, adding, by the work of my own hands, the other departments required, striving to arrive at, or as near as possible to, the standard of excellence presented by Snetzler's handiwork. He would then be able to show what that master did in the past era of organ building, and how closely he could walk in the master's footprints. See to it, good "Musicus," and in due time give us all the pleasure of knowing the successful result of your labours. Take the word of one who devoted many years to the maturing of his dream of what a Chamber Organ should be, that your skill and patience will be rewarded. In the mean time, do not forget to let us hear all about your charming little one manual.

G. A. Audsley.

EGYPTOLOGY.

[26225.]—I am glad to see this subject brought forward, as being one in which I am much interested, thanks to our good Editor, for it is scarcely scientific, and certainly not mechanical.

There is but little doubt, as Mr. Gerard Smith says, that the time of Joseph's power was during the rule of the Hyksos, or shepherd kings, in Lower Egypt. This seems to be a well-established point. On the other hand, it is the generally-accepted opinion, by Egyptologists of the present day, that the Exodus took place in the reign of Menephtah, the son and successor of Rameses II. (or the great), and that this same Rameses was the chief oppressor of the Hebrews, the oppression having probably however begun earlier. I need only give the very high authority of Dr. Birch for the above statement, though I could mention many others. Rameses II. was a great conqueror and builder, and it is certain that he employed captives and bondsmen in his great works, and that he used forced labour. Thothmes III. did the same; but it is not so certain that the "Aperu" mentioned in the time of this king were the Hebrews, although some think so. It seems to me probable that the period of oppression lasted much longer than is generally supposed, and that possibly Thothmes III. had to do with it as well as Rameses.

How about the chronology? Obscure and difficult as it is, and, in fact, impossible to attain to exactitude from any Egyptian data, yet we can get a good general idea of it. In the first place, take the period of the shepherd kings, I believe the length of which has been much exaggerated—Manetho is quite unreliable as to the duration of this, for the sources from which his history has descended to us are inconsistent with themselves—*e.g.*, Africanus gives the names of six kings, who reigned 284 years for the 15th dynasty. Eusebius gives virtually the same names, but calling them the 17th dynasty, and reigning 103 years. Josephus gives the same names, but allows them 259 years. For the 16th dynasty Africanus gives 32 Greek shepherd kings with no names, reigning 518 years, and Eusebius five Theban kings, unnamed, for 190 years. For the 17th dynasty Africanus gives 43 shepherd kings and 43 Diospolite, all unnamed, and reigning 151 years. Thus, according to Africanus the rule of the shepherds lasted nearly 1,000 years, while Josephus puts it as 511 years.

So much for the uncertainty of the historians. Now from monumental evidence, and also by comparison of the Egypt of the 12th dynasty and the Egypt of the 18th, it seems highly probable that these two dynasties were consecutive; that the 18th directly followed the 12th, or, at most, only a short interval elapsed. The 12th was Theban, confined to Upper Egypt, and during this the shepherds held sway in the Delta for an uncertain period of time. At last Aahmes, or Amosis, expelled them, and founded the 18th dynasty reigning over all Egypt. Doubtless this dynasty was unfavourable to Joseph and his nation, and probably the oppression had continued for some time before it became so extreme as at the end.

How are the dynasties between the 12th and 18th to be disposed of? There is no better established point than that many of the dynasties were collateral, and not consecutive, as Manetho meant to imply. Writing, as he did, for the edification of the Greeks, he doubtless did his best to extend the Egyptian antiquity, and he thus enumerates them. The 13th consisted of 60 Diospolite kings, unnamed, reigning 453 years; collateral, if real. The 14th of 76 Xoite kings for 184 years. This, possibly, was a small native line ruling in the Delta. The 15th is probably the genuine dynasty of shepherds; the names agree in the three sources of Manetho, and also with some found on the monuments of Lower Egypt. The 16th and 17th are exceedingly questionable, as we have seen above.

Now, as to the length of the 18th dynasty. From the various numbers given by the epitomists, and from certain numbers found in inscriptions, something like a dozen totals can be made. Poole adopts

185 years, and Bunsen 216 years for this dynasty. In round numbers, let us call it 200, and allowing over 100, perhaps 150, years for those kings of the 19th dynasty down to Menephtah, we have from 80 to 130 years as the time of the residence in Egypt of the Hebrews during the shepherd kings' rule. This is, of course, following the statement in the Hebrew, and consequently the English version in Exodus xii. 40, that the residence in Egypt was 430 years, and this is borne out by Genesis xv. 13, and also by Acts vii. 6. Fully in corroboration of this also is the statement on one of the monuments in which Rameses II. records that it was 400 years from the time of Set or Saites, the first of the shepherds, to one particular year of his reign, which one, however, is not mentioned. This also is totally against Manetho, and it considerably curtails the length of the Hyksos rule. It is interesting that about this period of the 15th dynasty, there was a famine lasting many years; it is mentioned in an inscription in the tomb of a nobleman named Baba at El Kab. Possibly this was the same famine as is mentioned in the book of Genesis.

In conclusion, I should be obliged if Mr. Gerard Smith would tell me where the best account of this recently discovered mummy of Rameses II. can be had, and also, as he states he has been to Egypt, and doubtless has seen the Great Pyramid, will he give us his opinion of how much sober truth there is in the statements that have been made about it. It may interest others beside his professional brother. **H. F. L.**

EGYPTOLOGY.

[26226.]—IN reply to Mr. Smith (26168), I remark that the historical references to Israel in Egypt are doubtful, and look as if written by very different people long after the fact. But the reason why Rameses II. is supposed to be the Pharaoh of the persecution, is because the Bible says the name of one of the cities built in Egypt by the Israelites was Raamses.

Raamses is generally identified with Zoan (Tanis) a large city near Goshen, and at the Palestine end of Egypt. It was one likely to be well known to the Israelites at all periods of their history. It was an old city, but, as R. S. Poole says, at page 75, in his "Cities of Egypt," "Zoan was rebuilt and called Pe Ramses, 'the house of Ramses,' carefully distinguished in the inscriptions as Ramses II., first apparently the name of a quarter, then that of the whole city." As Rameses II. was the greatest of the Egyptian Pharaohs, and as he lived within measurable distance from the time of the Shepherds, it is probable he was referred to.

Manetho says the Shepherd domination lasted for 511 years, and both Mr. Poole and Mr. Sayce, both excellent authorities, think it probably was so.

James Fergusson, in his "History of Architecture," gives the length of the 18th and 19th dynasties, which elapsed between the departure of the Shepherds and the Exodus of the Israelites, as about 500 years; but these numbers are not certain, and it is difficult to know how long the Jews were in Egypt.

In Ex. xii. 40, it is said: "Now the sojourning of the children of Israel who dwelt in Egypt was 430 years"—not the descendants of Abraham, but those of Israel—yet it is generally held, partly in deference to Galatians iv. 17, that the 430 years include the time from Abraham's visit. Again, but four generations are mentioned as living there, and as a generation usually is reckoned at 30 years, it is necessary to make a new calculation.

Indeed, from the various discrepancies, to say nothing about the large facts of the case, it seems unlikely that the numbers can be relied upon; the other numbers given—such as the ages of the patriarchs—seem doubtful—thus, Abraham, 175; Isaac, 180; Jacob, 148; Joseph, 110; Aaron, 122; Moses, 110.

The Israelites are not mentioned in any Egyptian inscription or papyrus, though the Shepherds are; and it is very strange that the period assigned to them is nearly the same as that assigned in the Bible to the time of the Israelites there; also, that their army and the Jewish army were the same in number (600,000).

As yet all inquirers must go to the Bible for information respecting Israel in Egypt; but it is not improbable that a section of Shepherds who were enslaved escaped into Palestine during the reign of Menepthah, the weak son of Rameses II. **Memnon.**

SOLENOIDS AND COILS.

[26227.]—THE explanations usually given of the behaviour of solenoids through which an electric current travels do not appear to me to sufficiently account for the fact that under such circumstances they assume a direction parallel with a magnetic needle.

We are taught that a wire conveying an electric current exerts a magnetic influence all round it with an equal intensity all round. Since a solenoid is but a wire coiled into a spiral, it follows that the magnetism outside each convolution should be precisely equal to, but in the contrary direction to, that inside. As a matter of fact, if the solenoid is encircled by a soft iron tube on its outside, this tube exhibits strong magnetic polarity precisely the opposite of that of an iron core when placed inside it.

I should like to know why, when no iron whatever is introduced into the arrangement, the magnetism on the inside of the solenoid preponderates over that on its outside. In all magnetic appliances I have seen, the magnetism exerted on the outside of the coils seems to be altogether ignored, and that only radiating from the interior of the coils is made use of.

This, in practice, may be most convenient; but it is not impossible to conceive that the magnetic influence radiating from the exterior of the coils might be impressed into active service. At present it is not only wasted, but being energy exerted in a contrary direction, it would seem to be likely to detract from the force now turned to account in all magnetic apparatus. **R.**

CURATIVE POWER OF MAGNETS.

[26228.]—I MUST beg the Editor's indulgence for a brief rejoinder to Mr. Caplatzi (p. 16, Vol. XLIV.), although I am conscious of somewhat deviating from the subject, because a clear statement seems to me very necessary. I will put the matter in a small compass, and endeavour to be concise and final.

I am glad that his statements are now reduced to "suggestions," which he has "by no means made up his mind are the right ones." Give me leave to say that, in connecting as cause and effect "extra charges of magnetism" (whatever that may mean) with "genius and special mental powers," he is working in a wrong direction. I will admit to the full the influence of magnets or electricity, or the physical man, or whatever else Mr. Caplatzi likes, on the intellect; moreover, I will go beyond that, and affirm that the intellect is often completely mastered by them. This shows a *connection*. To say that it is one of cause and effect in the sense that the magnetism, &c., causes the intellect, is a "leap." Doubtless a few particles of strychnine might have hindered the writing of the play called *Hamlet*. Shall we, therefore, erect altars to strychnine?

I rather think it the mark of a true scientific observer to have no pocket explanation at all in such a case, and especially to shun a *simple* (in the sense of easily understood) one. All stupendous facts may be attempted to be described in a few words, and every schoolboy is ready with what he calls the "causes" of the French Revolution and other simple matters. May we not rather say that not only words, few or many, are sometimes inadequate, but that there are things in heaven and earth which the intellect cannot in the least grasp, and which call forth a higher faculty of the soul?

Mind subsists by matter and by light, heat, electricity, magnetism, and chemical attraction, but not as the effect of which these are causes. The records of heroism exhibit the triumph of mind over these forces. Even Mr. Pitt, roused from his sleep by news of a mutiny, "orders the batteries to fire upon the ships," and turns over to sleep again—surely a "man in danger" who takes it coolly enough. The capture of Quebec wanted a surprising combination originating in the brain of its author, and no small "physical achievement." Yet Wolfe was the victim of an incurable and painful disease. I fancy the attempt to treat intellect of any sort like horse-power or electromotive force will end disastrously. Clairvoyance and mesmerism may be as calculable as hysteria; but as to what is the "cause" of strong intellect, the simplest and most natural statement is, "*I don't know.*" **E. Willmore.**

KREOCHYLE—BARFF AND WIRE LIQUID MEAT.

[26229.]—I WAS interested in the paragraph in "Scientific News" last week referring to my respected friend the late Professor Barff; but will you allow me to correct an error you have inadvertently made? Kreochyle was *not* invented by Professor Barff, neither has the secret died with him. I am the sole inventor of kreochyle, and Professor Barff found the money to perfect it; he became joint patentee with me, and then assisted to form the Kreochyle Company, which still makes both kreochyle and boroglyceride.

Leytonstone, Sept. 4. **Alfred P. Wire.**

A PSYCHOLOGICAL PROBLEM—THE TERRESTRIAL TELESCOPE.

[26230.]—IN answer to "H. W." (letter 26193, p. 13), I will give a case in point. I find myself in a great battle, in the exercise of my duty, with a heavy cannon fire directed on my battery. My imaginative faculty at once gives me a picture of shattered bones and bleeding flesh, and if I obeyed it I would at once run away. But I consult my reasoning faculty, which tells me that after all very little real damage is being done by the shells, and that the odds are that I shall not be hit. Now a change comes. The enemy's battery has gained an eminence whence it commands my guns, and the position becomes clearly untenable. Both my imagination and reason now tell me to retreat. I have no orders to do so; but no one could blame me for saving myself and my battery from destruction. Now comes in my will, and tells my imagination and my reason to hold their peace, and my reluctant body to stay where it is till it gets orders. Is not the will the superior here? Was any act of *true* heroism ever done to please the reason or the imagination? I should like to go further, were the ENGLISH MECHANIC a suitable vehicle for the utterance of religious truth, and enlarge upon the fact that when a man was a true Christian and had subordinated his will to God's, the ruling will was then an attribute of God, or rather God Himself in one of His aspects. But on this I will not enlarge here.

I do not care to reply to "E. W." (letter 26196, p. 13). His is the old argument ascribing physical facts to imagination. I suppose it is of no use to tell him that some animals can be mermerised, or that a person can be mesmerised without his or her knowledge at the time. I have no intention personally of discussing the matter any further unless I can really assist any true inquirers after truth; and even they I should recommend to leave the subject alone.

In answer to query 60324, "Terrestrial Telescopes," I cannot well answer "D. G.'s" question without knowing what degree of portability he requires. If he can carry about a light stand, say from one window to another, or to a convenient wall, then I should certainly recommend a 3in. telescope of say 50in. length, with a long draw tube worked by rack and pinion. I fear, however, he would have to get one made specially. If the telescope be for the purpose of carrying about from place to place without a stand, he might get a 2½in. made, to be 40in. long when in focus and fold up to 1ft., with a leather case and slings and a pancratic eyepiece giving powers of say 20 to 35. He might then have an astronomical eyepiece giving a power of 50. The whole ought to be made under £5, and would be a most useful instrument. For long terrestrial distances I always use an astronomical eyepiece, for one can read print, or flags, just as well upside down, and the clearness obtained by the dispensing with two lenses is of great avail.

I would advise "D. G.," if near London, to go to Negretti and Zambra and ask to see one of their telescopes made for the War Department for army signalling purposes. Their wholesale price to the War Department is only 19s. 6d., and they are marvels of workmanship for the money, and as good, small, portable instruments as could be desired. **Garrison Gunner.**

[26231.]—I HAVE not been able to see anything "curious" in "A Fellow of the R.A.S.'s" experience. I have often dreamed I was *dreaming*—and that I *suspected myself to be dreaming*—and once, even, that I *woke up*; also that I have been (which seems the most remarkable to me) doing outrageous things under the consolation that "I am only dreaming, so it won't matter." This last *does* seem to me strange, because it never did happen in my waking life—I don't see how it could, in fact. But I see nothing to wonder at in the fact that a person dreams that he does things which he would probably do in real waking life *if the same unexpected scenes occurred*. I only learn two things from it: 1st. That pinching, or writing, if done in waking moments, would prove no more than it did in the dream (as long as it lasts it proves nothing—only when it is found to have been fancy). 2nd. That what the eye (of imagination?) sees in dreams is wholly independent of the reason, and that the reason produces results (acts) which are attributed to a supposititious "will," acting under its guidance. **Crumby.**

BACTERIAL FERMENTS.

[26232.]—OUR next ferment is soon disposed of, as it is of not much importance in everyday life. B. subtile is somewhat like the butyric ferment, and is frequently mistaken for it at first sight; on further examination, however, the illusion is soon dispelled, for the properties of the two germs differ widely. In the first place B. subtile does not produce any products of fermentation like B. lactis and the butyric form; it grows very quickly, and, of course forms its structure from the medium in which it is living. Its great distinctive property from B. amylobacter is that it requires a comparatively large amount of oxygen to sustain its life. It secretes an enzyma or soluble ferment, which is capable of peptonising and dissolving albumen; a piece of white of egg boiled placed in contact with B. subtile soon becomes transparent and dissolves.

I am glad to find in "Ignoramus" another who is anxious to study this interesting branch of

pathology. The theory of germs demands much investigation and thought; any new fellow-worker is hailed with acclamation by the rank and file of bacteriologists. There is room for much research and discovery in microbian pathology, and none can say to what extent we shall be able, by patient observation and toil, to enlighten ourselves and the world. To prove beyond doubt that these minute forms of life are really the prime cause of many, if not all, of our maladies, will be one of the greatest struggles that scientific men of this day, and many days to come, will have. And, after all, I often think it will make us feel rather small to know that we, the "lords of creation" (save the mark!), owe all our ills to such an apparently unimportant factor as the presence or absence of a few minute germs. If we can prove that these germs do exist as the cause of evil, and are not the result of spontaneous generation, then to quote M. Pasteur, in his "Studies on the Silkworm Disease," "Man will have it in his power to cause germ diseases to disappear from the surface of this earth." And certainly it is quite within the reach of possibility that we realise the truth of this statement, provided we can find out an antidote germ or poison of a harmless nature to all but the germ that we desire to destroy.

We have, as an instance of antidote germ, the harmless common product of decay, Bacterium termo, which is able to supplant and destroy the dreaded consumptive microbe, Bacillus tuberculosus. Consumptive patients have been successfully treated by an Italian doctor, Cantani, by allowing the patient to inhale air containing B. termo, which settled on the lungs and supplanted the dangerous germ. We want to find the antidote germs for the various fevers, and such harmful bacilli as B. anthrax, the cause of "wool-sorters' disease." Disinfectants are at present used to kill off the fever microbes, and on the theory that most diseases are non-recurrent, inoculation with a modified form of the disease microbe is becoming a favourite mode of treatment for many diseases.

The introduction of an antidote germ gives an apt illustration of Herbert Spencer's theory of "struggle for existence." After all the parasite theory is an ancient one in medical science, and its revival by such men as Koch, Davaine, and Pasteur, has proved many of its former theories and added a vast amount of new truths and valuable information.

I would recommend "Ignoramus" to purchase, for general bacteriological information and the use of the microscope, &c., either an "Introduction to Practical Bacteriology," by E. M. Crookshank, M.B., F.R.C.S., (London: H. K. Lewis); or 'Microbes, Ferments, and Moulds," by E. Trouessart (London: Kegan Paul, Trench and Co.) Both books were brought out this year. And further, "Ignoramus" should possess Pasteur's "Etudes sur la Bière." The microscope that I use is by Crouch, cost £10 10s., and does all I want with a $\frac{1}{10}$th objective.

Wrexham, Sept. 4. **W. S. S.**

LAUNCH ENGINES.

[26233.]—I WAS much interested in the letter of "Engineering, Manchester." I have seen the engine mentioned by "R. N." The chief feature is that one slide valve controls the admission of steam to both cylinders. A large port is cast in the back of the slide valve, and this conveys the exhaust of the high-pressure cylinder to the low-pressure cylinder. The cylinders are, of course, tandem. Steam is carried in each cylinder for $\frac{9}{10}$ths of the stroke, which, of course, means that the expansion of the steam must be accomplished by the proportions of the cylinders. This accounts for the high ratio mentioned by "E. M." Also it is claimed for the engine that the very full admission of steam in each cylinder causes a very uniform effort on the crank, and I agree with "E. M." that is a great advantage, especially in a single crank engine. Altogether the arrangement is very compact; but I doubt if it is as economical as it would appear at first sight to be, for it is obvious that we lose the great advantage of a compound engine—viz., the reduction of losses by cooling—by dividing the extreme range of temperature between two cylinders. **G. D. Seaton.**

ENGLISH v. FOREIGN MICROSCOPES.

[26234.]—THOUGH calculated to benefit the English maker, I much doubt whether a "Briton's" letter will not bring about the contrary effect, with those who have to consult their pockets at least. For a price, the best English makers can hold their own, especially the stand makers; but how many such makers have we? Could they at present supply a fourth the demand? How many firms are there with a first-class reputation? When you descend to second and third-rate makers, the Englishman's price is double that of the foreigner. Need that be so? Must it always remain so? I say no. The circumstances are certainly in our favour if we choose to avail ourselves of them. The raw materials are here as cheap and as plentiful as on the Continent. Living can be made as reasonable, though three-fourths of our food is imported; our centres of industry are seaports, or near to them; our carriers and merchants can compete with the world. Why, then, can the foreigner under-bid us? Because he is better trained, more industrious, soberer, and more provident; because he takes more pride in his work, his calling, and his independence; because he does not encumber himself with domestic cares as soon as he is out of his apprenticeship; but wanders about from capital to capital, from shop to shop, and picks up new models, new ways, and new tools, learns languages, good manners, and gathers in a store of knowledge and experience, whilst his English competitor spends his good wages in acquiring expensive habits, improvidence, and carelessness.

The microscope, like many other instruments, is a *want* and a *luxury*. The humble student, the head of a numerous family, who feels the heavy item of education, only attends to the former. He wants an instrument for *work* and not for *show*; he listens to the recommendation of the professor, who, if worthy of his profession, has only the interest of his pupil at heart; but if mercenary, becomes the indirect agent of the seller, and receives a "tip" or commission. Let our makers attend closely to the strict wants and avoid superfluities. Taste and elegance are not incompatible with cheapness, and need cost no more than the clumsy, unsightly article. The exhibition of taste brings its own gratification in the process of manufacture; it elevates the worker to his dignity. I think that if our makers were to study a little more the ways of their formidable rivals they will benefit themselves and their country.

A. Caplatzi.

[26235.]—OUR friend Mr. Bottone (26212) has, to his own mind, settled the question, and finally put it out of the power of the British artisan to have a chance of living. Hold! friend Bottone—not so easily settled this matter. The "enormous disparity" no one denies, and those who have a practical knowledge of the trade, those who really can test and examine a microscope, also can and do aver, as I do myself, that the "enormous disparity" in the quality and value of the work is greater than the disparity in the wages. Indeed, Mr. B., the matter to my mind, if I went in for a summary settlement of it would be thus:—Although the foreign artisan works cheaper (perhaps not proven in this connection) he has not yet equalled the British one in making achromatic objectives for the microscope. Shade of Andrew Ross! What would it say to some of the ill-polished ("semi-worked" he would call it) achromatic lenses by the biggest Continental cracks now in the market. Workmanship is "out of the hunt." If our legitimate makers were to drop their standard to the same level they would simply spoil an English industry, for your English buyer, if of a *certain order*, would test all parts of the English instrument under the magnifying glass; while the foreign instrument would be passed through finger and thumb with closed eyes. Before leaving this part of the subject I do assert that not one of the German or French objectives I have seen (quite a number of the very best) is equally worked to contact where required; a lot of filling with the Canada balsam is requisite, and this in our best English shops is an important thing, and should be so, as stability of performance depends greatly upon this.

Can or does Mr. B. take an objective to pieces, clean out the lenses, and try for contact with strained balsam or "Newton's" rings. Then balsam the o.g., reset its parts, producing the best position, finally squaring the lenses in their cells? If Mr. B. does this, he will soon find how far behind that branch of work is compared with Ross, Powell and Lealand, and Beck and Becks. The public buyer can no more judge of the quality of a micro. o.g. than he can of a watch as far as its perfection of internal construction is concerned. An inferior watch may keep fairly good time, and look well outside. So with the objective; it may define perfectly at first, but a subtle power is at work in most foreign ones between the surfaces, and want of stability of performance is the result.

These two glaring defects of construction pass unnoticed, frequently unknown, by a lot of people who judge at the eyepiece end alone. I know there are at this present time being sold by some agents a quantity of French lenses of terrible make. These, of course, sell to the ignorant and bad-principled, and take their places in English instruments, thus thrusting out the well-made English lenses of the past. Produced by some wretchedly-taught designers of the slums of Paris, they are bought up by persons who know not the difference between a cast and a worked lens, and eventually rob our good workers of their bread; placing upon our shoulders, too, the discredit in the future of having worked them ourselves, a sort of fraud that "the industrious foreigner" will, I have no doubt, make all possible capital of.

Now, as to fine brass-work, nearly all foreign work is dependent on a daub of lacquer, most cleverly put on, for its outside finish. This is soon done, and has the appearance, *while it lasts*, of good bottom-work. The beautifully-prepared grain of the metal is, however, not there, as it is in the work of *our* best makers; and the result is that an instrument worked out in this way becomes a black, patchy, shabby affair in a short time. The working parts of mechanical staves in foreign microscopes are mostly dependent upon poorly-made fittings, as they cannot, at their prices, afford to discard bad fits. The foreigner (and here I give him credit for clever vamping) can, with a few dexterous taps with a polished-faced miniature hammer, so doctor a "bad fit" that it will work like a good one, until it is sold, at all events—perhaps for a year afterwards. Such vamping would never occur in our shops, as a price is generally charged that will allow of good work being done, and slippy, accidental pieces are consigned to the foundry again to melt up.

In conclusion—for I fear I am trespassing on your valuable space, sir—allow me to assert that the only reason why there is a difference in the prices of English and foreign microscopes is that most of the foreign work is "make-believe," while our own is genuine; and also allow me to assert that fair, honest inspection of the stocks of our own best makers will prove that foreigners cannot at *any price* equal us yet. Of course, a continual run upon foreign microscopes or other instruments will drive experts to trades in which the competition is fairer. Our microscope makers are capable men in any branch of metal work.

Hoping that the ventilation of this subject will result creditably for all "Britons," of which I have no doubt—however much Mr. Bottone and others interested in pushing in foreign stuff may arrange things to suit their own pockets. The English artisan, assisted as he is with appliances and machinery, to say nothing of a better physique, and an optical training dating a long way further back than his foreign competitor, earns more, does more work and better work. To deal with him means to deal direct—thus the agent's occupation would be gone. **Prismatique.**

THE THIMBLE BATTERY.

[26236.]—PERHAPS it may interest some of your readers to hear the result of a run with a little battery I constructed, which I have named the "Thimble Battery." No connections are visible except small thimbles protruding slightly from a frame, and filled with mercury, which carry the electrodes. The battery consists of eight small ebonite cells with small porous pots, two zincs, one carbon. The inner fluid, 3oz. of a chromic mixture; the outer, 9oz. of sulphuric acid and water (1 in 20). With this little battery I ran a 15 volt 5-c.p. lamp for 12 hours, and for a couple of hours more a lamp of less power. The cost of the charge was 5d. The zincs at the end of the run were quite clean and not much deteriorated.

I have had a battery of *large* cells running (with one charge) at intervals for some 54 hours, and lighting, alternately, dining or drawing room, hall, or orangery, as required, and is still in use for single reading lamps.

Sept. 6. **Charles Penruddocke.**

MIXED TRAINS.

[26237.]—I NOTE, p. 15, that Mr. Stretton quite agrees with the Board of Trade Circular that passenger carriages should be at the *front* of a mixed train. Now, Sir, I must disagree with both that gentleman and the Board of Trade. Suppose the train runs into another train, the nearer the passengers are to the rear the better. If they are put in front I don't see the advantage, and I note the *Engineer* writes in the same strain.

Anti.-Vac.

THE HEBERLEIN BRAKE.

[26238.]—MY attention has been called to a short notice signed "Brake," and published in this week's *Railway Review*, as taken from your columns, and which I now find is the answer to a previous query, No. 60096, and reads as follows:—

"The Heberlein brake on the Colne Valley does not fulfil the 'conditions.' In the first place, it is not fitted to the engine and tender."

I suppose I may take it for granted that the "conditions" here referred to are those laid down by the Board of Trade, and as they are, probably, better judges than "Brake" of the meaning of their own circular, I write to inform him and your other readers that, by a letter dated May 15th, 1885, we are informed by the Board of Trade that the Heberlein automatic brake on the Colne Valley Railway will always be retained as complying with the conditions!

The engines in use on that railway have no tenders, and it is exactly on that special point

(which has been overlooked by "Brake") that the whole question turns, as we invariably fit Heberlein Brakes to the tenders of any engines, and work them with the continuous brakes; but the engine driving-wheel brake (which, if not already present in the shape of a steam or hand-screw brake, we also fit on the Heberlein principle), is always treated as only available for the engine-driver as a brake for cases of danger.

Charles Fairholme.

Heberlein Self-acting Railway Brake Company, Limited, 18, St. Dunstan's Hill, E.C., August 31st.

RAILWAY SIGNALS.

[26239.]—I SHOULD like to know what our railway men have to say about how far a signal arm should go down. Should "all right" be the arm at 45° or right down in the post? What does "Libra" think of the Midland distant signals—a board turned on edge so that you cannot see it? Should a junction have one *distant* signal or two? Also, is it or is it not advisable to have a blue danger light for sidings? **Anti.-Vac.**

[26240.]—I SHOULD like to know what "Libra" thinks about distant signals. On the Midland we have got a lot of the "square discs"; when they are off, they are on edge—you see nothing. Should a signal-arm go right down into the post, or only down to "caution"?

We have got a lot of fixed signals: they are always "on"—there are no wires, &c., to get them off. When signals are on the wrong side, the green back-light of one is just in line with the green "all right" signal of the other. Now this is just the difficulty we have got to contend with. That signal at Binegar was on the wrong side: the driver, in the fog, looked on proper side by mistake; he missed it, and ran too far, and the signalman has got into prison over it—but it was all the bad signalling.

"Libra" (p. 576) says, "How if there are four lines?" Why, that is nothing; put all your signals on the "left-hand" of road, of course. Then there is another thing we have to contend with: some signals are very high: but the lamp is low down the post, so the positions of the day and night signals are different.

Some of your writers seem in a great hurry to attack Mr. C. E. Stretton personally on the proper position for signals: they don't seem to know that the railway men discussed the matter over years ago, and the "proper position" is insisted on by the Amalgamated Society unanimously, and even forms one of their 23 requirements. **Ajax.**

CONTINUOUS BRAKES.

[26241.]—I SHOULD much like to ask your practical readers to be good enough to discuss and answer the following ten practical questions so far as they refer to the Westinghouse and vacuum automatic brakes:—

1. Can the engine and tender (or two engines and tenders when two are employed), and every vehicle in the train be fitted with the complete apparatus for each system?
2. In case of accident, or if the engine and tender, and every vehicle were uncoupled, would the brake act automatically?
3. If the brake on one carriage is out of order, can it be shut off without affecting the apparatus on the rest of the train?
4. Can vehicles be uncoupled for shunting purposes, without trouble or delay?
5. In case of shunting vehicles when uncoupled from the engine, is the brake available either from the vans or automatically?
6. Is the brake instantaneous in action?
7. Can the brake be put on and taken off without trouble, especially upon long trains?
8. Does the brake cause trouble by using steam from the boiler, and does it cause extra consumption of coal?
9. Can trains be controlled when running down long inclines?
10. Are there any parts in the brake which give trouble or require improvement?

If some of your practical readers will come forward and answer, perhaps we may be better able to see how the Battle of the Brakes really stands.

A Railwayman.

LOCOMOTIVES, &c.

[26242.]—I AM reading all the letters on locomotives; but I must say I don't just yet know where the subject is going to come to a final ending, and I don't see that we are working in that direction. If I was a member of Parliament I should want to call order and ask correspondents to keep to the motion. I quite think, Sir, with Mr. Grey, that we have not the figures we want. What is the tractive power of the Mid., G.N., and L. and N.W. locos? How much coal and water a mile do they each use? What is the load in tons? the gradients and average speed? When we know this, then we can set to work to form a comparative idea of merit.

I am a very strong advocate of single-wheel engines with a sandblast.

"Q." speaks of Midland Nottingham express. Well, an engine with 19in. cylinders, 1668 class, ought to be able to run six or eight coaches to time. Surely one of the old 30 class of singles would run the trains without trouble.

What we want is some "single" engines, 19in. by 26in., 7ft. wheels, without bogies, 160lb. of steam, and 1,500ft. of heating surface, 18 tons on driving wheels, and a sand blast. **M. R.**

[26243.]—I CAN tell Mr. G. D. Seaton that the B.G. 8ft. run a stopping train each way between Bristol and Newton Abbot in their turn. The 7.10 a.m. from Bristol and the 5.28 p.m. from Newton Abbot are taken by Bristol men, whose opposite trips each way are on the up "Zulu" and down "Dutchman." I know that there are five or six of the Great Britain class kept at Bristol, besides a few old Bristol and Exeter singles, which are of two kinds, some very similar to the Great Britains, but with 7ft. 6in. driving wheels, the others being single framed 8ft. bogies. The Bristol and Exeter singles are so old that probably they will be withdrawn before long.

The run of the 11.38 a.m. Midland express between Birmingham and Cheltenham was a wonderful performance, considering the weight of the train and the rough road as far as Bromsgrove; but Mr. Seaton has given the mileage, via Camphill and Worcester, not by way of the new line out of Birmingham and over the loop from Stoke Works to Wadborough. It cannot be much over 46 miles, as run by the 11.38 a.m. and 3.12 p.m. trains, which, with the corresponding up ones, are the only passenger trains that use the loop line. I have travelled by the 11.38 a.m., and have remarked the very high speed between Bromsgrove and Cheltenham.

I cannot agree with Mr. W. B. Thompson in thinking "Kappa's" comparison (p. 527) hardly fair. Although the Brighton line is hilly, and there are many junctions, its very best express ought certainly to run faster than any company's fish train. The 5 p.m. from London Bridge only runs between two places, 50 miles apart. The fish train has come, perhaps, 200 miles before the L. and N.W. takes it over. The Brighton train is generally run by one of the Gladstone class of engines, the fish train by a Precursor, with wheels a foot smaller, less tractive force, and far less heating surface. I grant that the Brighton line is rough, and that there are many junctions; but are any of its inclines between London Bridge and Brighton anything like as long or as stiff as that between Low Gill and Oxenholme, and are not trains just as likely to be delayed at Oxenholme, Carnforth, and Lancaster, where there is probably more shunting of goods and mineral trains in a day than on the Brighton line in a week? The Brighton express is one of the very best appointed trains in the world, with selected carriages, and fitted throughout with the Westinghouse brake. The fish train may be made up anyhow, and has only the hand brakes to rely upon; and last, but by no means least, not only is there much greater probability of the weather being bad in the Tebay district, but if it is really rough it is generally rather different among the Westmoreland Fells to what it is in Surrey and Sussex.

I quite agree with Mr. Thompson's statement that a run from Rugby to Willesden in 91 minutes, with a 4-minutes stop in the middle, is a very fine performance indeed. As Mr. Webb's Precedents, which really are not very large engines, do such wonderful running, why cannot an enlarged edition of that excellent type be issued with 18 by 26in. cylinders, 7ft. wheels, and Dreadnought boilers? If as good in proportion to its size as the Charles Dickens, I believe it would beat any coupled engine going; but what I should really like to see on the L. and N.W. express trains is a 7ft. 6in. single, with cylinder and boiler capacity as above. For such an engine, London to Manchester in four hours ought to be a very easy performance.

D. H. P. Scourfield.

Williamston, Haverfordwest.

[26244.]—YOUR correspondent, Ghilleasbuig McTomae, says this week that the Caledonian company use the vacuum. Is he *quite* sure? If they do, it must be a new departure; for up till a very little time ago, they would have "nothing to say to it," as "Brake Block" has already stated. Will "G. M." be good enough to name a train on the Caledonian on which one may see it at work? Or will he tell us of one or two engines fitted with it? I have never seen or heard of any except one in the Edinburgh Exhibition, which has both the Westinghouse and vacuum brakes.

He then goes on to say, "They do not fit the vacuum on for the accommodation of the L.N.W.R., as there is only one through carriage in a regular way." Exactly. But the trains running over both Caledonian and L.N.W.R. are nearly all made up of W.C.J.S. coaches, which belong as much to one company as the other, and are fitted by each company with its own system. Notwithstanding this, however, nearly all the better Caledonian stock—coaches, horse-boxes, fish-trucks, and, indeed, everything that may be expected to run on N.W. passenger-trains, has been fitted with either the brake complete, or, at all events, the connecting-pipe, *simply to accommodate the North-Western.* If your correspondent concludes that the Caledonian use the vacuum from seeing some of their stock fitted with the connecting-pipes, he is no more justified than he would be if he told us the N.E.R. used the Clayton, because they have for years had a few carriages able to work in Midland trains to Bristol, &c.

Of course, fitting stock with brake apparatus to oblige another company is not the same thing as using that brake yourself.

I notice in this week's *Railway Review* that it has now been officially decided to make the L.N.W. brake into the automatic vacuum. The letter characteristically says that the N.W. trains are now to be fitted with *the best brake out.*

One recognises at once the familiar "cocksure" phraseology of Mr. Moon, who for so many years applied the words to the chain brake. Three years ago, however, he told his shareholders he was going to replace the best brake out by a better—viz., the Smith Vacuum, to which was, of course, attached the magic "F. W. Webb's patent." This system soon was brought into prominence at Penistone, and directors began to think that even "the best brake out" was hardly perfect yet. Still, £110,000 was thrown away before an accident nearer home—at New-street last May—showed them that if they meant to stick to their present idea they must be prepared to set aside good round sums for compensation and replacing damaged stock, &c., resulting from the brake failing and playing expensive pranks with the trains. This they appear to be rather afraid of in these days of bad dividends, so are now about to take up the automatic vacuum as used on the South Western and other lines. This, notice, is now the best brake out. How long will it remain so?

As each of these systems has been in existence contemporaneously with the others, one would rather like to know what the N.W. people mean by "the best brake out"? I suppose it is a euphemism for "the brake we have decided to adopt for the present," as the words seem to be applied without the slightest regard for fact. Why not admit at once that the Westinghouse is the best system that has ever been put into the field, and adopt it at all events, till something better be invented?

The last brake used on the line has been in favour just about as long as the small compounds, and I suppose the unfortunate shareholders must submit to see their £110,000 thrown away from time to time in adopting similar fads, which must in the course of nature be almost immediately discarded when applied to practical working.

I see there has been another series of brake trials in America, in which the Westinghouse, as elsewhere, has been proved distinctly superior to any of its rivals. One feature of the trials I thought rather novel: the brakes were tried on a train of *fifty* vehicles, and were found satisfactory only in the case of the Westinghouse.

In face of such arguments, it seems beyond comprehension why our greatest companies should be the slaves of an absurd prejudice as to spend untold sums on systems that don't profess even to be its equal. **W. B. Thompson.**

[26245.]—CAN anyone give me particulars of the new 7ft. 8in., inside cylinder, on the Great Western Railway, No. 10?

In my letter 26091 I had written "four and a quarter hours." Through a printer's error, therefore, my letter seemed to misrepresent Mr. W. B. Thompson in 26070. I see, however, no reason to withdraw my statement about the L. and N.W. being able to run to Manchester in $4\frac{1}{4}$ hours over the Midland gradients.

My reasons for stating that I did not consider 91 minutes from Rugby to Willesden (with one stop and 12 coaches) the limit of a L and N.W. engine's performance are—(1) That I have myself come from Rugby to Willesden in slightly over Mr. Thompson's time with 19 coaches and one engine (Precedent). (2) That Avon (Precedent) ran one day with eight coaches this $77\frac{1}{4}$ miles in slightly over 80 minutes. (3) That I have made runs with Compounds on this line which, by comparison, are fully equal to Mr. Thompson's runs in 26070. Some of these I may publish *in toto.*

It is but idle discussing points with Mr. Seaton if he will not be serious. Surely he does not expect anyone to receive his statement (26136) that "loads of 17 to 19 are nothing for such expensive and heavy engines" in sober earnest. Mr. Seaton seems to be ignorant of the fact that Tring is almost exactly as much above Euston as Lea-

grave (the highest point between London and Bedford) is above St. Pancras. *As much ground must be climbed in one case as in the other.* The Midland certainly rises more steeply; but it must be remembered that the long steady pull of about 1 in 400 from Willesden to Tring tells nearly as much on an engine as two short five-mile pieces of 1 in 176 and the rest gently rising, falling, or level.

It is as well to be accurate in making statements, and I may remark that Compounds are not *always* banked up from Euston to Chalk Farm. A few nights ago Harpy took out 21 (12-ton) coaches without pilot or bank engine. A start on a bank of 1 in 70 with this load looks like business.

Mr. Seaton is again wrong in saying that I think highly of the N.W. Compounds. I candidly confess that I do not. I am animated with a desire to give justice, and nothing more, to these engines. In my recent letters I have simply endeavoured to notice a few good traits in these engines; but I am sorry to say that your correspondents (or many of them) seem to have made up their minds to hear nothing of the Compounds nor of their few good works.

I am sure that Mr. Speed will, before this, have seen how hastily he made certain remarks in the eighth paragraph of 26127. I do not think Mr. Speed has any right to use the words "unjust and false" in reference to my remarks on Midland punctuality unless he is prepared to prove his case by observations as comprehensive as my own. This I am afraid he will be unable to do—Rugby is a bad place to see Midland unpunctuality. When I tell Mr. Speed that the arrivals of every train at Euston, St. Pancras, Carlisle, and Liverpool are at my disposal, he will at once see that my opinion on the subject must carry greater weight than his—simply because my means of judgment are far greater than his own. I have given long and great attention to punctual arrivals of trains, and my judgment on the Midland must remain. In my statement, "the Midland trains are timed so fast that they cannot even now and then keep time," I do not mean to cast any doubts on the engine. In several of my letters, indeed, I have given great praise to the Midland locomotive (see 25777, 25959, 26020, and 26046).

In compiling a time-table much more than the capability of the locomotive should be allowed for. If signal and other stops, for instance, are known to be frequent, then a minute or so must be allowed for them. For instance, there are several Midland trains, London to Liverpool, which are timed at a good pace between Marple and Liverpool. As there are several conditional stops to be made (and they generally are made), the result is that the express never keeps time between Marple and Liverpool. Again, look at the conditional stops from Bradford to Leeds by the Leeds expresses. Is it possible for any engine to do 13½ miles in 20 minutes with about five conditional stops included? I say it is not possible. These and other instances might be expanded to prove that traffic arrangements, &c., frequently (I might may, generally) are sufficient to ruin the performance of any engine on the Midland Railway. It therefore comes to this, that if the Midland people wish to be as punctual as their competitors, then either most drastic measures must be taken to obtain for the expresses a clear road, or a few minutes extra should be allowed to those expresses which are known to be troubled by incidental stoppages. A general rearrangement of the time-table is also eminently desirable. I could point out off-hand quite a dozen instances where one train is timed seemingly for no other purpose than that of impeding another.

I would point out to "Gorton" (26152, first paragraph) that the work of N.W. and Midland engines is not the subject of discussion. Punctuality is the subject in hand.

I should very much like to see "Q.'s" run from Nottingham when he made up 25 minutes. Unless complete details are given, I must express myself that I think there must be some mistake somewhere.

Mr. Thompson (26155) is quite right in pointing out that although advertised as Scotch trains, the 5.15 a.m. and 12 (night) from Euston are not through trains to Scotland. It is very misleading, and so also is it misleading that the 5.15 a.m. St. Pancras, with through Manchester coaches only, should be advertised as for Leeds, Glasgow, and Edinburgh, that the 3.40 p.m. (Mancr. and Liverpool) should be advertised as a Leeds express, and that the 12 (night) should be advertised as a through Scotch train, when changes have to be made at Leeds, Hellifield, and Carlisle before Scotland is even entered upon. P.

MIDLAND EXPRESSES — LOCOMOTIVES.

[26246.]—As regards the question of Midland punctuality, I quite agree with "P." and others that the Manchester is the only punctual service into London. The morning Scotchmen are the most unpunctual trains I know of. The Leeds expresses are fairly good, however, except those due St. Pancras 3.0 and 5.50 p.m., which are rather erratic in their movements. I saw the former arrive on Saturday, 21st, at 3.23, and also recently travelled by this train, arriving 18 late. On the other hand, the 7.50 p.m. is almost invariably punctual or before time.

I believe it is the fact that Midland down trains are punctual as a rule, but as regards the up trains there can be no question about the matter, whatever "Q." (26160) may say. Whatever the cause of this unpunctuality may be, I feel perfectly certain it is not the fault of the engines. Everyone knows the Midland engines are among the very best in existence, and when travelling by the Midland I always find the engines keep time—indeed, they generally make up time. I fancy that when Midland trains are late it must be due to signal stops, of which travellers generally experience such an abundance. For instance, the 3.0 p.m. down Leeds gets stopped about Sharnbrook something like five days out of seven, and the 12.20 down is also stopped there, but not so frequently—say three or four days out of seven.

Taken as a whole, the Midland Railway is as nearly perfect as anything human can be, and it is a great pity it is disfigured by unpunctuality of the trains I have alluded to.

I agree with "P." that the Midland mile posts are most confusing. They should all be numbered from London (where possible), whereas between London and Leicester alone they are numbered from three different places. It will be of service to those who desire to time M.R. trains to learn that Bedford Station is 65 chains north of post 49, and 72 south of post 17.

I recently made the following run, and consider it an excellent specimen of the locomotive performances of the Midland.

m. ch.		h. m. s.	Speed.	Remarks.
	St Pancras	10 10 38	—	due 10 10
1 52	Kentish Town	10 15 11	—	„ 10 14

The 13 coaches were made up as follows:—Van, two 12-wheel bogies, Pullman, van, two 8-wheel bogies, van and slip coach for Luton. The Pullman and 12-wheel bogies are counted as two, and the 8-wheel bogies as one and a half coaches. There was a moderate breeze with occasional showers.

I should inform Mr. Thompson that, in addition to the run I quoted of the North-Western fish train, the same train runs at 42 miles an hour Carlisle to Tebay (37 miles in 54 minutes), the line rising 845ft. in the first 30 miles. It runs at 45 miles an hour Rugby to Bletchley, and 46 thence to Camden goods station, which it reaches in 7 hours 9 minutes from Carlisle. We all know the compounds are worthless, but Mr. Thompson should not let his indignation against them blind him to the general excellence of the N.W. It is rumoured that the Chinese are thinking of building railways. The N.W. compounds could well be spared, and they would be capital engines for that ancient people to make a beginning with.

The following is extracted from a Pennsylvania paper, the *Bucks County Intelligencer* of August 14th:—"Another of the new style passenger locomotives being built by the Philadelphia and Reading Railroad Company, was taken out of the Reading shops on August 6th on a trial trip, which proved very satisfactory. This engine is intended for the Bound Brook division, and is mate to the one turned out some weeks ago, and which made the remarkable time of a mile in *forty* seconds"—90 miles an hour. Those who are of little faith may possibly doubt the concluding statement.

Kappa.

THE density of liquid atmospheric air has been found to be 0·59 at 146·6° Cent., and 45 atmospheres of pressure. Calculations from the densities of liquid oxygen and nitrogen give the figure 0·6.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[59762.]—**G.W. No. 9 Compound.**—Yes, I mean the 7ft. 8in. single, with eccentrics outside. I thought she was a compound. I shall be much obliged for full dimensions as well as sketch. I cannot quite understand the valve gear. NORTH-WESTERN.

[59842.]—**Effect of Time on Chances.**—My best thanks are due to "R. E. F." for his beautifully neat and simple method. I had searched through all available books on the subject for an explanation without success. In reply 59842, No. 1,119, p. 17, eighth line, ·069 is obviously a misprint for ·69. I was not aware that I had suggested any such table as "E. L. G." gives in No. 1,119, p. 13, nor do I see its utility. What I wanted was a table with which questions like the following could be solved by one multiplication only: "If the odds against success in one trial be 100 to 1, in how many trials will the odds be only 5 to 1 against?" It is evident that "R. E. F.'s" table is capable of far more extensive application than "E. L. G.'s," which merely gives two or three particular cases. I must beg "E. L. G." to excuse me answering his query (60318, p. 23), because I cannot understand it in the least.—ALIOTH, Earl's Court.

[59842.]—**Mathematical Probabilities.**—The notions of querists like "J. M." are gradually clearing themselves, and his last query, p. 582, is a very clear and usual one; almost daily blundered over, though quite simple, and always easy with logarithms, but hardly soluble without them. If we say the chance against a thing happening at one trial, or in a given time, is a to b, this is calling its improbability $\frac{a}{a+b}$, or its probability $\frac{b}{a+b}$. The two chances for and against anything are proper fractions, and their sums must be 1. Now, looking at the larger of these, the effect of doubling the trials, or the time, must be to square this fraction; and the effect of multiplying the trials or time by n, to lower it to its nth power; any power of a proper fraction being less than its root. If it be 20 to 1 against a thing happening to-day, and we ask in how many days this will be reduced to a proposed smaller odds, say 2 to 1, this is asking what power of the fraction $20 \div 21$ will be as little as $2 \div 3$, or what is the value of x in the exponential equation $\left(\frac{20}{21}\right)^x = \frac{2}{3}$. But, to avoid negative logarithms, we may reverse it thus: $\left(\frac{21}{20}\right)^x = \frac{3}{2}$. If we asked in how many days the chances will become even, we have similarly to find the x in $\left(\frac{20}{21}\right)^x = \frac{1}{2}$, or (what is the same), in $(1{\cdot}05)^x = 2$. Or, if we ask in what time the odds will be reversed, or be 20 to 1 that the thing does happen once at least, we have to find what x applied thus $\left(\frac{20}{21}\right)^x$, will bring it down to $\frac{1}{21}$, or, in other words, would raise $(1{\cdot}05)^x$ up to the value 21. This we do by simply dividing the logarithm of 21 by that of 1·05. Thus, 1·3222193 $\div$ ·0211893 = 62·4. In 62·4 days, then, the odds about the first day are reversed; or in 63 trials it becomes more than 20 to 1 the thing will happen. But as for "J. M.'s" question, in what number the adverse odds of 20 to 1 are reduced to 10 to 1, we may, to all practical intents, say simply 2. For though squaring the $\frac{20}{21}$ gives strictly $\frac{400}{441}$, this is so near ten-elevenths that the defect is not worth regarding. The effect of prolonged time, however, in converting improbability into probability, and this to an extreme degree, is most unexpected, and often more difficult of belief to those who guess without calculation than any of the geometrical progression paradoxes, the corn for the inventor of chess, &c. A case, perhaps never to be equalled, occurred in an early number of Mr. Proctor's *Knowledge*, while he was giving its readers a series of lessons on "Probability Reckoning." A report had got abroad, he said, that he thought the earth likely to run into a certain comet's head in about 15 years. He wished the world to take notice that he thought such an event more likely to be deferred 15 million years than to happen within 15. Now, the chance of its occurring in any decently businesslike term, say 15 years, is decidedly small—perhaps smaller than any of us would guess. Prof. S. Newcomb compares it to the probability of a blindfold man, by firing a gun upwards, killing

a bird. But, given the frequency and sizes of birds, and of his shots, of course that would be calculable; and so is the earth's chance of comet-shooting, with given statistics of her and their sizes, orbits, and frequency. Taking that of all those observed, and those known to have come but not observed, in the quarter century that the Danish prize for discovering any existed, I made out a centurial average of safe and unsafe ones, or those crossing and not crossing our orbit; and that (by the statistics of the sizes and paths, not of those in that period, but in all history) the odds against our running into one within a year are about 230,000 to 1. That would make the odds against our doing so in 15 years, 15,332 to 1; because the bringing fractions so small, or so near unity to their 15th-power, or even their 100-th, does not practically differ from adding or subtracting 15 or 100 times. But we have to compare this big fraction, 15,333 ÷ 15,334 with its millionth power. Its logarithm (or say that of its reciprocal) the difference between log. of

	15334 =	4·1856555	
and of	15333 =	4·1856271	
comes out		·0000284	
which, × 1,000,000, gives		28·4	but the
log. of a quadrillion is		24·0	
or is here exceeded by		4·4 = log. 25,118.	

That is, the odds against Mr. Proctor's supposition, the earth's avoiding all such encounters during 15,000,000 years, are above once and a-half as many quadrillions as the odds against one occurring within 15 years are units! Was there ever another guess, I wonder, or will there ever be, by calculator or rustic, so unlucky as to err beyond a quadrillion-fold?—E. L. G.

[59842 and 60052.]—**Box Filled with Spheres, &c.**—What I called paradoxical was that we may have two numbers of shot, of which the less number, if they are to fit into a rectangular case, need a larger one than the bigger number needs. Of course they will go into the box prepared for the bigger number; but they are to fit, or leave no room for another. Let "G.," or "Linkum Doddie," make, for instance, 364 fit into a case no bigger than the cube that holds 365. Now, as to my way of answering "J. K. P.," he having introduced, and referring only to these rectangular spaces, wanted to know whether, for those to hold "a large number," the base layer should be like that of a triangular pile or square pile. It must resemble neither (at least where more than 35 are to be held), and this is what I undertook to show, but which "G." has never hinted, and wrote p. 558 without knowing (though rightly correcting me about the smallest number). The remark that he says "incidentally answered 'J. K. P.,'" could not, for it was one that "J. K. P." had already made. As for my inventing a formula "wrong for any kind of pile," no kind of pile was ever in question, and it is right for all such spaces as were in question—namely, rectangular, and holding "a large number." I said, for safety, 40; but, in fact, any over 35. My square or oblong tubes, to run various ways, were doubtless a clumsy, roundabout way for showing that no face of a box must be a honeycomb layer, nor any edge a close row; but these were points essential to prove, and which "G." has never even stated. So they could have nothing to do with covering retreat, "fireworks" or not. A shorter way, perhaps, ought to have sufficed—namely, pointing out that the close rows of balls run in six directions and no more, all being visible at the six edges of a tetrahedron pile; that each of these is perpendicular to the opposite one, but never to more than one, whereas the edges of a box are in three directions, each perpendicular to both the others. Hence no such three can ever be found among the former six, and as the three box-edge directions thus cannot all be those of close rows, "J. K. P." might conclude, on the "principle of sufficient reason," that none of them should be so. He needed no telling that each ball, in any layer, must touch four in that layer; but this by no means makes the square layer, as "G." says, merely one of those in a square-set pile "looked at diagonally." That in the pile is bordered all round by close rows, and turning this diagonally will not make a square, none of whose border balls are in contact. And the former consists always of a square number, which the latter never does. If square in plan, it has to contain either the half of an even square number, or half of an odd one ± ½. As for the directions that I called cleavage planes, though "the most uncleavable of all," if you choose to go "right through the centres of a plane of balls," that is necessarily so with all directions so called. I maintain it is their right name, nevertheless. A crystal of salt, fluor, or alum, doubtless thus built, does cleave in those seven directions only. "F.R.A.S." was mistaken about anything having been "only fun"—mine or anybody's.—E. L. G.

[59961.]—**Frosted Letters on Glass.**—Seeing no correct answer to this query, I recommend "D. R." to use fluoride of ammonium. It is easily made by adding carbonate of ammonia in crystals to hydrofluoric acid till effervescence ceases or nearly so. It will leave a matt surface instead of the clear and almost invisible lines left by liquid hydrofluoric acid. A common steel pen will answer in writing on glass. The action is almost instantaneous. A body may be given to the fluid by mixing in it finely-pulverised sulphate of baryta (heavy spar), lessening a tendency to spread from the pen. This mixture has been sold under the name of "Diamond Ink" in small bottles at an absurd price, as its composition has not been generally known. It will be found a great convenience by all experimenters using glassware, also for lettering microscope slides, &c.—W. MAIN.

[60005.]—**G.E. Locos (U.Q.)**—I can tell Mr. Campling that those engines in the Norwich accident were so broken up that they did not pay to rebuild, and were replaced by new ones. The others he refers to are not about to be broken up; there is a lot of good work in them yet.—G. E. R.

[60027.]—**Varnish for Violin.**—Many prefer to stain to the desired colour, and then French polish; but if you must have an oil varnish procure the best pale amber, such as is used by the coachmakers. A variety of recommendations will be found in back volumes, but most people, I think, prefer a spirit varnish. Recipes for stains and a varnish on p. 538, No. 776.—NUN. DOR.

[60029.]—**Specific Gravity of Liquid Potash.**—Procure a Twaddell (or Tweddell) hydrometer from dealers in instruments of the kind.—ALKALI.

[60044.]—**Pressure on Pipes.**—Most of the formulæ required to solve this problem have been recently given in other answers, but they can all be found in Molesworth's Pocket-book. As the query stands, it is a very pretty sum, which would take a little time to work out.—J. K. M.

[60045.]—**Estimation of Sugars.**—I would venture to recommend "G. J." to procure Landholt's "Handbook of the Polariscope," published by Macmillan. He will find it useful.—LIBRARIAN.

[60048.] — **American and other Tinned Meat and Fruits.**—The question has been frequently answered. The object is to raise steam inside the tin, which drives out the air, and when sealed and cool there is a partial vacuum. To do that the cans are placed in a bath of chloride of calcium or brine, or some other liquid which does not boil until a temperature greater than 212° Fahr. is reached, and when steam has issued freely from the hole for a minute or so a drop of solder is placed on it and the sealing is complete. Some of the fruits are, however, preserved in syrup.—NUN. DOR.

[60050.]—**Shot Paradox.**—The object of my putting the above query was to ascertain whether those who have evinced an interest in the subject of piling spheres were aware of the reason for what, in the "Book on Building," to which "E. L. G." first drew my attention, in note, p. 180, is called "singular"—viz., that the air-spaces are of the same capacity in either arrangement. This passage set me examining the subject at the drawing-board, and I soon discovered that the arrangement of the interior of a mass of spheres is the same in whichever of those ways you commence laying them, and this is what I thought must be the case if the "singular" circumstance of the equality of the air-space was a fact. I am even now not sure that "E. L. G.," or the other "G." either, has shown in his answers that he is aware of this, confessing, as I must, that I do not understand "E. L. G." on p. 583, when he talks of seven directions of cleavage, &c., which may possibly include the evidence. No doubt the honeycomb is the closest possible arrangement, but that does not exclude the "chequer" from being as close. I fancy that the calculus is required to show the fact of the honeycomb being the closest possible demonstration of which may be found in Hall's "Differential Calculus," p. 88, which may answer "Linkum Doddie." "E. L. G." has even now not given the solution of the "Shot Paradox." I concern myself with "space," not with boxes or tubes, or cubes, and asked for a solution out of mere curiosity.—J. K. P.

[60050.]—**Shot Paradox.**—The paradox is confined, as far as I now see, to pairs of numbers of which the larger is half of an odd cube + 1, as 365, or 666, or 1099. "Linkum Doddie" may readily see that the farther we depart from a cube, the more waste, because, as "J. K. P." said, and "G." more recently, planes through the centres of all the outer balls inclose a space within which there is no waste. Whatever its figure—cube, tetrahedron, octahedron, or part or prolongation of any of these—the matter will be the full maximum of ·74, &c. All the falling short of this ratio is confined to an outer layer, the depth of a ball's radius. Hence the fewer outside balls, compared to inside ones, the less waste. The only figures of box that will economise more than a cube are those coming nearer to a sphere—namely, with 14 faces, 6 squares (whose corners approach each other), and 8 either triangles or hexagons; preferably neither of these regular figures, but alternate-sided hexagons, as nearly equalling the squares as may be. The only rule I can suggest as to the number for a rectangular box, is that its double, or else its double less 1, must be resolvable in three factors, preferably all odd, and the nearer alike the better. Thus $2 (501) - 1 = 13 \times 11 \times 7$. There is more waste than in $2 (500) = 10^3$, because more outside balls.—E. L. G.

[60052.]—**Painting on Silk.**—Have you tried isinglass size?—T. P.

[60073.]—**Battery.**—To "G. D."—(See end of this No. in Replies, October 3, 1883). Leclanchés, so made up, with agglomerate blocks, are rather better than those with porous pots, because their internal resistance is less. Zinc plates give a larger current at any particular time than rods; but the total life of the cell is the same in either case, being just in proportion to the work done.—E. CONRY.

[60095.]—**Westinghouse Vacuum Brake.**—This brake was fitted to the Grosvenor locomotive and 15 carriages at the Newark brake trials in 1875. It requires an apparatus the same size as an air brake by use of the triple valve. It has a 1in. brake pipe. The Westinghouse Co. tell me it can either have a pump to work out the air or a steam ejector. It has an auxiliary reservoir. Certainly I should think it would give better results than the Gresham, because the triple valve is not so liable to stick as the ball-valve. From the description it can be seen that it can be worked with the air-brake.—TRIPLE VALVE.

[60136.] — **Galvanic Battery.** — "Holt's" queries have only just come under my notice, or I would have replied before. (1) I generally use the battery for about an hour and a half at one time, then lift out all the couples, and leave them till wanted again, and I find I can do this for ten or twelve times before it is absolutely necessary that I should clean and resilver them. (2) I have never found it necessary to encase the couples in any material, and I do not think it would have the desired effect. (3) My rack is merely a frame made of four pieces of wood with crossbars of same on which the couples are hung in such a position that each one will drop into its place when the rack is lowered. (4) A galvanometer is not necessary; the sensation experienced when the sponges are applied to the skin being a sufficient test. (5) A large number of cells is required, because intensity is required with very small quantity. No doubt a battery of Leclanché or any other cells would be equally useful, and the Leclanché far less trouble to keep clean, if they could be got small enough; but I think that a few cells of the ordinary size would raise sores on the flesh and yet not penetrate to the seat of the disorder. The battery I have in use at present consists of 56 cells. These cells are made of beeswax and blackened, a plan I adopted in order to economise space, and saves weight. The couples are ½in. wide and 2in. long, and can be lowered into the liquid just as far as can be borne without discomfort by the patient, and this will depend a great deal upon the cleanliness of the battery at the time, also the parts to be operated upon; the spine, for instance, taking a much stronger current than the face. With this battery I have cured scores of cases of neuralgia, and have never failed in any case; and if "Holt" is within reach of South London, and will advertise his address, I shall have pleasure in showing it to him, or even in curing his neuralgia, if he is so unfortunate as to have it.—W. S. W.

[60143.]—**Thames Steamers.**—I find I can answer some part of this query. I am told by the pier-men *Merlin* has been broken up—when, I don't know. The pier-men tell me *Citizen A* is still running, and *Citizen B* is still running, as I saw her on Wednesday night.—TRIPLE VALVE.

[60153.]—**Waggon Couplings.**—Seeing this query still unanswered, I give following description of Attock's coupling. The hand being placed on the rod, and then turning it, the coupling link becomes released from its position, and the rods, being actuated by a lever, the coupling can be stretched out to its full extent; or, if the waggon buffers are close together, full control is obtained over the links, so as to couple or uncouple in any position. One of the main advantages in the links being suspended on the drawhook is, that in cases when waggons are fitted with spring buffers and they are buffed up, the drawhooks sometimes become so close together that there is not space sufficient for the link to pass between them when the coupling is hanging below; in this case the engine will not have to separate the waggons before they can be coupled. On page 220 I gave "Inquirer" (letter 59460, p. 202) a description of Betteley's coupling. I could not give him a description of Wheeler's; but now will. The

following is the description of Wheeler's, in reply to above queries: The apparatus is fixed at each end of the waggon, immediately beneath the head-stock, by hangers or brackets, which are bolted thereto, and consists of a transverse bar, having keyed thereon a series of short levers consisting of four in number. A light transverse operating bar extends, and is attached, to these levers across and from side to side of the waggon, carrying in the centre two arms which have their fulcrum upon the extremity of two of the short arms or levers, which enables the operator, by moving the hand lever at either end of the cross-bar, to raise or depress these two arms, also to enable him to move them in a longitudinal direction. At the extreme of the arms is attached a simple and effective trunnion bolt, which grips the end link of the coupling chain centrally, and allows it to accommodate itself to any form of drawbar hook, thus assuring a successful operation to couple or uncouple without danger to operator.—TRIPLE VALVE.

[60160.]—**Varnish for Clay Pipes.**—If "O. W." will use a solution of silicate of potash, about as thick as gum, he will have a glaze which will suit him.—PAUL WARD.

[60167.]—**Working Drawings of G.N. Expresses.**—Mr. Lee, of 76, High Holborn, has a set of six detailed working drawings of the G.N. 8ft. single; full size of model 1in. to 1ft.; the price is £1 1s. I have no doubt Mr. Lee will be happy to supply further information to your correspondent. —TRIPLE VALVE.

[60175.]—**Induction Coil.**—If "Induction Coil" will tell me the exact disposition of his two lots of secondary, I will help him, if possible.—PAUL WARD.

[60179.]—**Gelatine.**—These sheets are made by pouring a solution (hot) of clear gelatine (coloured when desired by the anilines) on to sheets of glass properly levelled, if thick sheets are wanted. If thin, the glass is coated as a collodion negative, and the excess run off.—PAUL WARD.

[60186.]—**Mathematical.**—As I notice another correspondent ("Toodles") has given an answer identical with mine, I should like to point out that we have both apparently misunderstood the question, or overlooked the fact that the 3 balls can be arranged in a triangle but diagonally in the box, which would, therefore, be, as "E. L. G." says, $10\frac{1}{4}$in. each way. But there is a lot of waste space in it, and the other two sizes are alternative and smaller, but not cubical boxes.—T. C., Bristol.

[60190.]—**Leclanche for Quantity.**—Thanks to the friends who have noticed this query. I am sorry I cannot perform the suggested experiment with a short, thick coil galvanometer. The fact is, with one cell connected to my "quantity" instrument, the needle deflects to the full extent of the scale. To get it within readable limits, I have to insert 30 ohms. This gives a greater external resistance than the instrument referred to in my query. As I cannot get satisfactory results, would some one having the proper appliances please try the effect of increasing the size of the zincs, and publish the results at the first opportunity.—M.M.I.Sc.S.

[60194.]—**Strawberries.**—My experience of strawberry culture (supplementary to "Gardener's" reply) has proved that once in three years is often enough to dig up and remove the plants. The first "runners," if pegged down and slightly manured, ready for separation at the end of a couple of weeks, and not transplanted till the first wet day or two in early October, or late in September, *will bear fruit* the *next* year. If "our" "Lady" has her beds bordered with strawberry, she will need to renew *every third plant* each year, to maintain a fair supply of fruit. Decayed leaves, &c., must be removed as soon as decay sets in; but this year's leaves *should not* be cut down until the spring ones are well grown. The foliage of plants is a necessary provision of nature, like the bark of trees, for nourishment to the vital parts; and the shelter afforded to the heart of the plant by the broad, old summer leaves is essential to next year's vigorous growth. Guano—yes, if expense be no object; but everybody has command of quantities of liquid manure, in the house-slops, and the dirtier suds and rinsings are the more plant-nutriment is in them, and the more will they bear dilution with water. Of course, no one will let impure liquid touch the foliage or fruit.—H. P. B.

[60204.]—**G.E.R. Locos.**—With reference to the six-wheeled tanks, I know little more than I stated in letter 26129; but the older of the two classes of these engines was, I believe, designed by Mr. Johnson, and has leading and driving wheels coupled 5ft. 4in. diam., trailing wheels 3ft. 9in. The four-coupled express goods engines are Nos. 255—264, Hawthorn and Co., 1877, and Nos. 265—274, Dübs and Co., 1876. The 6ft. four-coupled outside cylinder engines run from 307 to 416, and of these the following have a bogie: 308, 311, 314, 317, 320, 324, 327, 329, 342, 349, 360, 366, 370, 381, 385, 406, 412, and 416. I believe there are one or two more; but the above are all I know. Nos. 140—145 (Hawthorn and Co., 1880), are front-coupled bogie tanks; and 686-689 (Stratford, 1884) are Mr. Worsdell's six-coupled goods engines. I have not a complete list of makers of 7ft. singles; but 0299—0304 were built by Schneider.—EAST ANGLIAN.

[60205.]—**Compound Engine.**—Thanks to "T. C., Bristol," and "Engineering, Manchester," for their replies to my query; I forgot to put the steam pressure, which will be 80lb. or 100lb. As room is no object, will it be advisable to make the engine a horizontal tandem, the l.p. cylinder behind the h.p. one. In your reply of Aug. 27 the pressure is taken at 50; with the extra pressure I am using will the l.p. cylinder have to be made larger than the size stated, viz., $3\frac{3}{4}$in.? Also, will a receiver be necessary for the steam; or can it be taken straight to the l.p. cylinder? Are two eccentrics necessary, or can it be worked from one? I have given up the idea of condensing as there will be too much work, and as I live in the country I can turn my steam where I like. Any information respecting the above will be gratefully received. I apologise for not thanking you last week (being away from home) for your interesting replies.—H. R. W.

[60237.]—**Steam Hammer.**—I simply gave a $2\frac{1}{2}$ H.P. boiler as being about the smallest size to put in a works, and it would really supply half a dozen hammers alone; but taking your figures as now supplied, the volume of steam required would be as follows:—Assuming cylinder 12in. × 7in., as I forget the size you named, volume of cylinder $= \frac{7^2 \times \cdot 7854 \times 1}{144} = \cdot 26$ of a cub. ft. multiplied by number of double strokes per min. $= 70 \times 2 = 140$. This makes only $140 \times \cdot 26 = 36$ cub. ft. of steam per min. at 60lb., neglecting cut off; but you would be a smart workman to keep the hammer going at that rate for any length of time.—T. C., Bristol.

[60244.]—**Air-Gun Trigger.**—The accompanying sketches are half size, and will show the arrangement without much explanation. The trigger

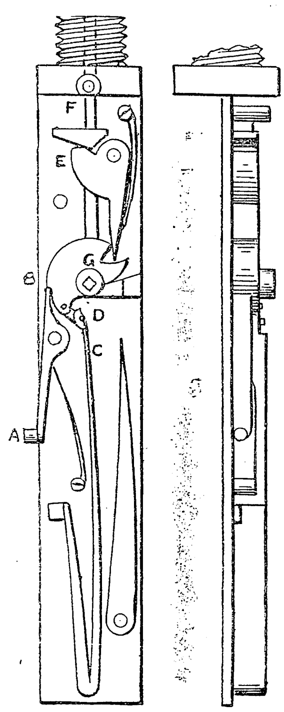

FIG. 1. FIG. 2.

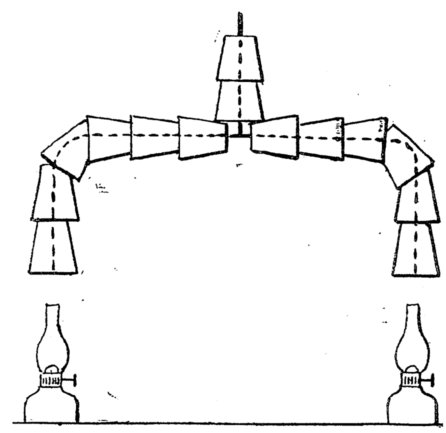
is not attached to the valve, it (the valve) being on end of air chamber not shown. The plate for keeping parts in place is removed on purpose to show the levers and springs which are represented "full cock." On pressing the knob A, which projects through outer case of gun, it releases the lever B, the spring C pulling round lever B by a shackle D, throwing forward lever E, the gin F striking the point of valve. A spring on end of valve spindle instantly throws back pin and lever in readiness for cocking. The square hole G being used for that purpose, a key is inserted through outer case, and turned to the right. Fig. 1 is a side view of trigger.—R. L. READDIE.

[60246.]—**Heating Small Conservatory.**—Gas and petroleum are both successfully used to heat small conservatories; but as it does not do to burn the gas inside, it is used in connection with a boiler and hot water pipes. The boiler is either constructed of spiral tubing, which raises heat very quickly, or is of the ordinary saddle form. For the latter I would recommend Fletcher's oven burner (7s. 6d.) as the most economical. If the



greenhouse covers less than 100 square feet, ordinary petroleum lamps will suit, arranged with flower-pots in the above fashion:—B.SC., Plymouth.

[60247.]—**New Caledonian Single Engines.** —Dimensions of above—viz., Diam. of single driving wheels, 7ft.; diam. of bogie, 3ft. 6in.; diam of trailing wheels, 4ft. 6in.; boiler, 10ft. 3in. by 4ft. 3in.; 196 tubes, $1\frac{3}{4}$in. by 10ft. 7in. Heating surface:—Tubes 950, 36 sq. ft.; fire-box, 102·98 sq. ft.; total, 1,053·34 sq. ft.; area of grate, $17\frac{1}{4}$ sq. ft.; weight, empty, 37 tons 18cwt.; in working order 41 tons 19cwt. This engine has Adams's (of S.W. Railway) patent sand blast, which is worked by a jet of air from the Westinghouse air-pump, blowing the sand directly under the driving wheels. Seven of these engines are to be built for the Northern express traffic.—NORTH-WESTERN.

[60252.]—**Gravity.**—Your first supposition is nearly correct. The velocity of the weight would increase until it reached the centre of the earth, when it would be at its maximum. The velocity would now decrease until the weight had travelled past the circumference on the other side to a distance from the circumference equal to the height of the tower that the weight was originally dropped from. Then the velocity would be 0. The weight will now fall back again and continue to fall until it reaches the top of the tower again, when its velocity is again 0. The explanation of this is as follows. Let S be the distance from the top of the tower to the centre of the earth. Let V be the velocity of the weight after having traversed distance S, and let M be the mass of the body; then by the laws of falling bodies the kinetic energy stored up in the body when at the centre of the earth after having passed through $S = \frac{1}{2} M V^2$. This energy will carry the body on until it has travelled a distance S past the centre on the other side. Now the kinetic energy is all converted into potential energy, in virtue of which the body will commence to fall back again, and so on for ever, since no work is done, and therefore none of the energy in the body used up. But this would only hold good in a vacuum. For owing to the resistance offered by the air, the oscillations each side of the centre would get smaller and smaller, until at last the weight would come to rest at the centre of the earth. With regard to the second part of your query, the earth attracts a body as if the force was acting from the centre of gravity of the earth, i.e., the centre of the earth, so, as I have explained, the matter behind the body does not retard it, and the velocity only begins to decrease when past the centre. A body having no weight would not be attracted by the earth at all. I do not understand your last query. I should say that a leaden ball at the centre of the earth would still be a leaden ball. If I have not made this clear to "Angulus," I shall be happy to give him further information. —RED LIGHT.

[60254.]—**Tricycle Driving Gear.**—I am afraid that one great objection to the use of gut bands for above is that they would slip round pulleys without propelling machine, especially going up hill. Driving a tricycle is quite a different thing from driving a lathe or a sewing machine. —P. L. R.

[60255.]—**Hydrostatic Problem.**—"T. C." has mistaken my meaning entirely, though I thought that the query was explicit enough. Surely he might have known that I would not apply to the "E. M." simply to learn that $6 - 2 = 4$; nor would I have asked for both the length immersed and the depth below the surface, as they are identical when the rod is vertical. Suppose

now the rod is displaced from the vertical position, it will, as you say, tend to become horizontal, but cannot do so, as its upper end is fixed 2ft. above the surface of the water. Less and less of the rod will be immersed as the lower end rises towards the surface, until at last the upward pressure of the displaced water exactly balances the downward force due to the weight of the rod, and stable equilibrium results. I should be much obliged for a few hints how to find the length of rod immersed, and depth of lower end below water. It may simplify matters if I say that the sp. gr. of the wood is 820.—ALIOTH, Earl's Court.

[60257.]—**Curative Power of Magnets.**—This may be represented with sufficient accuracy for all practical purposes by a nine with the tail cut off.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60260.]—**Aneroid.**—The answer to this question involves a good deal more than perhaps "X." is aware of. For altitudes in arithmetical progression the density of the atmosphere decreases in geometrical progression, and therefore the value of 1-50th of an inch is not a fixed one. The temperature of the atmosphere also affects the calculation, so if "X." desires further information on the subject, I should advise him to buy "Surveying and Astronomical Instruments," published by Lockwood and Co. in Weale's Rudimentary Series, price 1s. 6d.—T. K. W.

[60268.]—**C.G.S. Units.**—According to Mr. E. Conry, page 20, this means one gramme lifted one centimètre high in one second. This is absolutely incorrect. The unit rate of working in the C.G.S. system is one erg per second; that is, a force of a dyne overcome through a distance of one centimètre in a second. One gramme lifted one centimètre in one second is not a C.G.S. unit at all.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60268.]—**C.G.S. Units.**—The centimètre gramme second units are the fundamental electrical units. The centimètre as the unit of length; the gramme as the unit of mass; the second as the unit of time. The C. is equal to 0·3937in. in length, and *nominally* represents $\frac{1}{1,000,000,000}$ (one thousandth-millionth) part of a quadrant of the earth. The gramme is equal to 15·432 grains, and represents the mass of a cubic centimètre of water at 4° C. The second is the time of one swing of a pendulum, making 86,164·09 swings in a sidereal day, or the 1-86400th part of a mean solar day.—J. LOW.

[60273.]—**Effervescent Drinks—Seidlitz Powders, &c.**—The aperient property of seidlitz powders is chiefly due to the tartrate of soda they contain (Rochelle salts). Each powder should contain 2 drachms of this ingredient, in addition to that which is formed by the combination of the other ingredients—carbonate of soda and tartaric acid. It is a curious error to suppose that these "destroy" each other.—PHARMACIST.

[60273.]—**Effervescent Drinks—Seidlitz Powders.**—These powders are generally composed of bicarbonate of soda and tartaric acid. 20 grains of commercial bicarbonate of soda neutralise about 18 grains of tartaric acid; but it is usual to have a slight excess of the soda. The gas generated (carbon dioxide, or carbonic acid gas) makes it an agreeable and refreshing drink, and the resultant tartrate of soda is partially digested by the system, and is converted into carbonate, which acts as an antacid.—M. ISADER, Lewes.

[60274.]—**Mushrooms and Salt.**—I can only repeat that a neighbour of mine dressed a field with salt in the spring of last year, and sure enough he had plenty of mushrooms in the autumn.—F. WYKES, Alvechurch.

[60281.]—**Bottle Stopper.**—Let "Happy Jack" put a little thin mineral oil, or, I might say, any thin oil on the stopper; or if a small bottle lay it altogether in oil, and let it remain a few days before he tries to remove it; if still fixed, let it remain a week or two and then try.—T. WILSON.

[60282.]—**Air Valve.**—The back pressure ought to force the valve even without the aid of a spring. The only thing that appears faulty, without knowing more of the apparatus, is the joint where pipe enters through disc. Is this tight?—P. L. R.

[60294.]—**Steam.**—Yes; the 4lb. at A are exhausted into the pipe, which acts as a receiver, and when port is opened for diag. No. 2 the steam is admitted and is the 2½lb. at C; there is always a reduction of pressure. The 7lb. at B is the same steam expanded to 4lb. at A; the diag. does not how the 17lb. you name at D, so that if it exists it would be caused by the cushioning of steam owing to closing of exhaust pipe, and is quite a usual thing. The l.p. cyl. should cut off later than the h.p. cyl. I presume these diags. are taken with engine throttled; as a single engine would be more economical if 17lb. boiler pressure is your regular working pressure.—T. C., Bristol.

[60295.]—**Battery and Lamp.**—TO MR. BOTTONE.—Yes; a 5c.p. lamp would light such a sized room, but not well. An ordinary fish-tail burner burning low gives 5c.p. You would want at least two fives, and if you used two of the specials mentioned by me in previous letters, having a resistance of about 7 ohms, you could light both with your six-cell battery. Do not use a box-form of battery, as it is sure to leak electrically. Cut your carbons with an old saw and sand. Make six cells, as figured by me in reply about Wonderful Lamp and Battery in the "E. M." for August 20th, and charge with chromic and sulphuric acids. Note that if you use all six cells on to one 5c.p. lamp you will burst it.—S. BOTTONE.

[60298.]—**Norway and Sweden.**—Between 66° and 68° of latitude you are near the Arctic circle, and will require a fur coat, cap, and fur-lined boots, which are far cheaper if bought on your way, viz., at Hamburg, Copenhagen, or Christiania, than if bought in this country. Buy "Baedeker's Guide," and it will give you all the information you require. If you are going to the mines or timber factories there will be provision made for your winter feeding; but if going about the country, you will have to depend very much on your gun for variety.—B.SC., Plymouth.

[60299.]—**Locomotives.**—Dimensions of Midland boilers, 1327 and 1740, have several times been given in back volumes; but I would refer G. D. Seaton either to the *Engineer* of 8th May, 1885, or to Mr. West's useful locomotive sheets for more minute particulars.—ANTI-VAC.

[60300.]—**Battery for Lamp.**—Why, chromic acid, of course. See p. 420, No. 1,111, where there is something about a wonderful lamp, which, strange to say, ceased to be a wonderful lamp on p. 16. Why do you want the zincs always to remain in solution? Why not lift them out?—A. S.

[60300.]—**Battery for Lamp.**—Carbon division—saturated solution of bichromate of potash; zinc division—1 part sulphuric acid to 10 water, keeping the zincs standing in a little trough or box, with some mercury in it. Do not put the mercury into the bottom loose. The above solution is one example; there are several good ones, all much about the same in value.—E. CONRY.

[60300.]—**Battery for Lamp.**—Make a paste of mercuric sulphate with water. Pour this round the carbon plates. In the cell containing the zinc place a dilute solution of sulphuric acid (1 acid, 10 water). Keep your zincs well amalgamated, and remember that this battery soon runs down, but recovers quickly when the circuit is broken.—S. BOTTONE.

[60301.]—**Electric Lighting.**—TO "RULE OF THUMB."—I quite sympathise with your remark about the electrical books published. The absence, in them, of any information that is really and practically useful is deplorable. As a rule, they are stuffed with long, useless, algebraical formula and high-flown scientific theories that would be useless if true, and one half of which are all nonsense. So far as my own acquaintance (a considerable one) with electric lighting literature goes, there is not a single table published that would enable an ordinary linesman by turning to it to see at once what gauge of wire he must use for a certain current and E.M.F. for any particular distance. The following may be of service to you. It is deduced from practical experience, and applies to all ordinary sized house installations, as, for instance, where the wires attached to the lamp have not to run more than at most 20 yards each way without merging into a larger gauge, and where none of the branches have a longer stretch than this without increasing their gauge.

No. 20 B.W.G.	wire	takes	¾ of an ampere
„ 18	„	„	1½ to 2½ amperes
„ 16	„	„	6 „
„ 14	„	„	11 „
„ 12	„	„	18 „
„ 10	„	„	24 „

This table applies to any E.M.F. If you have longer stretches than those described above you must use proportionately larger wire—*e.g.*, 16 for 18, 18 for 20, &c., bearing in mind that it is in the small wires, 16, 18, and 20, that the resistance mostly lies, more so in proportion than in the mains and larger wires. To apply this table, you must, of course, know what current a single lamp of the sort you are going to use takes.—E. CONRY.

[60302.]—**Pigmy Motor.**—TO MR. BOTTONE.—Field-magnet, 4in. long, 3in. diameter, $\frac{5}{16}$in. thick; armature 4in. long, 2in. diameter, ¼in. thick. Wind the armature with about ½lb. No. 20 d.c.c. wire, and the fields with about 1lb. No. 18.—S. BOTTONE.

[60303.]—**Captive Balloons.**—Probably Mr. Eric Bruce's balloon was spirited away from the Palace by the previous invention of Mr. Arthur Shipey, which was, according to the President of the Balloon Society, patented and exhibited by the latter gentleman in the year 1881, and lighted by electricity. Being present at a lecture given by General Bruce last month at the Royal Aquarium, the Brine system was explained by the general, which was at once criticised by Mr. Shipey, the original inventor, who said, although he claimed the so-called Bruce system as his, Mr. Bruce was welcome to it, as it was useless for military purposes, and gave a number of reasons why he had abandoned it. Pressure of business had prevented his completing a new invention; but he hoped to do so at an early date, when he would, as an electrician, introduce a system which he thought would meet the requirements of the War Office. I mention this fact as to him to whom honour is due as an original inventor. The fact should be recorded, and being an old balloonist I am a lover of fair play, and subscribe myself—SYCLONE.

[60304.]—**Circular Valves.**—Make ports equal 15 sq. in., say, 10in. by 1½in. If you mean "Corliss," 5in. diam. would suit for valve; but your query is not quite clear.—T. C., Bristol.

[60305.]—**Bending Thin Weldless Steel Tubing.**—Fill with sand pretty tight, stop both ends, heat, and then bend, when it will not flatten.—E. CONRY.

[60305.]—**Bending Thin Weldless Steel Tubing.**—For small tubes I have found the following plan answer. First fill the tube with lead, bend into proper shape, and then melt lead out again.—DUNDRENNAN.

[60307.]—**Analysis of Silver Alloys.**—The querist had better try this gravimetrically, as he finds difficulty with the volumetric process. Precipitate the silver as chloride, filter, wash, dry, ignite, and weigh; 143·5 grains of the chloride contain 108 grains of silver. I purposely refrain from giving minute details for two reasons: first, I do not think I could do so better than many textbooks on analysis; second, no amount of written instruction will enable "G. E." to do the operation unless he has had previous training in similar work.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60308.]—**Soundproof Doors.**—Thick curtains.—E. CONRY.

[60309.]—**Legal.**—"Shylock" has lent £100 to a widow on the security of her house, shop, &c.; but if the widow marries again the house goes to her daughter. The widow is going abroad, and her friends threaten that rather than continue this liability she will get married, and offer £30. "Shylock" must decide for himself whether he will accept this amount (I would not), or run the risk of the marriage, for if the marriage does take place "Shylock" has nothing to do with whether it is consummated or not, and he will never get it annulled on that ground. Again, there is no "conspiracy to defraud" in the widow getting married. When "Shylock" lent the money he knew of the condition on which she held the property, and he ought to have calculated on this probability.—B.SC. (and solicitor), Plymouth.

[60311.]—**Slide-Rest.**—Have the tool very slightly rounding in front; use soap and water, and give a very slow feed and a light cut; then, if everything is tight and the work does not spring, you should have a good result.—T. C., Bristol.

[60311.]—**Slide-Rest.**—The cause of the imperfection in the work is a little play in the rest. This you can easily rectify, or the makers would do it. I think if you use a spring tool to do your work, you will do it quite to your satisfaction, even without tightening. I have one of the Britannia Company's rests, and do not wish to see smoother work.—H. D.

[60311.]—**Slide-Rest.**—The marks complained of by "W. A. S." are caused by dulness of tool. Either it is placed too high in relation to work and angle of clearance, so allowing the tool to rub a little below cutting-edge, thus destroying its sharpness, or tool is too soft. Finishing-tools (having light duty) should be left "dead hard" or set down to a very light straw; but good steel properly heated will not fail if left as hard as can be made.—J. H. R.

[60313.]—**Ozone.**—TO MR. BOTTONE AND OTHERS.—Ozone may be prepared on a large scale, first by blowing a current of moist air through tubes containing phosphorus: secondly, by causing brush-discharges from specially-constructed Wimshurst machines to take place in oxygen (this latter mode gives it in the purest form); thirdly, by the action of strong sulphuric acid on permanganate of potassium. The cost of the plant would depend entirely on the output required. A good Wimshurst, capable of ozonifying to the highest point about one cubic foot of oxygen per hour, would cost about £3, and a small engine to drive this about £10.—S. BOTTONE.

[60315.]—**Salt in Steam Tubes, &c.**—You can only totally take the salt out of the water by evaporating it—i.e., by using a surface condensing engine, which would condense its own supply. A

bucketful of soda in a boiler would help materially to prevent the formation of scale, and to remove scale already there; but to absolutely remove such thick scale as you mention there is nothing for it but getting inside the boiler and chipping it out with a hammer and chisel. If the water is salt or dirty you should blow your boiler out frequently, and when it is blown out get inside and take up in a bucket any sediment that may be left on the bottom. Beware of "boiler compositions": nearly all of them are remedies worse than the disease.—E. CONRY.

[60316.]—**Electric Timeball.**—TO "WATCH-MAKER."—Will work out what you want, and send it next week.—E. CONRY.

[60319.]—**Chemical Salts.**—The best way is to dry the deliquescent salts; but it is necessary sometimes to be careful about the temperature. Ammonium thiocyanate melts at 147° and decomposes at a higher temperature; it keeps perfectly well in solution.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60320.]—**Fossils.**—The Silurian and Cambrian slates of Wales are purely of marine origin. And it is very doubtful if any ferns existed during the Cambrian and L. Silurian epochs. They certainly would not be found in the cleavage planes, much less in strata of marine origin. "Spes" has come across one of those cases in which the mineral kingdom somewhat roughly resembles the vegetable. He has not a fossil, but possibly a Dendritic marking—most likely a "manganese Dendrite"—which is most common in the N. Wales slates, and is built of crystals, probably from salts.—P. H. MARROW.

[60322.]—**S.E. Ry. Brakes.**—The brake on the S.E.R. seen by "G. N. R.," is the trial train with the automatic vacuum brake ball-valve pattern, like that used on the Lanc. and York. and L. and S.W.—ANTI-VAC.

[60325.]—**Polishing Celluloid.**—This is done by either "scraping" the surface, or working it down with glass paper of various grades (same as for ivory); use a "buff," with water and whiting, but no oil or spirit. When polished, wipe over with a clean rag, moistened with equal parts of methylated spirit and water. See advt., 6d. sale column, "Celluloid."—PAUL WARD.

[60326.]—**Weak Ankles.**—Try cold bathing once or twice a day for 10 or 15 days at the time, using a rough towel for drying with, smart rubbing until the skin is red, indicating a healthy reaction. This, with attention to the general health, should in time much improve the matter. Avoid all mechanical appliances, except as a last resource.—H. S.

[60327.]—**Electromotor.**—TO MR. BOTTONE.—Field-magnet cores 3in. diameter, 18in. long; massive standards, 18in. high, 4in. wide, 1½in. thick; armature, 9in. diameter, 5in. wide, 1in. thick. The size of wire used for winding will depend on the voltage of battery employed. With a voltage of about 100 you might series-wind the machine with No. 16 on the armature and No. 14 on the fields.—S. BOTTONE.

[60329.]—**Fire without Smoke.**—Get a spirit-lamp to burn with methylated spirits, or a Bunsen burner for air and gas from any ironmongers.—E. CONRY.

[60326.]—**Weak Ankle.**—The information given is so scanty that it is a matter of great difficulty to form any opinion on the case. If there be no history of rickets (in which case both feet are usually affected), it may be either talipes valgus or flat foot; if the former, manipulation under an anæsthetic may suffice in the early stages, but in confirmed cases an operation to divide certain tendons will be necessary, and a suitable boot will have to be worn. Flat foot arises from causes which over-tax the natural elasticity of the arch of the foot, such as prolonged standing, carrying heavy weights, or a lazy habit of sliding the feet along the ground in walking. Most frequently, those barbarous high-heeled boots are responsible for the mischief, the inner side of the heel wearing down more rapidly than the outer, tends to turn the sole of the foot outwards. The general health should be improved by means of tonics, and the causes of overstraining the foot removed. Large boots with wide toes and extra-large heels should be worn, and a convex pad of cork or indiarubber placed to support the arch of the foot; the upper leathers must be strong, reach well above the ankle and be laced firmly. To strengthen the ankles they may be rubbed with salt water twice a day, an elastic indiarubber bandage may be applied, or light iron supports worn. Possibly this strengthening treatment, and the adoption of a pair of boots which will outrage nature a little less than those which an idiotic set of shoemakers at present thrust upon us may preclude the necessity of recourse to more severe measures.—R. E. F.

[60329.]—**Fire without Smoke.**—Get a catalogue from Mr. Fletcher, Warrington, and select the article that you think will suit you best.—SAML. RAY.

[60331.]—**Signals by Means of High Potential Currents.**—The best way to effect this, with a minimum of cost, risk, and alteration of existing instruments, would be to shunt off a portion of the current from the main. This can easily be done, and to any desired extent.—S. BOTTONE.

[60332.]—**Ferments.**—I would suggest for perusal the paper entitled "Fermentation and its Bearings on Surgery and Medicine," by John Tyndall, F.R.S., &c., a discourse delivered before the Glasgow Science Lectures Association in the year 1876, and now incorporated in "Tyndall's Fragments of Science," sixth edition, Vol. II., published by Longmans, Green, and Co., London; this work is in every good library. The most exact information concerning the power of the microscope best adapted to this study, and also the proper works to study, may be obtained by addressing a query to any of the following (at the same time inclosing a stamped envelope for reply), viz.: Mr. William Crookes, F.R.S., 7, Kensington Park-gardens, London, W.; or Prof. Balfour Stewart, M.A., F.R.S., the Observatory, Cambridge; or Prof. Barrett, F.R.S.E., &c., 6, De Vesci-terrace, Kingstown, co. Dublin.—JOSEPH W. HAYES.

[60333.]—**Electro-Motor.**—TO MR. S. BOTTONE.—If wound in series, about 10lb. No. 16 on field, and 1lb. No. 20 on armature. I should not use such high tension as 55 volts; but if you must do so, and are driving from a dynamo, wind your motor as nearly like your dynamo as you can.—S. BOTTONE.

[60334.]—**Falling Bodies.**—The downward motion of a falling body in the first thousandth of a second may be found from the formula $S = \frac{1}{2} g t^2$. Taking g to be 32·18, the space fallen through is 16·09 × ·000001 = ·00001609ft. The motion to the eastward, due to the velocity imparted by the rotation of the earth, may be found independently of the latitude, if the height above the earth at which the body begins to fall is known. Let us suppose that the body is dropped from a height of one mile, then whatever the latitude of the place may be, or the size of the circle described by it, the body at the higher station will describe in 24 hours a circle which is 2π miles longer in circumference than that of a body at the earth's surface. For, let the radius of the circle described by a point on the earth's surface at any given latitude be x miles, and the body be dropped from a height of d miles, then the circle described by the point at the surface in 24 hours is $2\pi x$ in circumference, while that of the higher body is $2\pi(x + d)$, and the difference between them is $2\pi d$. From this the following formula can be obtained—

$$S_1 = \frac{2\pi d t}{8640}$$

Where S_1 is the eastward motion in feet during t seconds, and d the difference of height in feet, the circular arc being practically a straight line for small values of t. When d = ·00001609ft., t = ·001sec. S_1 = ·000000000012ft., that is the distance to the eastward. If we call θ the angle which the falling body makes with the horizon—

$$\text{Sin. } \theta = \frac{S}{\sqrt{S^2 + S_1^2}}$$

or more simply $\tan. \theta = \dfrac{S}{S_1}$

from which θ can readily be found.—R. E. F.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last, "G. E. R." has replied to 60005.

59847. G.E. Locos, p. 403.

60059. G.N.R. Locos, 493.
60069. Railway Signal, 493.

M. BERTILLON, in the course of a lecture delivered at the Hygienic Exhibition in Paris, stated that out of every 1,000 inhabitants of Paris only 360 are natives of the city, 565 belonging to the departments of France or the colonies, and 75 being foreigners. There are in proportion, as well as in actual numbers, more foreigners in Paris than in most other large cities, the proportion being 75 in 1,000, as against 14 in 1,000 in Berlin and Trieste.

QUERIES.

[60335.]—**Turnbull Transmitters.**—Would any subscriber let in a little light on the following items relating to the Turnbull telephone transmitter, which was described in the "E. M." of Aug. 6? Are the carbon electrodes hung exactly upright, and, if not, how much inclination ought they to have? How are they (the carbon rods) kept from touching each other when hanging on the carbon pivot? Would ordinary electric-light carbons, about 5-16in. dia., do for the electrodes, or are they too smooth? What length are the rods? What thickness is the vibrating diaphragm? Any other items relating to this would be gratefully received by—TRANSMITTER.

[60336.]—**Keeping a Pony.**—Would some of your readers give some hints to an utter ignoramus who thinks of keeping a pony for the first time? Heads of information desired: best size of and market for animal, hints for building cheap substantial stable and coach-house, proper food, necessary quantities, and probable cost of same, how often to give it; how to clean the animal, harness necessary and cost of same; best sort of conveyance to keep and probable cost. The pony is to be kept simply to drive self and few other friends out occasionally, and will live in a grass country, where hay and grazing are cheap. A word or two on diseases of horses and simple remedies desirable; and please bear in mind querist's ignorance, and that consequently full details will be valued.—GEE UP!

[60337.]—**Small Compound Engine.**—Can any reader kindly tell me the best size and proportion between cylinders for a compound surface condensing engine to indicate one horse-power, or a little more, and the heating surface required? Also cooling surface in condenser?—A. L.

[60338.]—**Legal.**—A. becomes bankrupt, and goes into the court, but afterwards compounds with his creditors to pay 4s. in the pound, and gets two sureties, which arrangement his creditors, save one, accept. This one, B., holds a life assurance policy, which more than covers his amount, and with which he is content, refusing to join the other creditors. After A. gets clear of the court, B. offers him some business, on the condition of A.'s giving up to him half of the salary towards payment of the old debt, for which he holds policy as security. Should A. agree to this, will it bind him again to the old debt, and thus do away with all the benefits accruing from his compounding, or simply make A. liable to give half of whatever he may earn from B., and in no other way acknowledge the old debt? Having entered into such an arrangement, could B. claim other money?—COSMOS.

[60339.]—**Instantaneous Shutters.**—I am desirous to know the correct principle for landscape and marine? It has been stated that a longer exposure is required for foreground; yet the drop shutter, which does not give this, seems to be greatly used. The advice of an "expert" will be greatly esteemed.—AMATEUR PHOTOGRAPHER.

[60340.]—**M.R. and G N.R. Locomotives.**—Could any reader of the "E. M." give me the classes of the Midland or G.N. Railways? I see in last week's number someone says something about D class of the L.B. and S.C.R. Can you inform me if they call them by letters on the M.R. and G.N.R.?—H. VERNON.

[60341.]—**Mechanics.**—A capstan is worked by two men on opposite sides, each pressing a capstan bar with a force of 30lb., at a distance of 4ft. from the axis. The rope is wrapped round a drum, whose diam. is 1ft. What would be the pull on the rope which would balance the pressure on the capstan handles? Would any reader kindly show me how to make a diagram showing the action of the forces, and find the pressure upon the central shaft on which the capstan turns? Would this pressure be the sum of the two weights—that is, the two men = 60lb., and the tension of the rope, which I suppose would = (as the velocity ratio is 8 to 1) 480lb., would the pressure be 480 + 60 = 540lb., or would the pressure equal the moments round the centre of axis, 480 × 1 = 480, and 60 × 8 = 480? Would the sum of these two moments = pressure upon central shaft = 960lb.? Would anyone kindly favour with a rough sketch of section through the firebox of a locomotive boiler, showing particularly the method of supporting the flat surfaces, particularly the top of firebox? Could anyone tell me of a good book showing how to find the strains on different structures?—NOVICE.

[60342.]—**Green Stain for Furniture.**—Will some reader inform me how to make the green stain cabinet-makers use for furniture?—JOHN JONES.

[60343.]—**Heating Small Conservatory.**—If conservatory is heated by gas, or a lamp, is it necessary that there should be a pipe to take the fumes or heated air out of the building? Also, does the light damage plants, or should the light at night be screened off or shaded?—HOUSEHOLDER.

[60344.]—**Loco. Sand Blast.**—How does the sand blast work on Caledonian and Midland engines, and what advantage is there over the ordinary sand pipes?—INQUIRER.

[60345.]—**Brakes.**—Is it correct that Midland engines 824, 102, 1309 have both Westinghouse and vacuum brakes combined, so that if the rear guard applies the vacuum it puts on the Westinghouse on the engine wheels? If so, how is the arrangement managed?—ANTI-VAC.

[60346.]—**Charging Accumulators.**—For some time past, I have been trying to charge a 6-cell accumulator, but have not as yet met with much success. The battery in question is of the Planté type; each cell consists of eleven plates 4½in. by 4in., and charged with water ten parts and sulphuric acid one part. For charging, I employ a dynamo similar to that described by Mr. Bottone in the "E. M.," only it is fitted with one of Jones' laminated armatures instead of a cast-iron one. Size of armature, 1½in. by 4in. I find that the dynamo seems to work best when the cells are connected in two series of three each. Although I have charged the accumulators many times, reversing direction of charge, yet they do not acquire much storage capacity. After receiving charge for an hour, they would drive the dynamo as a motor for about five or six minutes. I also find that when left charged they very rapidly lose their charge. After charging them for about two hours, I put the whole of the cells in series, and connecting them for a minute to the dynamo, found that there was E.M.F

enough to drive it splendidly. I then disconnected it from dynamo; but in less than three-quarters of an hour the potential had fallen so low as to be scarcely high enough to drive the armature round at all. Ought this to be so? If not, I shall be obliged to any correspondent who will point out cause and cure. There is also a considerable sediment of a greyish-white colour deposited in the cells. What would this sediment probably be, and ought it to be there? When the cells are receiving charge, there is a tolerably free evolution of gas, which, I take it, is a sign that the dynamo is equal to the duty demanded of it. Any information from those who have had experience with cells of this kind will be most thankfully received by—IOTA.

[60347.]—**Westinghouse Brake.** — An express driver on one of the principal lines (G.E., I think) told a friend of mine the following: The brake when applied acts with full force on engine, tender, and 12 carriages. From thence to end of train (supposing such to be one of 26 carriages) the power gradually decreases till the last carriage practically has none applied. What I mean is that the brake is not applied with so much force on the rear of the train as on the engine. Is this the case with Webb's? If true, can these defects be remedied? I should be much obliged if you will tell me which No. of the MECHANIC the Crook accident, June 24th, 1884, was described in. I do not seem to see it in Vol. XXXVIII. I have looked through Vol. XLI., which gives all the Inventions Exhibition in it; but do not see any description of the duplex brake of 11, Queen Victoria-street. Could any of your numerous correspondents and readers, with your permission, give me a sketch or description of it?—TRIPLE VALVE.

[60348.]—**Testing Gold.**—What is a "test stone and studs" for testing gold? How is it used? Is it any good for testing unrefined gold?—F. A. R.

[60349.]—**Florida.**—Can any reader give me information respecting Florida—its climate, productions, industry, &c., &c.? The fullest information would oblige. What chances would a man have of making his way in the country without capital, but willing and able to work?—EX-TEUTON.

[60350.]—**Large Field Eyepiece.**—Will some practical brother please say what is the largest field of arc obtainable on a 5in. o.g., 7ft. focal length, with astro. eyepiece, and also erecting eyepiece? Rather low powers would do. Good definition and light desirable.—CORONA.

[60351.]—**Coil.**—TO MR. BOTTONE, OR OTHERS.—I have a single wire medical coil. Core, 3in. long, $\frac{1}{2}$ thick; reel ends, 1in., and $\frac{1}{4}$ wide. I wish to convert it into a $\frac{1}{2}$in. spark induction coil. What amount of wire and size of condenser must I use to get the above results with two double bichromates, pint size? Would that length of spark do for ordinary experiments?—J. M. PECKHAM.

[60352.]—**Fire Engine.** — Can any correspondent oblige me with the measurements of Shand and Mason—namely, bore and stroke of cylinder, bore of pump, length and diam. of air vessels, diam. of flywheel, boiler tapers from bottom to centre, diam. of bottom and centre, length from bottom to top, outside?—J. K.

[60353.]—**N.W. Drivers and Postal Trains.**—Can any correspondendent inform me the number of days worked per week by the Scotch and Irish mail trains on the N.W., and what remuneration they get? Is it the same as the Crewe-Carlise men get, which is 16s. per trip, four trips a week? Also wanted the places and times where the up and down postal trains stop.—NORTH WESTERN.

[60354.]—**Testing Water with Nessler.**—(1) A sample of water is tested with Nessler's test, and a rusty or amber-coloured precipitate is produced. What is the nature of this precipitate, and what does it indicate? (2) The same test is applied to another water, which at first turns milky, then a flocculent substance is formed, which retains its white colour, and partly floats in the water. What is this white matter, and does it show that the said water is a better or a worse water than the first sample?—INQUISITIVE.

[60355.]—**Vitriols.**—What weight of vitriol, 150 T., should be made in 24 hours per cubic yard of chamber space, from good brimstone and from good pyrites?—A. CRAGGS.

[60356.]—**Fitting Brass Bushes.**—Will any reader inform me what allowance is usually made in turning brass bushes, for spring of bush caused by driving on to mandrel and into the hole for which it is made? Size of bush, 4in. dia., 6in. long, $\frac{1}{2}$in. thick.—BRASS.

[60357.]—**Gulf Stream.**—A number of years ago an experiment was made, by means of hollow glass balls hermetically sealed, to ascertain the direction and speed of the Gulf Stream. Can any reader give full particulars as to the number of balls, how they were marked, by whom the experiment was made?—in fact, any information on the subject will be interesting to—HYPERBOREAN.

[60358.]—**Spherical Trigonometry.**—Would some mathematical reader of the "E. M." kindly solve the undermentioned problems for me? (1) A, B, C is a great circle of a sphere. AA′, BB′, CC′ are arcs of great circles drawn at right angles to A B C, and reckoned positive when they lie on the same side of it. Show that the condition of A′, B′, C′ lying in a great circle is tan AA′ sin BC + tan BB′ sin CA + tan CC′ sin AB = 0. (2) If a point on a sphere be referred to two great cirles at right angles to each other as axes, by means of the portions of these axes cut off by great circles drawn through the point and two points on the axes each 90° from their intersection, show that the equation to a great circle is: $\tan\theta\cot\alpha + \tan\phi\cot\beta = 1$. Either a full solution or hints as to the same in both cases will be extremely acceptable to—SPHERE.

[60359.] — **Freezing Meat.** — What mechanical appliances are used for the above purpose? Also for keeping curing cellars in a frigid state? Could any kind reader give any information respecting the mode adopted by the Atlantic steamers in keeping the mutton and meat frozen brought over by them?—W. H. S.

[60360.]—**To "F.R.A.S."** — What astro. eyepiece should I purchase for a $3\frac{1}{4}$in. achro.? I have two of 75 and 90. Should I have any lower than these for clusters, nebulæ, &c., and what higher powers? Also which form of eypieces would be the best? Present ones are ordinary Huyghenian.—A. R. B.

[60361.]—**Organ-Accordion.** — Will anyone who understands making stand and pedal for above kindly oblige by giving instructions how to make? A rough sketch would help. How are the bellows worked?—is where the hitch is with me.—SAMBONNEI.

[60362.]—**Cold Compressed Air.** — Could any of "ours" inform me whether machinery for producing cold compressed air is made of a size suitable for use in a large dairy for cooling cream and butter? Whether a special apartment is required for its use? What power is required — I mean, is steam necessary? — DOCTOR MEDICINÆ.

[60363.]—**Phonograph Mouthpiece.** — Will any correspondent who has a successful mouthpiece be good enough to give me the particulars of it, such as the size and thickness of diaphragm, shape of tracing point? Also the speed of the barrel and thickness of the coil to get the best effects? I have a very good barrel, but cannot get the mouthpiece to act.—PHONOGRAPH.

[60364.]—**Beach's Developer.**—Will Mr. Bottone, or some experienced friend, kindly give me full details how to make up and use this developer?—B. DAVIDSON.

[60365.]—**Printing.**—Will any of your readers who have worked platen machines say which they have found the best—those having a "dwell" on the type, or not?—PICA.

[60366.]—**Tile Setting.**—How should tile pavements be laid? Should the tiles be packed as close as possible, and should liquid Portland cement be swept into the crevices? Any hints will oblige—MURANO.

[60367.]—**Gas Query.**—TO MR. FLETCHER.—Kindly tell me if it is right for a dry gas meter to continually click while gas is burning. Mine does so, and I am of opinion I am charged for much more gas than I consume. How can I have meter tested privately, as I am of opinion mine registers fast? I am sure a few hints how to burn gas would be very acceptable just now to a great many besides—GAS.

[60368.]—**Exploding Spirit Lamp.**—Would one of your clear-headed and courteous subscribers favour me with an explanation of the following? My spirit lamp is one of the ordinary tin ones, purchased for about 1s., consisting of a cistern for containing the spirit, with handle and tripod attached. In the top of the cylindrical cistern is a hole, into which drops loosely a small hollow cylinder, forming the burner, resting on the bottom of the cistern and projecting about $1\frac{1}{2}$in. above the top. The bottom of this tube is open, and into it is inserted cotton wick, reaching nearly to the top of the tube, which is closed; but it is perforated round the side, close to the top. An annular wick also envelops the lower part of this tube, extending just outside the orifice in the cistern. This external wick being lighted, heats the projecting tube above, and, of course, ignites the gas escaping through the perforation mentioned. A proper metal extinguisher incloses the burner, and screws down to the top of the cistern, preventing evaporation. Now frequently on lighting this lamp, a very forcible explosion takes place, due doubtlessly to my having, by screwing down the extinguisher whilst the lamp was warm, retained a quantity of pent-up gas, which forces its way out on proceeding to re-kindle the lamp; and so I now take the precaution of first raising the burner to allow the gas to escape. The other day, however, my lamp being empty and quite cool, I charged it with fresh methylated spirits, and on applying a light the explosion again occurred. This I am at a loss to account for, as the lamp contained no pent-up gas excited by previous heating. If not beneath the consideration of your clever readers, an explanation of the above would very greatly oblige me. I may say that the only effect of the explosion is that the burner (which fits very loosely), accompanied by a muffled bang, darts up to the ceiling like a rocket, and returns to the ground still ablaze, whilst the spirit within the cistern burns away placidly enough. No mischief has as yet attended the accident.—PUZZLED.

[60369.]—**Delta Cygni.**— Can "F.R.A.S.," or some other reader give me reliable measures of Delta Cygni? I have been much puzzled with the different results in this month's *Observatory*. Mr. Sadler gives in the "Star Guide," page 37, this star as a test for a 4in. refractor, angle 318·5°, distance 1·68″, I suppose computed for 1886, as stated on page 9 of "Preface"; but on page 308 of *Observatory*, angle is given from two nights' measures as 313·0°, distance 0·8″. I can see small star well with 5in. refractor, and can even just see it on diffraction ring with 4in., so I do not think it can be so close as 0·8″; still this measure was made by a practised double-star observer. I see Dr. Copeland's and Mr. Tarrant's measures come much nearer angle and distance as given in "Star Guide," but I do not remember seeing many measures by these gentlemen. I should like to know the latest measures of 70 Ophiuchi, δ (Delta) Herculis, ξ Scorpii, Σ 2525 Cygni. The last one I cannot see double, if I have found right star. What is the distace of 46 Draconis (Webb, 4th ed., page 304), and where can I find full text of Secchi's remarks on page 385 of Webb, as some passages seem to be omitted. Will "F.R.A.S." please supply omitted parts, if the quotation is from some not very accessible book, and say whereabouts in Cygnus the other spots referred to by Secchi are?—H. ATKINSON.

[60370.]—**Dynamo.**—I have one of Jones's dynamos, which should light six 20c.p. lamps; but I don't want to light 20c.p. lamps at all. I am using 10c.p., volts 14, and I can light four of them well; but as soon as I put on one or two more lamps (same as above), I cannot light any of them more than red, and the engine runs away as if there is nothing for it to do, and as soon as I take off the 5th and 6th lamps, and leave four, the engine appears to have more work to do. Machine is compound wound and shunt with laminated armature. If Mr. Bottone, or others, can tell me what is the matter I should feel much obliged.—TROUBLE.

[60371.]—**High-Pressure Gauges.** — M. E. H. Amagat measures pressures up to 3,000 atmospheres with a gauge on the principle of the manometer, with differential pistons. In order to obtain accurate results, the condition has to be realised of maintaining the pistons in complete action while keeping them perfectly air-tight. Will someone kindly state how the differential pistons work, and is Amagat's gauge of any practical use for a pressure of 20 tons per square inch? Are there any printed particulars about it?—R. T.

[60372.]—**Roller for Steam Launch.**—To "R. N." —Will you please kindly help me? I am building boat for steam launch, 22ft. long, for river work. Say what kind of engine is best and size suitable, best mode of condensing, size of cylinders and ports, length of valve, and travel of same. Boiler to be made of copper; say how thick it should be to stand 100lb. pressure, or more. Also the best way to make it, and what size. Give size of shaft and propeller and pitch. I want it to be a good fast boat, and I want to start the right way to do it; or if I advertise my address, will you give me rough drawings? and oblige—C. L. T.

[60373.]—**Battery Zinc.**—TO MR. BOTTONE, "SIGMA," AND OTHERS.—I have a battery of 18 cells, the zincs and carbons of which are 6in. long, $1\frac{1}{2}$in. wide; two carbons to one zinc. I find, after being in use a short time, that the zinc is nearly worn through in the middle, whilst the bottom appears to have been acted upon very little. Why is this? Would it be better to have the zinc shorter, say 4in. instead of 6in.? I have been using bichromic solution, but intend using the chromic, as I find it gives far better results than the bichromic.—QUIEPPE.

[60374.] — **Solder for Platinum.** — Will someone kindly oblige with particulars for soldering platinum to the ends of brass and steel screws, and other connections for electrical purposes?—WALTHAMSTOW.

[60375.]—**Lifting Power of Engine.**—Would any correspondent kindly answer the following question? A single engine with one 36in. cylinder, and a pair of coupled engines with two cylinders, each 24in. diam., each engine to have the same length of stroke; which engine will lift the most dead weight?—A. R.

[60376.]—**Trumpet Stop.**—I should feel obliged if Mr. Audsley, or any one of your organ-building correspondents, could help me out of a difficulty I have with my trumpet stop. Two of the pipes will not tune up. I get them very near, when suddenly they rise an octave. I have tried new reeds, but they serve me the same. I should like to know if cutting the pipe would effect my object.—QUINT.

[60377.]—**Breaking Strain of Cable.**—If a steamer of 560ft. in length, 52ft. beam, drawing 26ft. water, be at anchor with 90 fathoms of chain cable out in 7 fathoms of water, and a tide running 7 knots, what would be the horizontal pull on the steamer, chain, and anchor? What will be the vertical depressing on the bow? What is the rule to find this? Suppose the testing strain on a $2\frac{1}{2}$in. cable be 70 tons, what should be the breaking strain?—SAILOR.

[60378.]—**Beer-Raising Apparatus.**—Will someone kindly give description of apparatus worked by water for raising beer or other liquors from cellar to shop? Height of beer tap, 12ft. above barrel; pressure of water available, 60lb. to sq. in., and apparatus to be automatic.—VINO.

[60379.]—**Model Schooner.**— Will any of "ours" kindly give specifications for a model schooner, a good sailer, boat to be 2ft. long? Should like to know full particulars.—ATALANTA.

CHESS.

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,006, by J. Mackenzie, G. A. A. Walker, I. M. B., A. Dean, T. Quilliam, G. T. Stringfellow, "——," A. Bolus, Link, A Beginner; to 1,005, by Link (3), A. Bolus (8, including author's), F. W. S., G. T. Stringfellow (4), M. Blackmore (3), T. Quilliam, I. M. B. (8, with duals), A Beginner.

G. A. A. W.—Duals noted in 1,005.

E. F. GEARHTY, R. Pilkington, and C. J. Lambert are thanked for games.

WE should be glad to receive some original problems from our contributors.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Sept. 8, and unacknowledged elsewhere :—

F. PEARSON.—R. T. Omond.—Dr. N. B. Sizer.—Alvan Clark.—Medical Battery Co.—Cymro.—T. Wood.—A. S. I.—F. E. A.—Ampere-meter.—Pontoon.—Z. Y. X.—D. Booth.—Dubliniensis.—X.—A. J. W.—Organist.—Ajax.—G. R. Primrose.—E. Conry.—R. E. F.—W. Habgood.—Paul Ward.—W. Cooper.—S. E. Peal.

A YOUNG ENGINEER. (You should procure Reed's "Engineer's Handbook," published by T. Reed and Co., Sunderland.)—FRANCOIS. (They are manufactured from any cheap raw material which contains gelatine, and dried on plates. The best is prepared from picked cuttings, which are treated by sulphurous acid previous to extracting the gelatine.)—J. T. SMITH. (You will find many recipes for marking ink in back volumes. Perhaps you did not expose the other to the light. It is the action of the light that is supposed to render it indelible.)—J. FRANK STONE, Bethlehem, Pa. (If you cannot find them in Nystrom's or Trautwine's works, we do not know where to look for them. It is much a matter for experiment. 2. We do not know of any work specially devoted to roll turning. 3. There are some enamels in the market (mostly asphaltum varnishes) which dry quickly in the cold; but the best work is done by what is known as japanning, which requires a stove.)—BRONCHITIS. (You can have hot-water heating apparatus, paraffin oil-stoves, or coal-gas. Look through the indices, or procure catalogues from those who supply heating apparatus.)—NOSE MACHINE. (One of the little paper clips sold at the stationers will do.)—LITTLE JIM. (Better send it to the plater's and have it done properly and cheaply. If you want to know how it is done, see Vol. XXXIV. pp. 193, 237, 261, 381, and the indices of most back volumes.)—GEO. GRIFFITHS. (You can only apply to the locomotive superintendents. As a rule, you will find, that when they want men, they ask some of the engine builders in this country to recommend workmen whose abilities are known.)—ARIES. (We do not know, but presume the secretary of the society will forward them. The address is Paris, we believe.)—J. LOW. (If the signal never moves, it seems certain that it is not used now, but is left in case at any time it should be wanted.)—DISPAIR. (Consult a medical man. He will give you "a phosphoric vital restorative," if he thinks one necessary.)—RESERVOIR. (Tests are of little use in the case of water; it must be a complete analysis. See p. 434, No. 1060, and the indices of back volumes. 2. "Chemical Analysis," by Fresenius, 2 vols., Churchill; Valentin's work, same publishers.)—DUPLEX. (Doubtful if it can be done without a blast, unless you build a sort of furnace such as was illustrated in No. 1031, p. 373.)—HARMONIUM. (Cover one side of a piece of wood with swansdown, fluffy side outwards, and fix that over the sound holes. You should have given some idea of the dimensions, or the make, as it may be impossible or unsightly to adopt the above. If so, take it to a harmonium-tuner and ask him to soften the tone.)—YOUNG ENGINEER. (What is an "engineer"? Say which branch you mean; but at any rate try and get a berth before starting. You must apply to the shipping agents for terms. The advertisements will be found on the second page of the *Times*.)—WM. WASS. (Consult the teacher at your class. It is not one of the subjects of the Science and Art Department, but is in the list of the City and Guilds Institute. You will find "works of reference" recommended in the Programme.)—JUMBO. (A simple apparatus for the limelight was illustrated so recently as June 18 last, No. 1108.)—K. (One of the special preparations known as indestructible; otherwise a good red-lead paint, well covered with two coats of copal varnish.)—CONSTANT READER. (A "former" is an arrangement of pieces of wood with the ribs or folds cut on them, and supported through the centre by plugs. On removing the latter the side pieces can be taken out. If you only want to make one bellows see p. 224, No. 894, which contains illustrations.)—BROSCENICUS. (We should think so. 2. The jars can be used, but it rests with you what kind of battery.)—X. (The question about the thermometer was actually answered the week before last; see p. 583, No. 1118. If "shade" meant "night," night temperature would be the words used. 2. An optical delusion.)—S. N. D. (Do you not understand that you are asking for something that has not yet been invented? If the proprietors could make that preparation flexible, they would. See p. 84, Vol. XXXVIII., and many recipes in back volumes.)—AN AMATEUR. (The Upward battery was described on p. 384, No. 1110. Why should you use a battery to charge an accumulator which is to furnish current for two or three lamps in a bedroom one hour every night? Why not use a battery direct? As you have the accumulators, get them charged by some one who has a dynamo.)—A. L. (You can see a stereoscope at any optician's. See No. 895, p. 233, for a new form of reversible stereoscope. Are your lenses suitable, or will they require cutting in halves?)—AMATEUR. (See p. 206, No. 1,050; p. 94, No. 914; p. 116, No. 915, the indices of back volumes, and any of the cheap handbooks.)—ANXIOUS. (See previous answer.)—F. C. S. (The address of the Institution of Naval Architects is 5, Adelphi-terrace, W.C. The Earl of Ravensworth is the president.)—T. C. RHONDDA. (There are no regulations of the Board of Trade in connection with that matter. There are what are called the "conditions" of an efficient brake, and they have been frequently given.)—TESIG. (See p. 92, No. 1,071, or examine the valve of any gas-engine.)—J. W. B. (Bronzing gun barrels was explained as fully as possible in No. 1,035; but see also Nos. 1,044, 1,045.)—ALIOTH. (It simply means that a train must not enter a section until the driver receives the order to do so, by the lowering of the signal. The permissive system would allow him to run past if he saw the line was clear.)—TEMPLE. (It is simply a little piece of leather-faced wood hinged at one end, with a bit of wire and a lead weight at the other. A small hole permits the passage of wind, and the valve "trembles.")—J. S. C. (Certainly not; what has the lighting up to do with the number of streaks? 2. Tyndall's Belfast address will be found in Nos. 491, 492; It is also in "Fragments of Science," Vol. II., published by Longmans, and the same firm, we believe, issue it in a separate form.)—CONSUMPTIVE. (If you can get "any amount of cod's livers," don't waste them in making oil. Eat them. Epicures say they are delicious baked, fried, or boiled. If you must have the oil, cut the livers up and clean from blood, wash, and drain. Place with a small quantity of water in a vessel heated by steam. As the heat increases, the oil will rise to the surface; and can be skimmed off. Allow it to cool and settle, then filter two or three times through flannel, and finally through white blotting paper.)—M. SPENCE. (There is no work of the kind; but you will find information in Kemp's "Yacht Designing," and also in back volumes.)—PENDLETON. (For shocking coil, see p. 433, No. 1034; p. 152, No. 1047, and the indices generally.)—A. IRELAND. (Your query shall appear next week; we really do not undertake to reply to queries by telegraph.)—R. A. R. BENNETT. (Not an uncommon trick with unscrupulous publishers. Your friend's remedy is to apply for an injunction to stop publication, and then sue the publisher for damages.)

Pottery in the United States.—The report of the United States Potters' Association states that while in 1860 pottery was in a miserable condition, there are now about 275 kilns in operation in the United States. The total capital engaged in the industry is about 8,000,000dols. The amount of wages paid to the thousands of pottery hands is placed at from 4,000,000dols. to 5,000,000dols. per annum; and the annual value of the American pottery produced is upwards of 8,000,000dols. Up to 1863 there was no duty on imported crockery, but from that date a gradually increasing tariff has been imposed, until by the last addition it has reached the protective standard of 25, 55, and 60 per cent., the lowest rate being on common stoneware, and the highest on decorated porcelain. The imports of earthen, stone, and china ware, which reached the value of 8,693,273dols. in 1883, dropped under the blow of the last tariff levy to 4,368,531dols. They rallied a little in 1885, but they were still 2,207,903dols. less than in 1882. The best American makes include the opaque china of Trenton, made up after the models of the delicate French shapes; the Royal Worcester, also made at Trenton; the decorated table ware, which is admitted to equal much of the better French goods in design, tint, and colour; the hard French porcelain of Green Point, New York: the "Barboline" and "Limoges" made at Tarrytown; and the fine tiles of Chelsea, Trenton, and Pittsburg.

Cedar.—A correspondent of *Notes and Queries* states that the name cedar has been given very indiscriminately to cedars, cypresses, and junipers. It ought to be confined to that noble tree, the cedar of Lebanon, to which it was first given. This genus has but one true species, for the C. Atlantica, C. Taurica, and C. deodora, are mere varieties of the C. Libani. Their cones are indistinguishable. This I learned from the late Sir W. Hooker, and his son, Sir Joseph Hooker, has confirmed it. There is no higher authority. The timber is of extraordinary durability, but it is quite devoid of fragrance. The sweet-smelling wood of which so-called cedar pencils are made is a juniper, commonly called the Bermuda cedar.

AT the last meeting of the South Wales Institute of Engineers Mr. Archibald Wood, the president, gave some salutary advice to coalowners on economic washing, and remarked that in these days, when new motive powers were sought in electricity and in petroleum, too much caution could not be shown.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and CO., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII., XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., and XLII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.)

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XI., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words, afterwards 9d. per line. Paragraph advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d.
Twenty-four words	0	3
For every succeeding Eight Words	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Good Value Offered (cash or instruments) for all kinds of sound or repairable Scientific Appliances.—CAPLATZI, Science Depot, Chenies-street, near British Museum. Established 1862.

Tricycle, Coventry, 2-track, 50in. wheels, double-steerer, good condition. Offers in exchange.—FORD, 75, St. Paul's-road, Camden, N.W.

Want to exchange a 52in. **Bicycle** for 54in. ditto, value £7.—W. BARKER, Chepstow-road, Croydon.

Working Model Electric **Paddle Boat**, powerful Bichromate Battery, well made Motor, whole in faultless condition. What offers?—F. M., 41, Barnsbury-street, Islington.

Commutator, 48 sections, nicely fitted, small Gramme Dynamo, 10 am., 35 Volts. Offers, electric,—NELSON, 13, Orr-street, Glasgow.

Six-cell **Bichromate Battery**, carbons 2½ wide, polished mahogany frame, 16 by 12 by 4, for triple-wick Lantern. Mutual approval.—WRIGHT, 47, Blandford-street West, Ashton-under-Lyne.

Magic Lantern Slides.—Advertiser wishes to exchange for fresh ones. Comic slipping, Scripture, and a set—The History of a Grain of Rice; about 24 in all.—WALTON MOFFATT, Hexham.

Will exchange five solid **Steel Dies**, sizes from ⅜ to 1¼, for new 4in. Hot Water Piping.—Particulars from T. TIPPING, Painswick, Gloucestershire.

Remington **Type Writer**, prints capitals, cost £18, as good as new. Offers, by letter only, to W., 67, Azenby-square, Peckham.

Will exchange "**Bourne's Treatise on the Steam** ENGINE," 1846, 23 plates, good condition; for Vols. XXXVI. and XXXVII. ENGLISH MECHANIC, unbound.—A. HALE, 41, Tremlett-grove, Junction-road, London, N.

"**English Mechanic,**" large number of volumes, unbound. Wanted, light double-geared Head Stocks, 4½ or 5in. centre.—W., 22, York-road, Birkdale, Southport.

What offers? Half-horse Horizontal **Engine and** BOILER. Engine has governors, pump, &c. Boiler has all fittings complete.—PORTER, 62, Mantle-street, Wellington, Somerset.

Launch Engine, 3½in. link motion, and new gun-metal pump, wants putting together. Exchange offers.—SMITH, Stanley Villa, High-road, Gunnersbury.

Smee's **Battery** (gal.), lot of Steel and Agate Burnishers for plated goods, &c. Want good Leg Vice.—ELEY, 6, Edgar-road, Bromley-by-Bow.

Melodeons and Concertinas considerably under cost price. Melodions, 4s. 6d., 6s. 6d., with stop and bell, 10 keys, or exchange.—37, Tyneham-road, Lavender-hill, Battersea.

Flutes, several concert, 6 keys, tuning slide, 10s. 6d., each. F Flutes, 5 and 6 keys, 8s. 6d. Piccolos, 4s. 6d. and 6s. 6d., 5 and 6 keys. What offers?—37, Tyneham-road, Lavender-hill, Battersea.

Emery Wheels, three, 6in., 8in., and 10in. Exchange offers requested. Seen at RODGERS', 152, Bermondsey-street, S.E.

Steam Gauge, up to 100lb. pressure. Exchange offers.—RODGERS, 152, Bermondsey-street, S.E.

Engine, 2 H.P. vertical, wants little repairs, with pump. Exchange offer.—RODGERS, 152, Bermondsey-street, S.E.

$8\frac{3}{4}$in. **Metal Speculum** $2\frac{1}{2}$in. Achromatic O.G. Exchange. Offers requested.—W., 28, Hall-street, Bilston, Staffs.

Smee's Battery, six pint cells, amalgamated zincs, complete. What offers? Beginner's photographic set wanted.—R. HUGHES, 5, Lakefield-place, Llanelly.

Pair **Horizontal Engines**, 1in. bore, 2in. stroke, excellent working order. Exchange pair lathe heads.—HUNTER, Daisy-hill, Chester-le-Street.

Locomotive Engine.—Splendid set of Castings for the above, 15in. long, cylinder bored, &c., cost 50s., take half. Wanted a vertical boiler, 3ft. by 2ft.—R. P., 102, Teviot-street, Poplar, E.

Handsome **Gun**, central double breech, rebounding locks, left choke, horn heel plate, spring forend. Exchange for lathe or vice, &c.—GRIMSHAW, Paxton-street, Accrington.

Bench Drilling Machine, hand or power, drill to $\frac{3}{4}$, selffeed motion. Also Ditting Pillar, Ratchet, Pipe, Wrench, and a large modern Engineering Book, with 520 wood engravings. Will exchange for 1-H.P. Boiler, in good order, or offers. Particulars on application.—G. HOUNSELL, South-street, Bridport, Dorset.

For sale, splendid **Slide Valve Cylinders**, 2in. stroke, also 4 eccentrics, and 3 shafts, intended for loco., cost 36s. Exchange for Castings for a Launch Engine, 6in. stroke, single cylinder, or anything useful.—R. P., 102, Teviot-street, Poplar.

Strong **Fly Press**, 2in. screw. Offers requested.—H. B., 21, Pembroke-street, Copenhagen-street, Islington.

Burning Glass, 18in. diameter, melts lead in sun's rays, powerful condenser for any illuminant. Cost £20. Exchange offers requested.—W., 28, Hall-street, Bilston.

Rubber Stamp Apparatus, type, and full instructions. Cost 50s. Exchange offers.—W., 28, Hall-street, Bilston.

Six **Quart Cells**, zinc cylinders, about $3\frac{1}{2}$lb. each. Carbons, 8, $1\frac{1}{2}$, 1in. What offers?—WALKER, 37, Garnethill-street, Glasgow.

6in. **Lathe Head, T Rest**, back centre; also Jones' £9 Sewing Machine. Exchange for photographic apparatus or printing press.—JONES, 346, Upper-street, Islington.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

New Illustrated Price List of **Screws, Bolts, and** NUTS for Model Work, drawn to actual size, sent on receipt of stamp.—MORRIS COHEN, 132, Kirkgate, Leeds.

Fretwork.—Catalogue of every requisite, with 600 illustrations, free for 6 stamps.—HARGER BROS., Settle, Yorks.

Perspective, do you understand? "Knight's Practical Guide," 1s.—SIMPKIN and MARSHALL, or of J. P. KNIGHT, Art Master, Cheltenham.

Mica or Talc.—RICHARD BAKER and Co., 9, Mincing-lane, London.

Hardy's Patent **Safety Benzoline Lamp**, self-lighting, self-extinguishing, and unspillable post free, 1s. 3d.—THISTLETON, Oakham.

Wheel-Cutting to 12 inches diameter in brass only.—CLEGG, 18, Belinda-street, Hunslet, Leeds.

Planing to 12in. by 12in. by 8in. Boring, Turning, Screw-cutting, Slide-rests, &c.—CLEGG, as above.

Tracings heliographically reproduced at from 3s. Mechanics' drawings prepared.—Patent Office, Ashcroft-buildings, Victoria-street, Liverpool.

Patents.—Provisional Protection from £2. Complete from £5.—MANAGER, Patent Office, Ashcroft-buildings, Victoria-street, Liverpool.

Injectors, certain in action, easily fixed, no trouble, suit any boiler, and give perfect satisfaction.—POWELL.

Injectors, 2, 4, and 6 H.P., from 21s. Certain in action, no trouble.—POWELL, Engineer, Tunbridge Wells.

Lathes, 3in. to 7in. centre, chucks, tools. Illustrated List, 3d.—MILLS, Tintern-street, Sunderland.

Castings, Lathe Heads, Beds, Standards, Wheels, Slide Rests, Chucks, rough or machined. Illustrated List, 3d.—MILLS, Sunderland.

Launch Boilers and Engines up to $6\frac{1}{2}$in. bore. Locomotive Boilers, Engines, Castings supplied. State requirements.—MILLS.

Model Engines, Parts, Tubing, Screws, Castings, rough or bored, turned, fitted, finished. List, 3d.—MILLS, Sunderland.

Lathe Castings, &c.—See T. Taylor's advertisement in ENGLISH MECHANIC every other week. Established 1847.

Turning, Boring, Planing. Low rates. First-class machinery, best attention. Quantities estimated for.—PARFREY, Engineer, Hounslow.

Gas Engines, new patent, double acting, simplest and best in the market, $\frac{1}{2}$ to 100 horse-power.—Particulars of H. CREWE, 16, Montpelier Vale, Blackheath, S.E.

Electric Light Installations. Complete sets from £3, with and without machinery.—H. CREWE, as above.

Photographic Dark Slides, warranted light, tight; $\frac{1}{2}$-plates, double, 2s. 6d. each.—31, Yates-street, Aston, Birmingham.

Elastic Stockings, Abdominal Belts.—SMITH, 37, Breck-road, Liverpool. Only wholesale and retail makers in England.

Divining Cards for Discovering Ages and Number of Bank Note. "Cannot fail to give satisfaction."—*Bazaar*. One shilling, post free.—R. MORGAN, 33, Westow-street, Norwood.

Microscopic Slides for sale, or exchange for Lantern Slides.—S. HARRISON, Dalmain-road, Forest-hill.

Lard Oil.—Substitute for its Special Manufacture.—Write to J. M., 6, Hamlet-street, Bootle, Liverpool.

Agents.—25 per cent. offered on our celebrated **Black** BOILER COMPOSITION.—UNITED CO., 2, Jackson-road, Holloway, N.

$4\frac{1}{2}$in. **Screw-Cutting Lathe**, 4ft., £18, quite new; with chucks, tools, &c., £25; bargain.—E. B., 64, Park, Eccles.

$\frac{1}{2}$-plate **Instantograph**, 3 double dark slides and tripod, as good as new, 45s.—J. MILLER, 323, Springburn-road, Glasgow.

Calver $6\frac{1}{2}$in. **Equatoreal**, with finder, 4 eyepieces, Barlow, revolving body, &c., £21.—LEIGH, 44, Crescent, Salford, Manchester.

Bankrupt Stock.—Several 3in. **Electric Bells** at 3s. Pushes, 7d. each.—HUDDLESTON, 40, Samuel-street, Woolwich.

Living Micro. Objects.—Hydra, freshwater Polype. See page 571 last No. ENGLISH MECHANIC. Tubes 1s.—WM. SHILLINGLAW, L.D.S.I., Birkenhead.

Bentley's Electrical Stores, 7, Newton-street, Manchester. The cheapest house for bells, batteries, wires, and all fittings.

Lathe Castings, heavy geared heads; $3\frac{1}{2}$in., 5s. 6d.; 4in., 6s. 6d. Standards, Gap and Plain Beds, Chucks.—Below.

Taps, Dies, and Screws cut to order. Reply, stamp.—JARRATT, 15, Short-street, Queen-street, Leicester.

Piles.—Agonising cases cured first application.—T. PALMER'S INDIAN OINTMENT, $13\frac{1}{2}$d.—Chapel-terrace, West Auckland, Durham.

Dynamo, 30 c.-p., improved armature, 26s.; photo, 5 stamps.—D. WALTON, King-street, Hebden Bridge, Yorks.

Experimental and Lecture **Dynamo**, 10 c.-p., 18s. Dynamo Wires from 1s. 6d. per lb. Castings, &c.—D. WALTON.

Organ Pipes.—Metal Dulciana Tenor C, Wood Flute, Pedals, &c.—Mr. REID, Addington-villa, Wendover, Bucks.

Wimshurst Influence Machine.—Sole manufacturers of new and improved pattern. 12in. from 30s.—KING MENDHAM, and Co., Bristol.

Deposition of Smoke.—Complete Apparatus to perform this never failing experiment, with static electricity, 5s. 6d. and 10s. 6d.—As above.

Standard Ohm, in boxwood cylinder, guaranteed correct to ten thousandth of ohm, 18s. 6d., with copper poles, 21s.—As above.

Galvanometer Cards for tangent and ordinary combined, vertical, astatic, reflecting, and unmounted compass cards.—As above.

Variable Resistance Incandescent Lamp STAND, invaluable for battery power, vide ENGLISH MECHANIC, Oct. 16, 1885, price 3s. 6d.—As above.

Write for **King, Mendham, and Co.'s** large new and reduced Price List, post free, 4 stamps.

Water Motor, about half horse-power, price 15s.—9, Queen Anne-street, Stoke-on-Trent.

Soda-Water Machine, bargain, Recipes, &c. Particulars free.—NATHANIEL SAINT GEORGE WILCOCKS, 45, Avon-street, Bath.

Higher Powers attached to gentlemen's own Field Glasses.—BOOTH, Rownsley-street, Leeds.

"**Beginner's Guide to Photography**," one shilling. Wholesale of the publishers, LEJEUNE and PERKEN, Hatton-garden, London.

"**Beginner's Guide to Photography**," one shilling. Free from abstruse technicalities. Retail of Opticians and Booksellers.

Boilers, Vertical, Portable, and Cornish, one horse-power upwards.—GRANTHAM CRANK and IRON COMPANY (Limited), Grantham.

Xero 10-light **Dynamo Castings**, wrought cores, turned and taped, 45s. a set; finished complete, £10.—H. JONES.

Price List, rough and finished, one stamp. Plating Dynamo, 10 to 200 amperes.—Requirements to H. JONES.

Gramme Dynamo, laminated field cores and armature, high efficiency, 8 lights of 20 c.p., price £8.—H. JONES.

Dynamos sent on approval for cash, or may be seen working.—H. JONES, 48, High-street, Lambeth, S.E.

Perambulator Wheels, rubber tyres, with axles complete. Set of four, 10s. 6d.—CYCLE SUPPLY, Blackheath, London.

Tricycle Frames (front-steering central gear), all parts brazed, 50s. Photo, 3d.—CYCLE SUPPLY, Blackheath, London.

Sociable Tricycle, Starley and Sutton's Coventry, grand machine for hiring; perfect condition: £8.—CYCLE, Blackheath, London.

5in **Shaping Machine**, hand or steam-power, very strong; nearly new; a bargain.—F. BRITTAIN, 50, Upper George-street, Edgware-road, London.

Rotary Pump, cheap, hand or power, pump any kind of liquid.—J. STOREY, 37, Farringdon-street, London.

Organ Metal Pipes, voiced and unvoiced. Lowest prices.—SHIELD, 127, Little Green-lane, SmallHeath, Birmingham.

Lord Randolph Churchill has had his attention directed to the wonderful properties and increasing sale of Coca Leaf.

Coca Leaf.—Be prepared for a rise in price and give your orders at once. Sample packet, 13 stamps.

Coca.—A consignment just in, in splendid condition. Green and young leaves. By its use fatigue is unknown.

Members of Parliament, the Church, Army, and Navy, and all Athletes, especially Cyclists, use the sacred leaf.

The "**Family Doctor**" says:—"Bright hopes and grand results reside in the sacred leaf. It is essentially a temperance drink."

Coca or Cuca Leaf.—Sample packet, with medical and scientific opinions, 13 stamps.—MARKS and Co., 17, Newcastle-street, Farringdon-street, E.C.

Leclanche **Batteries**, 14s., 16s., 24s. per doz. Sample, 1s. 9d., free.—SEDDON, 5, Queen's-road, Chadderton, Oldham.

Best **Crucible Cast Steel** for drills, taps, turning tools, 6d. per lb.—GILBERT, Oxford-road, Sheffield.

For sale, 12 H.P. **Horizontal Engine**, 24in. stroke, latest improvements, in thorough working order. May be seen at work.—Apply, MORRISON and AUSTIN, 85, Worship-street, E.C.

For sale, **Soundboard**, six stops, CC to G, new within 6 years, and swell box, full size, warranted sound.—BLAND, Organ Builder, Chatham, Kent.

Also lot of Grond **Piano Keys**, in good condition, 6 octaves, cheap, and a piccolo stop, wood and metal, tenor C.—Apply as above.

Microscopical.—Large collection of Books, Slides, and Apparatus of amateur, cheap.—PARR, Ainsworth, Bolton, Lancs.

Fret Saws, 2s. gross. Glass Cutters, 9d. each, post free.—T. JAMES, Junior, Stratton Fosse, Bath.

Dynamo, F.M., planed and bored, very cheap, 4 cwt. copper wire, No. 10 cotton-covered, lengths from 250 yards, all clean, 6d. lb.—NELSON, 13, Orr-street, Glasgow.

One-man **Table Engine**, also Vertical Tubular Boiler, both fitted complete, £5 each, or £9 together.—J. SAGE, 42, Stanbury-road, Peckham.

Lathe and Circular Saw combined, 6in. centre, 4ft. bed, a bargain.—VALENTINE, Singlegate, Merton.

Trouser Lengths, 5s. Cheap cloth for ladies' jackets, ulsters, dresses. Patterns free.—HEWITT, Winfield Mount, Leeds.

Amateurs' Water Motors, half-horse, registered, Brass Sets, 12s. Full-size Working Drawings, 1s.—WHEELER, Preston.

Water Motors.—32s., 42s.: horse-power, £9; Half, £6; Quarter, £4; Eighth, £3.—THOMAS WHEELER, Preston.

Fan Castings.—Improved Registered Designs; set, 5in., 3s.; 6in., 4s.; 8in., 5s. Drawings, 4d.—WHEELER, Engineer.

For sale, cheap, 1 **Loco. Boiler**, equal to new, with dome, copper fire-box, and 72 brass tubes, tested to 150lb. per square inch, about 10 H.P.

Gas Engines.—Several Gas Engines, from $\frac{1}{2}$ H.P. to 4 H.P., equal to new. Taken out to make room for larger ones.

One **Phœnix Dynamo**, by Paterson and Cooper, to work 12 arc lamps, never been used; 4 J. F. arc lamps, never been used, by Paterson and Cooper.—Apply, S. GRIFFIN and Co., Kingston Iron Works, Bath.

Celluloid, black, amber, granite, malachite, marbles, for turning studs, fancy articles. Easy to work as brass.

Celluloid, for picture frames, can be cut with scissors, embossed, moulded, carved, and fixed with glue.

Celluloid. — Transparent, opaque, all colours. Superior to ebonite or vulcanised fibre. Absolute insulator for volt and am-meters.

Sheet Celluloid for Voss and Wimshurst Machines. Better than glass, unbreakable as sheet iron. Always gives satisfaction.

Celluloid is permanent. Does not decompose like ebonite, 2s. and 3s. lb.—PAUL WARD, 57, Chancery-lane.

Indigestion.—Remarkable cure for flatulency, &c. Send postal order 1s.—WATSON, care of 11, Gildredge-road, Eastbourne.

Fletcher's **Quick Washer**, 3 guineas; Clothes Airer, £3 12s., little used; 70s. the two.—44, Ivydale-road, Nunhead, London.

Fletcher's **Gas Fire**, X, 40s.; K, 21s.; 3F, 30s. Half-price.—44, Ivydale-road, Nunhead, London.

Benyon and Cox **Tubular Stove**, 4 000 cubic feet air per hour at 200 F., burning 12ft. gas, 4 guineas, price 30s.—44, Ivydale-road, Nunhead, London.

Violin, good tone, well made, bow and case, bargain.—37, Tyneham-road, Lavender-hill, Battersea.

For sale, 1,800 feet of $2\frac{1}{2}$in. **Inndiarubber** BREWER'S DELIVERY HOSE, slightly damaged outside. No reasonable offer refused.—Address, C. A., 107, Stamford-street, Blackfriars, London.

The Art of Staining, Graining, French POLISHING, &c., seven stamps.—HARVEY, 145, Halton-road, London, N.

Electric Depot, 10, Deansgate, Manchester. Handiest shop in the trade. Largest stock. Greatest variety. Lowest prices.

1s. **Rules for Learning to Write**, with exercises and instructions.—R. H. KAY, Ramsbottom-lane, Ramsbottom.

Britannia Co., London Showroom, first floor, 99, Fenchurch-street. All letters to Britannia Works, Colchester.

We are **Bona Fide Makers** of upwards of 250 varieties of Lathes and Engineers' Tools.—BRITANNIA.

Thousands of **Castings** for Lathes, rough or milled, drilled or turned. Give exact details.—BRITANNIA Co.

Surplus Stock.—New **Files**, 6in., 4d.; 8in., 6d.; 10in., 8d.; 12in., $10\frac{1}{2}$d. Sent per post 1d. to 2d. extra.—BRITANNIA Co., Colchester.

Patent Treadle **Saw**, easily cuts 4in. square.—BRITANNIA Co., Makers, Colchester.

Patent **Saw** and Samples of Work on view.—BRITANNIA Co., 99, Fenchurch-street, London.

$3\frac{1}{2}$in. **Electric Bells**, plated under domes, 4s. 3d., free. Ebonised or boxwood Pushes, 8d. free.—PENNING.

Chromic Acid, 1s. per lb. Salammoniac, crushed, 8d. Ebonite Cells, 7 by $5\frac{1}{2}$ by $3\frac{1}{2}$, 1s. 6d.—PENNING.

Wire, cotton and silk covered, per lb., No. 16, 1s. 7d. and 2s. 6d.; No. 26, 2s. 6d. and 4s.; No. 36, 6s. and 10s.—PENNING.

Ilford $\frac{1}{4}$ Dry **Plate**, 1s.; ditto, 5 by 4, 1s. 9d.—PENNING, Southsea Laboratory, Southsea.

The **Safety Governor**.—MATTHEW TAYLOR BROWN, 33, Hope-street, Glasgow.

Terminals, Terminals.—One shilling per dozen. Sample Terminal, free, two stamps.—CROOK, 77, Vernon-street, Bolton.

Brass **Door Plates**, 9 by 4, any style, sent free, 4s. 6d.—DEACON and SON, Ramsgate.

Brass Plates made and engraved at lowest prices Estimates given.—DEACON and SON, Engravers, Ramsgate, Kent.

Zinc **Stencil Plates** for marking sacks, boxes, &c. Estimates free on application.—DEACON and SON, Ramsgate.

Inventors.—Why not save half charges? Have your Patent Drawings done by draughtsman Below.—JOHN HART.

Foreign Patent Drawings executed at 10s. per sheet in duplicate by experienced Draughtsman. Address below.—JOHN HART.

Model Making in Wood, Iron, or Brass. Low charges. Working Drawings made. Address below.—JOHN HART.

Electrical Appliances of every description made and supplied.—Address, JOHN HART, 304, Kennington-road, London, S.E.

Non-congealable **Cotton Oil**.—For its special preparation, write to J. M., 6, Hamlet-street, Bootle, Liverpool.

Hot Air Engines.—Models that will work constantly, 12s. Particulars, stamp.—J. SEAL, Chapel-street, Hammersmith.

J. Seal's **Hot Air Engines** give satisfaction wherever supplied, and are pronounced well worth the money.

NOTES ON THE CHAMBER ORGAN.—IV.

By GEORGE ASHDOWN AUDSLEY, F.R.I.B.A.

CONSIDERABLE diversity of opinion obtains amongst organ builders and organists respecting the composition of Mixtures; but it is not my intention, in these Notes, to enter on any kind of discussion connected with the subject. I shall content myself by giving the composition of two Mixtures which I have tested and found to be perfectly suitable for introduction in the Chamber Organ. The first is of three ranks, composed as follows:—

C C to Gamut B	15 ...	19 ...	22
Tenor C to Fiddle B	12 ...	17 ...	22
Middle c^1 to b^1	12 ...	15 ...	17
c^2 to a^3	8 ...	12 ...	15

If the compass of the manual extends to c^4, five octaves, the highest octave—c^3 to c^4—should be composed of 1 ... 5 ... 10. This Mixture, if of small scale and carefully voiced, produces a pleasant bell-like quality; indeed, it was named by its originator—an organist of great celebrity—a "Carillon." The second Mixture is of five ranks, composed thus:—

C C to Gamut B......	19 ...	22 ...	24 ...	26 ...	29
Tenor C to Fiddle B.	12 ...	15 ...	17 ...	19 ...	22
Middle c^1 to b^1	8 ...	12 ...	17 ...	19 ...	22
c^2 to a^3 (or c^4)	1 ...	8 ...	10 ...	12 ..	15

This Mixture should be made of very small scaled (*Dulciana*) pipes, voiced to yield a delicate "silvery" tone, and regulated to the utmost nicety. When so treated it is most effective in both full and soft combinations. It is the Mixture I have introduced in my own organ, and which, as has been already said, can be played, in full chords, in combination with the softest unison stop of the instrument, producing an effect of the most charming character. In all respects it is preferable to the three-rank mixture first given. A stop comprising 290 pipes of so small a scale, all carefully voiced and regulated, is, of necessity, a rather troublesome and costly affair. On this account it will not be commonly introduced in Chamber Organs; but, from my own experience, I consider it well worth the money and trouble it costs. Its "harmonic-corroborating" tendency imparts great richness to the full organ tone, while it invests numerous soft combinations with almost indescribable charms.

Enough has been said, for the purposes of the present Notes, on the ordinary organ-toned and flute-toned stops, so a few remarks may now be passed on the string-toned registers, namely, those of the Viola-da-Gamba species, which more or less satisfactorily imitate the orchestral stringed instruments. A properly schemed Chamber Organ should contain either two or three stops of this class, of bright and assertive tones. They will frequently be used in rendering passages originally written for the violin or violoncello, and in producing, in combination, certain characteristic orchestral effects. For general remarks anent string-toned registers and their appropriate nomenclature, I may refer the reader to my article, entitled "*Suggestions for the Introduction of a Systematic Organ Stop Nomenclature*," on page 365 of the preceding volume. When a stop in imitation of the violin is introduced, it need not go below Fiddle G. If carried down to C C it becomes, strictly speaking, a Violoncello. Instead, however, of adding the bass to the manual register, where it will be most inconvenient on account of the space it requires, it will be advisable to insert a Violoncello in the Pedal department. In this case it should be a small-scaled, square, wood stop, on the Schulze model. I may mention that the late E. Schulze, of Paulenzelle, produced 8ft. and 16ft. registers of beautiful and strongly imitative quality, chiefly by a peculiar treatment of the caps of the pipes, and by the addition of a bridge-piece adjoining the mouths. Most effective examples of this class of stop exist, in the organ by him, at Hindley, Lancashire.

The chief difficulty attending the introduction of a Violoncello of this type is to voice it successfully on a light wind, that is, sufficiently soft for a Chamber Organ. The softer it is made the more it loses the string quality, and that peculiar rasping effect (like the bow on the string) which so materially aids the imitation aimed at.

The old-fashioned Viola-da-Gamba (conical pipes surmounted by bells), and certain small-scaled, cylindrical, pierced, and slotted Gambas are perfectly suitable for the Chamber Organ. They must be voiced, like all the other stops, to produce tones of a refined and delicate character; and must be very prompt of speech. Slow-speaking registers are of little value in a Chamber Organ. This is an important fact to bear in view.

It is the practice of some builders, as in the case of M. Cavaillé-Coll, to insert in nearly all their organs the stop designated *Voix Célestes*. In large instruments space may be spared for this purely fancy stop, but in small organs, and in Chamber-Organs in particular, the introduction of a stop of so little use is to be strongly condemned. It is formed of a rank of small-scaled metal pipes, drawn with the Viola-da-Gamba or some other soft-toned metal unison; and, through being made slightly sharper, produces with it a compound tone of a peculiar wavy or tremulous character. As I have remarked in a previous article (p. 342, Vol. XLIII.), "this stop cannot be said to be complimentary to the 'celestial voice,' at least, if it implies that it is affected with an everlasting vibrato; or that two celestial voices never sing together in perfect accord." However this may be, I am settled in my conviction that no stop which is invariably and systematically *out of tune* should be inserted in a small Chamber-Organ. The *Voix Célestes*, as an organ stop, is, to my mind, a specimen of trickery almost as paltry and undignified as the celebrated "barrel of pebbles" in the Lucerne organ. Perhaps there is some sort of relationship in their origin, seeing that both the "celestial voice" and showers of rain come from above. I have always been at a loss to understand what it is that has made the *Voix Célestes* so great a favourite with organ builders at home and abroad; and, I presume, from its frequent use, with organists also. To my ears, its prolonged use has a most irritating effect; but anything out of tune is, or ought to be, extremely unpleasant to a musical ear. Nothing in reason would induce me to introduce the *Voix Célestes* in my own organ, and, accordingly, I strongly advise it be omitted from the tonal schemes of all organs of a similar class. I dwell somewhat forcibly on this subject, for I have observed so frequently an absurd partiality on the part of organ builders for this specimen of out-of-tuneism. I have seen specifications for small organs of only four or five manual stops comprising the *Voix Célestes*. Could absurdity be carried further in the scheming of such small instruments?

In the construction of reed stops for the Chamber Organ the greatest care and skill must be exercised; for it is obvious that in an instrument which has to be listened to at a few yards distance at most, and generally only at a few feet from the keys, such assertive registers must be voiced with a degree of refinement altogether unnecessary in those intended for church and concert-room instruments. Distance, and the acoustic effect exercised by large buildings on the tones of organ pipes rarely fail to remove the harshness which may exist in reed and other loudly-voiced registers; but Chamber Organ stops are never, under ordinary circumstances at least, heard under the charm of distance or the advantage of any modifying acoustic effect. An apartment of moderate dimensions, carpeted, curtained, and in all probability overcrowded with stuffed furniture, is about the worst possible locality for such an instrument as an organ; it is entirely unsympathetic with aught that may be beautiful in its tones, while it provokingly accentuates its every imperfection. Let the reader imagine an organ containing about one thousand pipes, and in all essentials properly appointed, placed in a drawing-room measuring only 23ft. by 17ft., and 11ft. high, also containing a grand pianoforte and the usual drawing room furniture, and he will realise the full significance of the remarks just made. Yet I have known a Chamber-Organ of the size hinted at, and practically under the conditions detailed, so voiced as to be in all respects satisfactory; indeed, just as if it was made for its locality and no other.

Of the ordinary reed stops in the manual departments, the Trumpet, Oboe, and Clarionet are unquestionably the most suitable for the Chamber Organ; and all being unison registers, they impart great richness and dignity to the fuller combinations. As solo stops they are of the first rank. An octave reed stop is not of any real value in a Chamber Organ, and need never be introduced.

The Trumpet should be made to a medium scale, and voiced to yield a clear ringing quality of tone, free from that harsh, brassy character which appears to be aimed at by the generality of reed voicers. The diameter at the top of the C C pipe should not exceed 3½in., allowing for a wind-pressure of 2½in. or 2⅝in. The reeds used should be "open." As the tubes of the Trumpet can be mitred in any direction, generally with advantage to the tone, there is no difficulty, even in swell-boxes of only 5ft. internal height, in carrying the stop down to C C. On no account should such an important stop be inserted in an incomplete form, for the absence of the bass octave seriously impairs the general utility of the stop, and denudes it of the chief element of its grandeur.

The Oboe is a stop which should find an honoured place in every Chamber Organ, being invaluable in combinations of medium strength, and as a solo register. It ought to be of medium scale, shaded, and voiced with "closed" reeds. As the Oboe can also be mitred, it should, if possible, be of the full compass; but it is not so necessary as in the case of the Trumpet, that it should be carried down to C C. It may commence at Tenor C. This stop is usually voiced in two ways: one producing a soft, normal, reed tone of pleasing quality, mixing well with all classes of flue tone, and the other yielding a delicate sound closely imitating the orchestral instrument. The selection of either of these qualities may be left to individual taste in the generality of cases; but it may be pointed out that if a generally useful reed is aimed at, the former type is to be preferred: if a characteristic solo stop is desired, the Orchestral Oboe, as the latter variety is commonly called, is certainly the one to be selected. It produces charming effects in music of a light and pastoral character, and imparts an orchestral colouring to numerous combinations. In an instrument furnished with a Trumpet, as above described, the Orchestral Oboe is decidedly the most appropriate. As I have already said in an earlier series of articles (page 365, Vol. XLIII.), "The orchestral oboe only goes a note or two

below Middle c¹; accordingly the greater part of the two lower octaves of the organ Oboe has no relation to the instrument. As the fagotto furnishes the true bass to the oboe in the orchestra, the complete organ register may be termed Oboe and Fagotto, or, if preferred, Hautboy and Bassoon. The two octaves of bassoon quality thus obtained are of the highest value in a Chamber Organ, and in voicing the pipes every endeavour should be made to render their tones as imitative as possible.

As an imitative stop perhaps the Clarinet may be considered the most satisfactory of all the reeds yet introduced in organ building. On this account it should invariably find a place in every Chamber Organ worthy of the name. As its pipes occupy less room than those of any other reed stop—the CC pipe, producing the 8ft. tone, being only about 4ft. 10in. in total length and 1⅝in. in diameter—it can conveniently be carried throughout the manual compass. This stop is frequently labelled "Clarinet and Bassoon," the organ builder being apparently under the impression that the bassoon gives the true bass to the clarinet, or that the orchestral clarinets do not descend to the bass octave of the organ unison pitch. The orchestral clarinets, including the bass clarinet, cover the entire range of the organ manual keys. When skilfully voiced and regulated the Clarinet is a most charming solo stop, and also a valuable combination register. To enable it to be properly regulated throughout its compass, all its tubes, which are cylindrical in form, must be provided with sliding pieces at top, so as to allow of them being lengthened or shortened at will. On the perfect smoothness and equality of the tone, from the lowest to the highest note, depend much of the peculiar beauty and winning character of this stop.

The reed register next in importance (for a Chamber Organ) to those above mentioned is that known as the Vox Humana, and in which, as the name implies, the imitation of the human voice has been attempted. It must be granted that the insertion of this stop in a Chamber Organ is a matter deserving more than ordinary consideration. If good in tone, and perfectly adapted for its position, there can be no question as to its interest and value; but if it is voiced to yield the usual harsh, nasal sounds, and requires distance to lend enchantment to its tones, then it is an abomination in a room beyond the power of moderate language to describe. The expedient of giving artificial distance to this stop, by inclosing it in a separate box placed within the main swell-box, has only been to a small degree successful. By such means the tones of the stop are literally smothered; and it becomes a question if the cure, if so it may be called, is not worse than the disease. While I aim at imparting to the organ the highest possible powers of expression, I utterly condemn everything that muffles or circumscribes its free speech. If a Vox Humana is to be inserted in a Chamber Organ, it must be one made and voiced by the hand of a master specially for the position it is to occupy. All the delicacy and character required must be inherent in the stop itself; and, while distance cannot but impart additional charms to its tones, they must be independent of its ameliorating influence. That such a stop can be made I have satisfactory proof. It is well known that the imitative quality of the Vox Humana is almost altogether dependent on the vibrato effect imparted to it by the Tremulant, while it is vastly improved by the union of a very soft unison Flute; but it is not commonly realised that a well-voiced Vox Humana, without the Tremulant, is a valuable reed stop in combination with a variety of other registers. Such, however, is the case; and it is evident that the Vox Humana which is perfectly satisfactory in its dual capacity is the one to be adopted for a Chamber Organ.

In my opinion it is much to be regretted that English organ-builders have not given the construction of *free reed* stops their earnest attention; for had they done so the list of registers suitable for the Chamber Organ would certainly have been materially enriched. In this, as in some other directions connected with the art of organ building, it is apparently left to American builders to distinguish themselves. They are certainly producing some fine examples of free reed organ stops. In the Pedal department of my own Chamber Organ I have a very charming Euphonium, made by the king of American organ builders, Hilborne L. Roosevelt, of New York. Its tone is singularly pure, and, if one may be allowed the simile, as smooth as a piece of velvet. I am, of course, aware that examples of free reed stops have been inserted in English organs; but they present themselves to my mind as tentative essays, timid, and not altogether successful. The orchestral corno Inglese has usually been considered the instrument most easily imitated by free reeds; but how many examples are to be met with in this country I am unable to say. One appears in the Swell department of the organ in the Town Hall, Leeds. In the Choir of the same instrument is a free reed "Euphone" of 16ft. tone. Several free reed stops are known to me in Continental organs, notably those in the cathedrals of Lucerne and Fribourg, in Switzerland. In the former, the Fagotto & Clarinet and the Physharmonica, 8ft. tone; and, in the latter, the Physharmonica, 16ft. tone, and the Physharmonica 8ft. tone are constructed with free reeds. On examining these registers, I found the Physharmonica in the Lucerne organ to be of free reeds, inclosed in a special swell-box, but devoid of pipes*; while those in the Fribourg instrument are furnished with short inverted conical tubes, and also inclosed in a special swell-box. A stop of the latter class would be very suitable for a Chamber Organ; and, if voiced by some master hand in one of the "American organ" factories, would, I am sure, be a most pleasing addition to the ordinary organ tone. The Fagotto & Clarinet, in the Lucerne organ, has short pipes of tin rising from large square wooden boots.

With the above sparse and, I fear, unsatisfactory hints regarding the stops most suitable for the manual departments, I must conclude the present instalment. In my next I shall say a few words anent the registers to be recommended for the Pedal department of the Chamber Organ.

(*To be continued.*)

* It may be interesting to some readers to know that this Physharmonica was made by J. and P. Schiedmayer, of Stuttgart, a firm still in existence.

THE AMATEUR WORKSHOP.—XXV.

Self-acting Lathes.—(*Continued.*)

BACK-GEARED head-stocks may be made to mould in three different ways: one, in which the pattern is jointed in the longitudinal direction, is shown in Vol. XXXVIII. p. 164. In the other two the pattern is unjointed, and moulds either downwards or sideways. When moulding downwards—that is, upside down—drawback plates are necessary to lift away the sand over the lugs, or a single drawback plate can be used over the longer lugs, the shorter ones being skewered on. This is not a good plan with so small a pattern as ours. The other alternative is to mould sideways, the moulder's sand joint being made to follow the top edge of the pattern, while the hold-down boss, the bosses for the mandrel collars, and the lugs for adjustment, are skewered on. Fig. 269 shows the pattern thus made. This is given as an alternative to the method shown on p. 164 just now referred to, and although I have drawn pocket core prints, it would be as well, if power drills are available, to cast no holes in, but leave the bosses plain and solid. Still, if it is preferred to core them out, and the job is put into the hands of a careful moulder, he will stop them over neatly enough. There is, perhaps, rather less trouble in moulding from a jointed pattern; but the line of jointure will show in the casting, while in this case there would be no joint to show. Allowances for machining must be added to the dimensions given.

The pattern of the poppet can also be jointed, as in the instance figured on p. 164, or as an alternative it can be unjointed and moulded upon its side, on the same principle as the head-stock, or moulded instead, barrel downwards, the barrel being dowelled on loosely. Say we make the barrel in the bottom, then the pattern will have the appearance of Fig. 270, and this is a very common practice, everything being in favour of delivery, and the barrel is the only loose portion. The only hole cored will be one for the mandrel, ⅞in. in diameter, in the barrel.

In the matter of boring and facing, there are two courses open to our choice, one being to bore each casting with a fair regard to height of centres, &c., then to thread the two on a mandrel, and plane the bottoms of both head-stock and poppet off together. The other is to face the bottoms first, line out the centres, and bore them each in place, and preferably at one time. Assuming that the first course were adopted, the holes in headstock and poppet could be bored with a drill and broached out, the operation being done either in a lathe or on a drilling machine, or if preferred, instead of broaching the drilled holes, they could be finished with cutters set in a bar in the lathe. But perhaps the use of a planing machine had better not be taken for granted, and the making of a mandrel to carry the heads, and the setting of the same, and properly clamping down without the springing of either head out of truth, takes much time, and is not done without much care. Hence the readiest way is undoubtedly, in my opinion, to face the feet first of all, then to bolt the heads down to their own bed, line out the centres, drill holes through, under a machine, and finally bore and finish the holes with a boring bar and cutters. To obtain the correct centres, and to insure that they are alike for height, and also coincident with the centre of the lathe bed, the simplest way which I should recommend would be to make a templet of sheet metal (Fig. 271), as being better than attempting to scribe directly off from the bed with a scribing block on the four ends of the two heads. The templet will not be turned round, but always kept with one edge outwards when marking off each of the four centres. A small hole will be drilled as shown, and the centres marked directly therefrom with a scriber point through that hole.

Supposing the heads to be cast solid, which is preferable when power is obtainable for drilling, the centres will be marked directly on to the metal. Where holes are cored they must be bridged with hard wood, and the centres marked thereon. Strike the circles representing the holes, from these centres, centre pop carefully at intervals, and proceed to drill. After drilling, clamp the two heads down upon the bed in readiness for boring. Prepare two, or better still, three blocks of hard wood, and bolt these also down upon the bed, one at each outside end of the heads, and the third between the two, holes having been previously bored in each block corresponding exactly with the centres of the heads to be bored, the holes in the blocks being of such a size as to receive the cutter bar which will be used for boring the heads. The blocks will be marked off from the same templet as that employed for the actual heads. The bar is shown in Fig. 272. Three cutters corresponding with the holes in the poppet cylinder, and in the front and back of the headstock respectively, are inserted and fastened with wedges. The smallest hole to be bored is that in the poppet cylinder, 1in. in diameter, hence we cannot have a bar larger than ¾in. in diameter, and it should not be less. We could have stiffer cutters by boring headstock and poppet separately, using the same wooden blocks for both, and having the boring bar proportionally shorter. If bored together with ordinary care, their alignment must be practically perfect; if bored separately with the

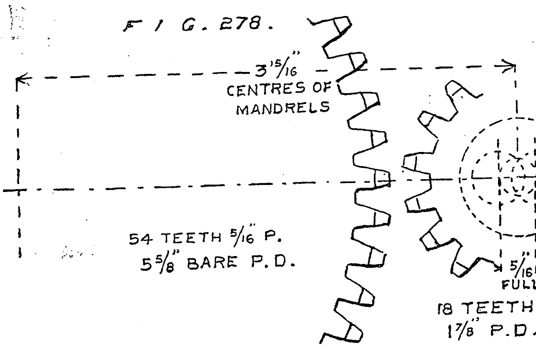

FIG. 280. SECTIONAL ELEVATION

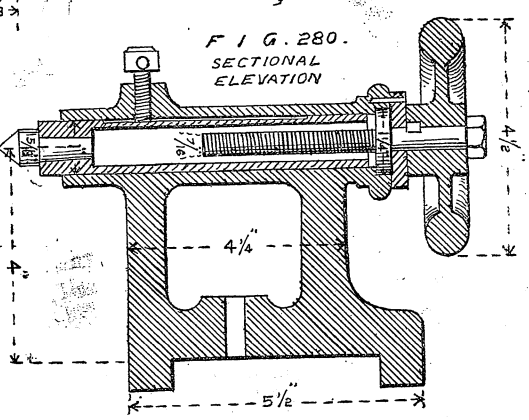

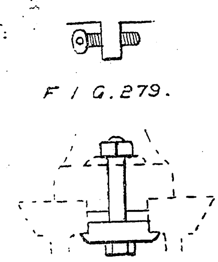

FIG. 279.

same blocks properly held down and not turned round, the same results ought to be attained, so that I think there is little to choose between the two methods. In respect to the manner of feeding the bar and cutters, at least three ways could be employed. One is to file one end square to take a spanner, and so turn the bar at the same time that it is fed forward by the poppet mandrel of a lathe, either of the same centres, or if of higher centres having the heads blocked up. Another is to let the squared end fit into a square hole chuck, and boring one head only at a time, bolt it to the saddle of a slide-rest, and so feed it against the cutters. A third will be to have the heads, either singly or both at once, bolted to a lathe bed, and the thrust of the boring bar taken by a block set at one end, the bar being traversed by means of a ratchet brace, which receives the squared end of the bar in its drill socket. This mode is shown in Vol. XXXVIII. p. 372. The cutters themselves may be made to cut at both edges, one edge being about $\frac{1}{64}$th in advance of the other, or on one edge only, as shown. The slot holes for cutters and keys will be first drilled, then filed out. The enlarged recess at the back of the poppet cylinder will be bored by setting one of the cutters out to the proper radius, and the faces of the various bosses will be turned with a broad-face cutter, right and left in turn.

I should recommend the fitting of hard gunmetal cone bearings to a lathe of this description in preference to those of steel. I know hardened steel cones are the orthodox thing, but nine-tenths of those not practically conversant with smith's and engineer's work would make a mess of the task, and unless properly done, they are better left alone. Gunmetal cones are, on the other hand, very easily fitted. Steel cones have to be welded as rings, or if small, bored from the solid, from shear or double shear steel, then turned, worst of all hardened, driven in, and ground in place. Gunmetal cones are cast, bored, and turned, and driven into place as simply as doing plain bushing, and they may be scraped or ground to a fit with the mandrel easily enough. The cones must not be made of common brass, but of good gunmetal, such as is used for bearings by good firms. Or if sent to the Phosphor Bronze Company, Summer-street, S.E., splendid bushes, tough, and almost everlasting, will be supplied in about a week. For the mandrel, a piece of steel rod of good quality is to be preferred to wrought iron simply, or to wrought iron having a steel neck welded on. The mandrel is turned to the dimensions in Fig. 273, and the coned neck and the end against which the back centre wears is hardened. In hardening, the nose is to be incased in clay to localise the heat, and preserve all but the coned neck as soft as possible. The colour for hardening should be a low red, and the mandrel should be immersed slowly and perpendicularly in water. After hardening, the coned neck should be ground in the lathe with a divided wood or lead lap, furnished with two handles for compression. The taper of the lap should be the same as the neck; consequently, there can be scarcely any longitudinal traverse, but there must be the least possible amount, just sufficient to prevent grooving by the emery.

The construction of the hinder cones is shown in Fig. 273. The headstock is there seen to be bushed with a cone driven tightly in, similarly to the one in front. Into this fits a reverse cone, which is bored also to fit the mandrel. Against the back of this abuts a collar furnished with a couple of projecting pins fitting into corresponding holes in the cone. The collar also slides on endways over a raised stud

or short feather sunk firmly into the mandrel at that point. At the back of the collar are two lock nuts. The collar, therefore, must revolve with the mandrel, and through the medium of the pins must drive the mandrel cone, and it cannot slacken back because the lock nuts hold it up to its work. These nuts are turned either with an ordinary thin spanner embracing flatted portions, or being circular, are furnished with holes for a tommy. The thrust of the back centre is taken by the bridge, which is retained in place by two pillars. The bridge can be slid off the pillars for the convenience of changing driver wheels for screw-cutting. A feather at the back of the mandrel receives these wheels. Another feather near the front end takes the main cog-wheel. The mandrel nose is screwed with eight threads to the inch, and the front bored up conical to the dimensions given, to receive the cone point.

I will now describe in as few words as possible the principle and the mode of construction of the mandrel-wheels and back-gear arrangements. The purpose of back-gear, I need scarcely say, is to cause an increase in cutting power with a corresponding diminution in speed. Whatever be the speed of the cone-pulleys, this increase and diminution takes place in the ratio of 9 to 1 in our example, the wheels and pinions numbering 54 and 18 teeth respectively. The back-gear spindle is thrown out of gear backwards in this instance by means of an eccentric, according to the common practice, instead of sliding endways, as is frequently the case in small lathes. The sectional view, Fig. 273, illustrates how the lathe is driven, either with or without back-gear. In the figure, the backgear is shown out —that is, the wheel A, which is slid on the sunk feather in the mandrel, is connected with the speed pulley, the locking nut being slid into contact with the grooves in the pulley face (see Fig. 274, showing front of wheel), and the backgear spindle is thrown back, so that its wheels are altogether out of contact with the wheels on the cone mandrel. Hence the mandrel is driven directly from the cone-pulley and at the same speed.

But when the wheel A is disconnected from the speed-pulley, the locking nut being slid out of contact with the grooves on the pulley face, into the open or clear space, the driving-belt turning the pulley carries with it the pinion-wheel B cast with it. This drives the wheel C on back spindle, and its pinion D also, because the two are cast on one sleeve. Pinion D drives wheel A, and the mandrel along with it, nine times slower than the cone pulley.

So much for the principle, now for the construction. Two gear-wheel patterns only will be required, one for the wheels A and C, and one for the pinions B and D. Let the wheel pattern be plated for convenience of alteration of bosses (see Vol. XLI. p. 250, where instructions are given for making wheels of this kind). Cut the pinion out of solid stuff according to the method described on p. 160 of the same volume. Turn the steps of the speed-pulley without giving any rounding in the pattern, and turn a plain stem for the connecting sleeve of the backgear wheels. Prepare the pattern of the pinion with the speed-pulley to be cast first, we will suppose, jointing the parts together with central turned studs, loosely fitting, for convenience of separation and delivery in the mould (see Fig. 275). The interior of the pulley will be cored out, the core box (shown in half-section in Fig. 276) being jointed longitudinally, and the strips being put on the ring in the box. To carry the core, a print 4⅜in. in diameter will be put on the one side, and one ⅝in. in diameter on the other. After this is cast, the wheel and pinion will be cast on the sleeve (Fig. 277), a boss being cast also on the front of the wheel. The core will be a chambered one (see Fig. 273), and carried by the two prints. Afterwards the wheel A, Fig. 273, will be cast singly, with bosses on back and front, and a thickening-up strip being fastened to the web, and a core print and core box for the slot hole being made. (See Fig. 274.)

The portions of these wheels which are necessarily machined are those in actual contact with bearing parts, as the bores and the faces of the bosses. But all other parts are turned up bright for the sake of true running and for good appearance. Hence slight allowances must be made for these in the patterns. It will be best in each case to bore the wheels first, and then to turn them upon an iron mandrel. Both operations require to be carefully done. A twist drill driven through with a light feed will answer for the holes, but it would be still better to impart a finish with a broach. A slight rounding is put upon the speed-pulleys, and a key-way is filed in the boss of the wheel to slide over the feather on the mandrel.

The mandrel for the back shaft has a solid eccentric turned at one end (Fig. 273, *a*). At the end opposite, a similar eccentric is keyed on. The mandrel is prolonged at *b*, into a square end, in order to allow of a spanner being used to throw the mandrel into and out of gear, and the amount of eccentricity is to be sufficient to allow the points of the teeth to clear, say, by ⅛in., when out of gear. As I have drawn the wheels, Fig. 278, the eccentric has a throw of $\frac{5}{16}$in. full at its extreme positions, so that the centres of the holes for the headstock and back spindle mandrels are 3$\frac{5}{16}$in. But it will be well not to drill the holes in the back-gear lugs until the wheel castings are made, and then to try these in gear, and take off their exact centres with compasses, both when in and when well out of gear, and take the mean for the centres of the holes, and half the amount of difference for the radius of eccentricity.

The back centre is simply a parallel, double-ended screw of steel, having a feather sliding in a key-way in the central hole of the bridge, which is of cast iron. The wearing end of the centre is hardened. The pillarets which carry the bridge are of wrought iron. Setting screws and hold-down bolt and washer (Fig. 279) complete the headstock.

At the present stage we suppose that the poppet cylinder has been bored truly in line with the headstock. The poppet mandrel can either be bored up out of a bit of solid wrought iron or steel rod, or it can be made from a piece of solid drawn hydraulic tube, into each of whose ends a bit of rod is either welded or screwed to form a collar of metal around the smaller holes to be subsequently drilled in it. The section (Fig. 280) shows this mode of formation, together with dimensions. The mechanism of the mandrel movement is also shown clearly in the same section, and requires no explanation. The screw may be either square or angular-threaded. The only portion of this work which is hardened is the centre point, the centre being, therefore, of steel.

HOW TO MAKE A MEDICAL COIL: WITH PRIMARY AND SECONDARY CIRCUITS AND REGULATORS TO BOTH.

By S. R. BOTTONE.

1. PROCURE a well-seasoned board of walnut about 21½in. in length, 3in. wide, and ⅜in. thick. From this cut one length 12in. long for the base board (Fig. 5) and three pieces 3in. square (like Fig. 4) for the coil heads; when cut, a fillet 8in. long must be nailed or screwed on the two sides of the base board (as shown at Fig. 5); these fillets should be ½in. square section. Corresponding square nicks must be cut of *two* of the square heads (as shown at *a*, *a*, *a*, *a*, Fig. 6). All the woodwork when thus squared and finished, should be soaked for a quarter of an hour in melted paraffin wax, and then rubbed dry while still warm.

2. Procure a thin brass tube (known in the trade as "triblet tubing") about ½in. diameter, 4½in. long; turn up a short plug and button to fit one end of this tube and serve as a handle (see Fig. 1, *a*). This may be fastened to the tube by driving in three fine brass brads, and filing off the heads flush with the tube.

3. Now cut up about 100 lengths of straight iron wire (best soft annealed) No. 22 gauge, say, about 4½in. in length; fill the brass tube with them as tight as you can fit them; cut them all to the same length (they must protrude a little beyond the tube). Now draw out about a couple of inches of the iron bundle, and wrap it tightly round with twine, leaving about ½in. free. Draw more out, and continue wrapping until you have wrapped to within ½in. at each end of the bundle. Tie the string, and withdraw the bundle from the brass tube. Melt a little solder in a ladle, dip the ends of the iron bundle into soldering fluid (zinc dissolved in hydrochloric acid), and then at once into the melted solder. Allow the bundle to cool; file off the superfluous solder, so that the bundle will just enter freely into the tube. It should appear like Fig 2 when the string has been removed.

4. The next operation is to make a good stout paper tube, also about 4½in. in length, into which the brass tube (Fig. 1) can slide easily. To make this, put a few turns of soaped writing paper round the tube No. 1, then roll and glue seven turns of good, stout brown paper, 4½in. in length, round this writing-paper, or else it will be difficult to draw out of the tube. This paper tube (Fig. 3) must be allowed to dry thoroughly while still on the brass tube (Fig. 1). When *quite* dry, it must be slipped off, the writing-paper lining drawn out, and then it must be soaked for a few minutes in melted paraffin wax.

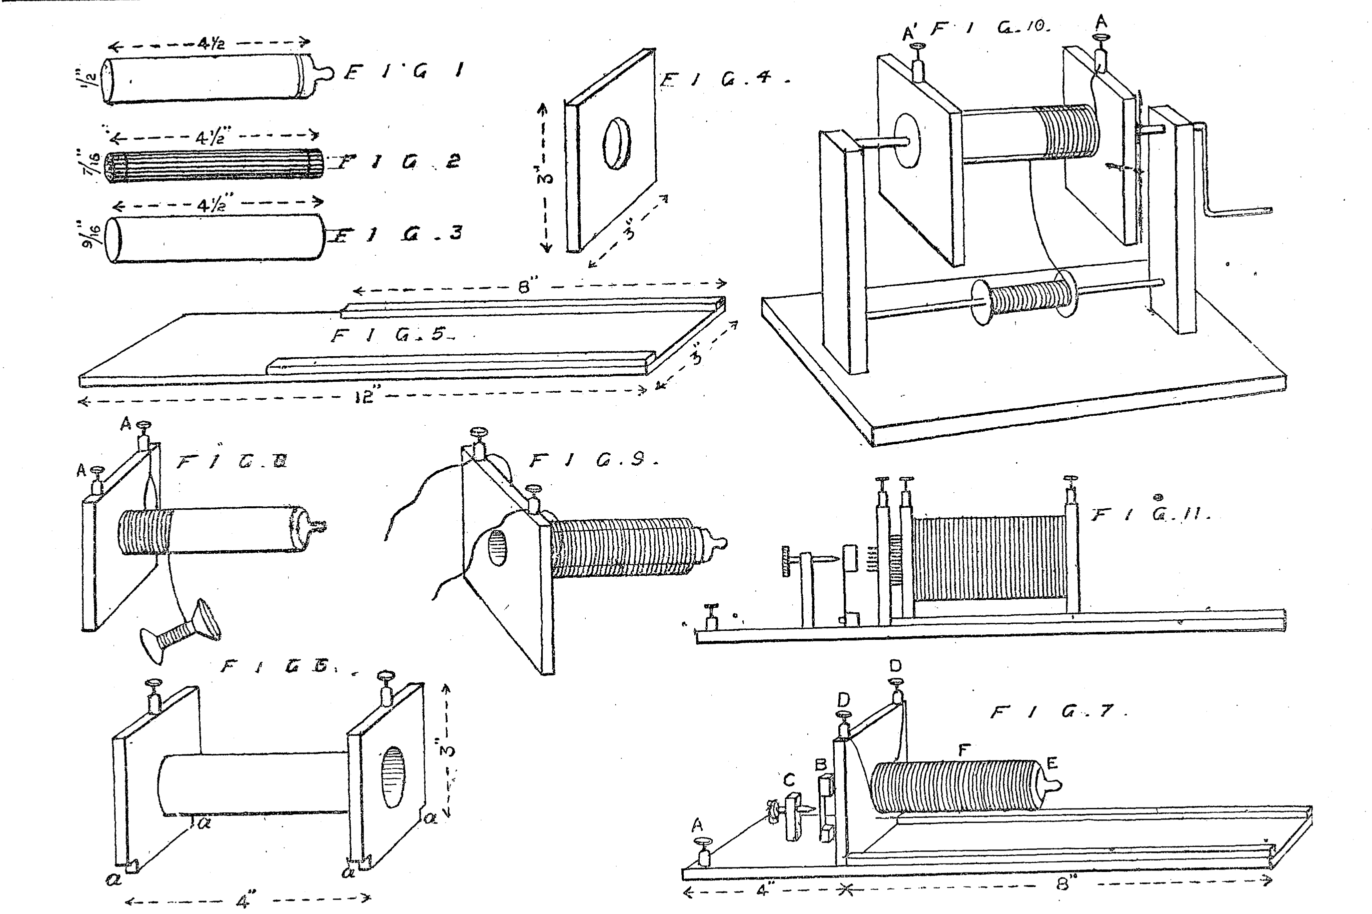
5. The iron bundle should also be allowed to stand in melted paraffin wax for some time, and then stood up to drain in a warm place. This will prevent rusting. When quite cold, all superfluous paraffin having been removed, a strip of brown paper, ½in. wide, is rolled round one extremity of the iron bundle, until it is of such a diameter as to fit tightly into the paper tube, Fig. 3. This paper strip must be cut off at this point, and glued tightly round the end of the iron bundle. The brass tube (Fig. 1) is then slipped over the iron bundle, until it just reaches the little paper collar just made. The brass tube and bundle together are pushed, button end first, into the paper tube Fig. 3, and when the paper collar around the iron bundle is just about to enter the paper tube, it is to be well served with hot glue and forced into the tube. The whole must now be allowed to dry and set thoroughly.

6. Taking one of the 3in. heads (the one which has not any nicks in the sides) we bore a central hole with a brace and centre bit, just large enough for the paper tube (Fig. 3), with its iron core, to fit tightly (see Fig. 4). Putting a little thin good hot glue round the free extremity (the end opposite that at which the brass enters), we push it into the hole in the square head, until it projects about ⅛in. on the other side. This must be allowed to dry thoroughly before proceeding to the next operation.

7. We may now proceed to wind the primary coil. To this end, we take about ½lb. of No. 24 silk-covered copper wire, and wind it round the tube, as shown at Fig. 8, from end to end in continuous layers, taking care to put a sheet of paraffined paper between each layer, and also to baste each layer with melted paraffin wax before winding on another. About four layers will thus be got on, and an even number of layers must be aimed at, so as to get the two ends of the wire at the same extremity, so as to be able to fasten them *under* the binding screws A A (Fig. 8). To effect this, before screwing down the said screws, the ends of the copper wire are stripped of their covering and wound once round the screw of the binder. Free ends of wire, at least 6in. in length, must be left for attachments, &c. This is shown at Fig. 9.

8. This primary coil, with its iron core, sliding brass tube regulator, &c., may now be fastened to the baseboard by means of two screws from underneath, as shown at Fig. 7, at 4in. from one end, and therefore 8in. from the other. One of the free ends of the primary wire is brought to one of the binding screws A, while the other connects to the clapper B. A short piece of wire connects the platinum screw pillar C to the other binding screw, which is not visible, as it is behind the platinum pillar. At this point it will be well to try the working of the primary coil. For this purpose couple up the two binding screws on the base board with a good bichromate cell. Connect the two binding screws D D (Fig. 7) with the two brass handles intended for use. Screw up the platinum screw C until the clapper B begins to vibrate. Now hold the handles in your hand. As long as the brass tube E is entirely over the iron core little or no sensation is perceptible. If an assistant pull out the tube, little by little, the current will be found to increase in strength until the regulator tube is quite out.

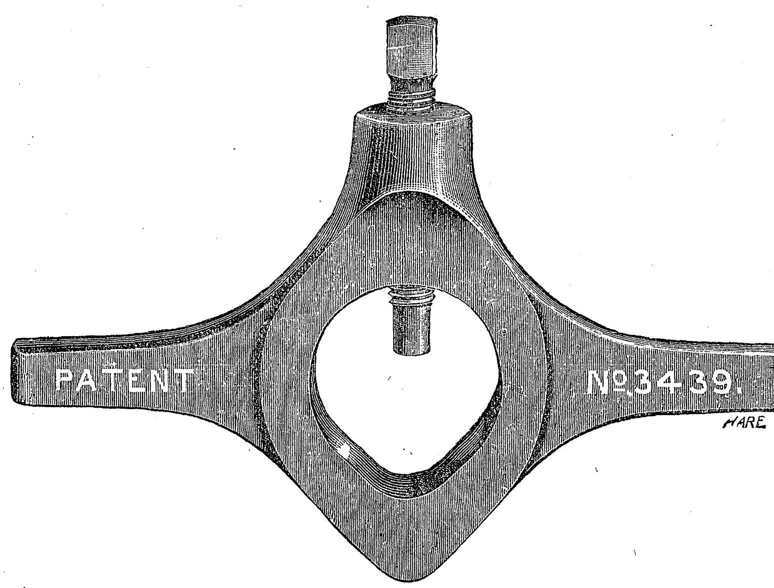
9. The secondary coil now demands our attention. A paper tube, precisely similar to Fig. 3, but of such a size as to slide *easily* over



the primary coil E, (Fig. 7), is prepared, and paraffined. This must be cut exactly the length of the coil F, leaving the knob E projecting. The two square pieces of board in which the nicks were cut (Fig. 6) must then have central holes cut in them to take this paper tube, and then glued, one at each end of the said tube, as shown at Fig. 6. Two small binding-screws are then to be inserted in the centre of the upper edge of each square. A bung is now placed in each end of the tube, and a ¼in. iron rod pushed through both, to serve as an axle. This is then mounted on two standards, as shown at Fig. 10, and beginning by attaching one end of the uncovered wire to the binding screw A, about ½lb. No. 36 silk-covered copper-wire is now carefully coiled on, being most diligent in avoiding kinks, breaks, or flaws of every description. Each layer must be paraffined and separated from its neighbour by paraffined paper. When the quantum of wire has been laid on, the finishing end is connected to the binding screw A¹ Fig. 10. The last coil should be covered with paraffined paper, and finally covered with a jacket of good silk velvet. The secondary coil is then complete, and may be slid in its place over the primary coil (see Fig. 11). When it is quite over the primary the secondary current will be at its strongest, if the metal tube regulator is drawn out; it will be weaker as the metal tube regulator is more and more inserted; or may be even more delicately regulated by sliding the secondary coil itself more or less over the primary. The secondary coil, while the primary is being excited with a freshly-made pint bichromate, will give a ½in. spark, when the regulator is out, and the secondary coil right over the primary. This will pass easily through a dozen persons.

DOUBLE DRIVING LATHE-CARRIER.

THE Britannia Company, of Colchester, have recently brought out a new patent double driving lathe-carrier, shown in the illustration annexed, the advantages of which will be seen at a glance. These carriers are in use in all sizes, from Nos. 1 to 6, at Woolwich Arsenal, and have found considerable favour elsewhere. The advantages claimed are—1. They equalise the strain, and reduce the thrust upon the lathe centres, thereby reducing the wear of lathe. When the lathe has not a Clement's driver an extra stud in the face-plate is required. 2. By their use truer work can be produced and saving of time effected. 3. They prevent the work being thrown out of the centres. 4. They are especially valuable when the work to be done is of large diameter. 5. The position of the grip screw prevents it being sheared off through being improperly used as



a driver, as is frequently done by the ordinary carrier. 6. They are made of steel, with steel set screws, and will be found to be the most handy and durable carrier yet introduced. 7. The price is but a trifle higher than the ordinary carrier. 8. The two wings act as handles, and are very useful as such when the work is heavy.

THE INVENTION OF RAILWAY COUPLINGS.

THE following remarks on railway couplings are from the *American Journal of Railway Appliances*:—There is something almost melancholy in the ignorance of the average coupler inventor and the public generally, relative to the state of the art, the amount of work that has been done, and the number of patents that have been issued for inventions of this class.

This multiplicity has been brought about to a great extent by the casual ventilation that the matter has received in the newspapers. A great deal has been printed about the necessity of having some form of automatic coupler that will protect the trainman from injury, and Railroad Commissioners and State Legislatures have been urged to take some action in the matter. Yet while all this was said and written not one word has been printed by these same journals regarding the requirements that must be met by the successful inventor.

That it is an easy matter to construct a device that will attach itself to another of the same sort, when the two are brought in contact, is witnessed by the four or five thousand patents that have been issued. Farmers, doctors, lawyers, merchants, and a very few railroad men have entered the race; and each has been encouraged by the patent lawyer to whom the application was intrusted to prosecute the claim and pay the fee. And now that the ball has started there seems to be no

chance of a stoppage. In the past two months of May and June the Patent-office issued sixty-two patents on car-couplers. Now, when the thousands that have preceded are taken into consideration it seems like a farce to think that any one of these sixty-two patents can embody any new or valuable features; and even if they do, what chance have they of success? Ignorance of the essentials, we repeat, is the probable cause of the trouble. What does the outsider, whose only contact with a railway has been as a passenger, know of the true coupler requirements? He simply knows that the coupler must fasten two cars together automatically, and be released from the outside, but knows nothing of the strength of the draw-bar, the cushion in drawing and backing, the slack required for starting, the necessity of being automatic with all kinds and degrees of draw-heads, and above all, of the absolute necessity for few working parts. The result of the travail is a complicated piece of watchwork that is no more suited to the purpose than a baby carriage would be for freight service.

This was particularly evidenced by the hook coupler that was on exhibition at the recent Master Car Builders' Convention at Niagara, and which, by the very multiplicity of its parts and utter unsuitableness, attracted a great deal of attention. The inventor brought it on, all the way from Kansas, and had evidently strained his resources to the utmost in order to meet his expenses, confident that could this child of his be once seen, the whole railroad world would be at his feet for the privilege of adopting it. His contact with the cold, hard facts that confronted him and told him that he was far behind in the race, must have been a staggering blow, and yet it is what all but a dozen or more of our sanguine five thousand patentees must receive. The coupler fiend which has so long been the terror of our railroad officials must soon become one to the Patent Commissioners, unless a little honesty is infused into the average of patent lawyers, and they can be induced to advise their clients not to try for a prize that is so far beyond their reach. But as this is a moral impossibility, it only remains to wait until the fever has run its course and died a natural death.

COLOUR VISION.

THE discussion on Colour Vision at the British Association was, as promised, carried on with some vigour, Lord Rayleigh opening by observing that the subject of colour vision having two sides had been treated rather from two opposite or divergent points, and it might be said that the recognised views on the matter were not altogether in harmony. From the purely physical point of view all light of defined refrangibility was one and undecomposable if the phenomena of polarisation are set aside. If that were the end of the matter the result would be in one sense very simple, and in another complicated. It would be conceivable with various mixtures of different kinds of light taken from different parts of the spectrum that each mixture might produce a perfectly definite effect. That, however, was not the case. No amount of practice in colour-matching or observation would allow the unaided eye to tell exactly what was the physical composition of a mixed light presented to it. It was well known that ordinary white light, as we had it from the clouds of the sun, was highly composite. It was possible to produce other kinds of white light than that by taking various kinds of light and mixing them together, and the unaided eye could not distinguish those various whites from the original white of the sun. However, we were able to make some distinctions. We recognised light as variously coloured, and the question of colour vision was to examine and analyse in what the power of the eye to distinguish chief kinds of light consisted. In that sense it was a physiological question, dependent entirely upon the properties of the eye. On the other hand it so happened that some of the methods by which the examination was most easily pursued was by physicists, and they had accordingly interested themselves in it. The first point established by the labours of various workers was that colour vision was threefold; that in ordinary people colours might be different in three ways. Perhaps the easiest way to understand that was to distinguish the differences of colour as dependent upon dilution with white and colour proper, or hue. The distinction of brightness everyone would understand—it was simply a question of more or less. Then there was the distinction, as for instance, between red and pink (using the words in a vague sense); and, thirdly, the colour distinction, by which was meant, for instance, distinction between the fundamental colours of red, yellow, green, blue, and violet. To prove that the ordinary colour vision was threefold, and threefold only, it was necessary to match colours. One of the simplest ways was by means of coloured discs so overlapping one another as to expose on the circumference sufficient of each colour to produce the desired effect. Lord Rayleigh gave several illustrations, and by means of Maxwell's triangle explained the relationship of one colour to another. Red and green give a yellow, so that yellow could not be a primary colour sensation; but the red and green, so far, might be. In this manner all colours but red, green, and violet might be proved not to be primary; but of course, it only proved negatively, not absolutely, that the three colours mentioned were primary themselves. The main difference between Hering's theory and Young's theory was in the latter's assumption that a mixture was more complicated than its ingredients. Then there was a further field in those described as colour-blind people. The term was incorrect, for these cases were only instances of partial colour-blindness. By comparing these defective colour visions with the ordinary colour visions complicated questions would arise, and to these Lord Rayleigh devoted the remainder of his paper, pointing out the arguments *pro* and *con.* in regard to some of the theories raised.

Dr. König said one could explain all phenomena of colour perception by supposing that each surface element of the retina consisted of three constituents, each of which when affected caused a different colour sensation. On this supposition all the various shades of colour were resultant of three fundamental sensations originating in those constituents. Young proposed red, green, and violet as the fundamental sensations, and a self-evident conclusion was that the sensation of white was the resultant of the simultaneous action of all three constituents. The knowledge of facts was too meagre to prove the ideas of Thomas Young till thirty years ago, when Maxwell and Helmholtz saved those ideas from utter oblivion. The results of the former's investigations must be greatly valued, because they contained the first measurements of spectral light. Latterly, more exact measurements had been carried out, and they were now extended to the whole spectrum by himself and his colleague, Dr. Dieterici. Dr. König detailed the method adopted to secure these measurements, and described the apparatus used. There were persons, he said, who could distinguish no different shades of colour, having one elementary sensation only. Another and more numerous class of persons were those called colour-blind, in whose case the whole spectrum could be divided into two parts. The third and very large class included all those not belonging to the former two. At great length Dr. König detailed the technical results of his researches, which, he contended, served to prove that Young's views, slightly modified by modern experiments, were perfectly correct.

Dr. Michael Foster discussed the subject from the physiologist's point of view, which he said was in antagonism to the physicist's in several radical points. He mentioned that the "pernicious practice of smoking" had the result, if persisted in for a long time, and particularly if the smoker confined himself to a particular kind of tobacco, of producing colour-blindness in the very central field of the red. We all of us were more or less colour-blind in the outside of the pupil; but those people who were called colour-blind really had, as it were, a patch cut out in the middle of their retina where they were colour-blind. They could not see red, or they could not see green; they called green yellow, and so on, and there was the further stage where they had no sense of colour at all. The more physiologists knew about the living body, the nearer they drew to the completion of the theory that there were two processes always going on in the body—a building up and breaking down. In the theory of colour perception this idea was carried out in the supposition that certain rays of light acting on the retina broke down its substance, and produced the sensation of colour from these rays, and certain other rays broke down the substance of the retina and produced another sensation of colour. When the breaking down went on, the sensation produced was yellow, and when blue rays fell upon the same substance of the retina it was built up. Then they came to a point where the breaking-down and the building-up neutralised each other, and they had no sensation of colour at all, or, in other words, colour-blindness. He alluded to the difficulty experienced by people partially colour-blind not being willing to submit to experiments. He could not come to the conclusion that yellow was a mixed sensation, and Hering's theory pleased him because it reserved colour from that degraded position.

Mr. J. Tennant, referring to Hering's and Young's theories of colour vision, pointed out that they had three independent variables, and led to the same general results. Dealing with the point of simultaneous contrast, he said that the only possibility of deception of the judgment lay in the fallibility of the memory. Simultaneous contrast was a real and not an illusory effect, and demanded a physiological explanation. Without accepting Hering's theory as established, he said that it formed the best working hypothesis in the immediate future.

Prof. Haycraft said he was no wiser after the discussion, and he did not believe anyone else was.

BRITISH ASSOCIATION.

ABSTRACTS OF REPORTS, PAPERS, &c.

Tidal Observations.

THE report of a committee consisting of Profs. G. H. Darwin and J. C. Adams, stated that the Indian tidal results, and those given in the various reports to the British Association, had been reduced by Major Baird to the standard form recommended in 1883. To these had been added the results derived by the United States Coast Survey, and the whole had been published in the *Proceedings* of the Royal Society. In the course of the Indian tidal observations a discussion had arisen as to the determination of a datum level for tide-tables. The custom of the Admiralty was to refer the tides to "the mean low-water mark of ordinary spring tides." This datum had not a precise scientific meaning. It was now proposed to adopt as the datum level of any new ports in India for which tide-tables were to be issued an authoritative datum, to be called "the Indian spring low-water mark." This datum was found to agree pretty nearly with the Admiralty datum, but was usually a few inches lower. The committee also presented a report on the "Harmonic Analysis of Tidal Observations." The report showed how harmonic analysis might be applied to the reduction of a short series of tidal observations, such as might be made when a ship lay for a fortnight or a month in a port. The examples given afforded evidence of the utility of even so short a series of hourly observations as would extend over a fortnight. An attempt was made to detect the 19-yearly tide. There were but few ports for which a sufficient map of accurate observations were accumulated to make the detection of the 19-yearly tide possible. From calculations founded on the values of the mean sea-level at Karachi for fifteen years (supplied by Major Baird), it was obvious at a glance that the oscillations of sea-level were not due to astronomical causes. The figure obtained showed that the actual change of sea-level between 1870 and 1873 was nearly 0·25ft., and this was just about nine times the range of the 19-yearly tide—viz., 0·028ft. It was thus obvious that this tide must be entirely masked by changes of sea-level arising from meteorological causes. It seemed unlikely that what was true of Karachi and Bombay was untrue at other ports, and therefore they must regard it as extremely improbable that the 19-yearly tide would ever be detected.

Electrical Standards.

The report of the committee on Electrical Standards was presented by Mr. R. T. Glazebrook, F.R.S. It contained the results of observations on the values of standard resistance coils by himself, Mr. T. C. Fitzpatrick, and Mr. J. T. Bottomley. Eighteen standard coils had been tested during the year, and certificates of their value issued. The attention of the secretary was called to the fact that the paraffin in some of the coils showed a trace of green colouration round the edges. This had been shown to arise from the action of a small amount of acid left in the paraffin on the copper of the case and connecting rods, and the committee were considering how to deal with the difficulty. At present the insulation resistance of the coils was extremely high, amounting to as much as 8,000 megohms. The committee expressed their sense of the great desirability of establishing a national standardising laboratory for electrical instruments on a permanent basis, and their readiness to co-operate in securing the same. The committee applied for reappointment, and for a grant of £50.

Report of Electrolysis Committee.

As the result of the discussion on electrolysis which took place last year at Aberdeen, a committee was appointed to investigate the subject. A number of observers have been working independently, and a few of their researches were communicated as an interim report. These papers will be printed and circulated among the members of the committee before appearing in the annual report of the association.—Prof. Oliver J. Lodge gave an account of his investigations on the migration of ions, as tending to confirm by direct experiment the velocity numbers calculated by Kohlrausch from conductivity data.

Magnetic Observations.

Prof. Balfour Stewart brought up the second report of the committee appointed for the purpose of considering the best means of comparing and reducing magnetic observations. Since the last meeting of the Association Mr. G. M. Whipple had made a comparison between the method of obtaining the solar diurnal variation of declination adopted by Sir E. Sabine, and that of Mr. Wild. These methods were applied to three years' observations at the Kew Observatory, and the results were compared with those deduced by the As-

tronomer Royal from the same three years at Greenwich. The committee thought that this comparison deserved careful study, but they did not feel themselves able to pronounce as yet upon the comparative merits of these various methods. Nevertheless, they were of opinion that it is highly desirable to record the daily mean values (undisturbed) of the three magnetic elements side by side with their solar-diurnal variations. After giving the results of observations, comparisons, and calculations made by various members of the committee, the report stated that extensive comparisons between the simultaneous traces of magnetographs in various places, combined with the Greenwich results obtained by Sir G. B. Airy, Astronomer Royal (who with other eminent observers had been added to the committee), seemed to show that an easy approximate method of recording earth currents might be obtained from magnetograph indicators. Observations by Prof. Stewart and Lant Carpenter appeared to show that there was some relation between solar disturbances and wind values. Prof. Stewart had pointed out certain general considerations which appeared to indicate that the solar diurnal variation might, perhaps, be caused by electric currents in the upper atmospheric regions. Dr. Schuster had made a preliminary application of the Gaussian analysis tending to confirm this hypothesis. His conclusions were sufficiently well-confirmed by observations, and thus rendered hopeful the first attempt to apply the Gaussian analysis to the solar-diurnal variations.

Fossil Plants.

Prof. H. Woodward read the report of the committee appointed for the purpose of reporting on the fossil plants of the tertiary and secondary beds of the United Kingdom. The results of their researches pointed to the conclusion that while the section known as Gymnospermus, to which the Coniferæ belong, was of the highest antiquity, being almost coeval with the first definite remains of plants in the Palæozoic age, there were no Angiospermous plants in British rocks of greater antiquity than the secondary period, except the problematic plant known as Spirangium. The same absence of Angiosperms, so far as British rocks are concerned, is continuous throughout the Neocomian and Gault, and it was only in the white chalk that they met with any indications of them, and these only took the form of a more than suspicious impression of a net-veined leaf, in the Jermyn-street Museum, and of some structureless bodies which were apparently some kind of fruit. Amongst the most interesting of recent discoveries was that of a plant remains in a small sandpit at Colden Common between Bishopstoke and Winchester, the first locality in the Hampshire basin that had yielded any of Woolwich and Reading age. Fruits and even flowers were comparatively abundant at Bournemouth, and the series now obtained numbered nearly one hundred specimens, being by far the richest of fossil Smilaceæ perhaps of any family ever brought together. Sir William Dawson read a paper on "Canadian Examples of Supposed Fossil Algæ." He explained that markings of various kinds on the surfaces of stratified rocks have been loosely referred to algæ or Fucoids under a great variety of names; and when recently the attempt was made in Europe more critically to define and classify these objects, a great divergence of opinion developed itself, of which the recent memoirs of Nathorst, Williamson, and others might be taken as examples. The author, acting on a suggestion of Sir R. Owen, was enabled, in 1862 and 1864, by the study of the footprints of the recent Limulus polyphemus, to show that not merely the impressions known as Protichnites and Climactichnites, but also the supposed fucoids of the genera Rusophycus, Arthrophycus, and Cruziana are really tracks of Crustacea, and not improbably of Trilobites and Limuloids. He had subsequently applied similar explanations to a variety of other impressions found on Palæozoic rocks.

Report on Underground Waters.

Mr. C. E. De Rance, F.G.S., read the report of the committee of inquiry into underground waters. During the thirteen years that investigation had been going on, much accurate and valuable information had been obtained. The complete dependence of the supply of underground waters to the proportion of annual rainfall varying with the amount of rainfall and the character and porosity of the strata on which the rain fell, had been completely established; varying from 1in. to 12in. of rainfall annually absorbed on each square mile, 1in. of rain giving 40,000 gallons per day for each square mile of surface exposed. The great value of underground supplies had been shown during severe drought, the dry-weather flow of the streams and rivers being wholly dependent on underground supplies issuing as a deep-seated spring. That a large quantity of water could be obtained by deep wells in suitable situations was well shown by the Corporation supply at Birmingham.

Evidence of Pre-Glacial Man in North Wales.

Dr. H. Hicks, F.R.S., read a paper on "Evidence of Pre-Glacial Man in North Wales." He described the conditions under which some flint implements had been discovered during researches carried on by Mr. E. B. Luxmore and himself in the Ffynnon Beuno and Cae Gwyn caves in the Vale of Clwyd in the years 1884-86. These caverns were explored by himself and friends for the first time in 1884, and some of the results were given by him in a paper at the last meeting of the British Association. The facts then obtained had led him to the conclusion that pleistocene animals and man must have occupied the caverns before the glacial beds which occur in the area had been deposited, as it had been found that, although the caverns are now 400ft. above Ordnance datum, the materials within them had been disturbed by marine action since the pleistocene animals and man had occupied them. Moreover, deposits with foreign pebbles, similar to those in the glacial beds, were found in the caverns, overlying the bones. Last year a grant was made by the British Association for the purpose of carrying on the exploration, chiefly with the object of getting further evidence as to the age of the deposits in the caverns. The results obtained this year were highly confirmatory of his views, and had an important bearing on the antiquity of man in Britain. It was found that the main entrance to the Cae Gwyn Cave had been blocked up by a considerable thickness of glacial beds, which must have been deposited subsequently to the occupation of the cave by the pleistocene mammals. A shaft was dug through these beds in front of the entrance to a depth of over 20ft., and in the bone earth which extended outwards under the glacial beds on the south side of the entrance a small, well-worked flint flake was discovered, its position being about 18in. beneath the lowest bed of sand. It seemed clear that the contents of the cavern must have been washed out by marine action during the great submergence in mid-glacial times, and then covered by marine sand and an upper boulder clay. He believed that the flint implements, lance heads, and scrapers found in the caverns were also of the same age as the flint flake—hence that they must all have been the work of pre-glacial man.—Prof. Boyd Dawkins said those who had read his works would know that he was not in favour of accepting evidence on this question of the antiquity of man that was not absolutely conclusive, but he must say that he fully accepted the conclusions which Dr. Hicks had so well put before them. The small splinter of flint which was found was as good evidence of the presence of man in the preglacial time as if they had found a watch; and thus they were driven to the conclusion that man was living in the Vale of Clwyd before the deposits took place.—Mr. Durance expressed a similar opinion, and Mr. W. Pengelly said the first flint implements found were nodule tools, and then came flake tools. It was therefore possible for a mere flake to be evidence of human existence, and he believed this was a case of the kind. Though he should not call it an implement, he as firmly believed in its artificial origin as that a tailor made the coat he wore. To him it was a delicious discovery, inasmuch as he had for long stood to a great extent alone in the opinion that the nodule flint tools in Kent's Cavern were of pre-glacial make.—Prof. Lebour suggested that for the sake of accuracy Dr. Hicks should substitute the word interglacial for pre-glacial in his paper.—Dr. Garson remarked that the questions which would naturally occur to the minds of those who had listened to Dr. Hicks's paper would be—what was the date of the glacial period? How long back had they evidence of man's existence? The secular variations of climate had been shown to be caused indirectly by changes in the eccentricity of the earth's orbit. This gave the means of ascertaining the date and duration of the glacial period. If it was found that these flints were the work of pre-glacial or even inter-glacial man, as there seemed to be very little doubt, after what they had heard, they had direct evidence of the long period during which man had existed; and the opinions of human morphologists were confirmed by independent and direct geological evidence.

Westward Extension of the Coal-Measures.

Prof. Boyd Dawkins, M.A., F.R.S., read a paper on "The Westward Extension of the Coal-Measures into South-Eastern England." He said that geological evidence is conclusive that the valuable coalfields of South Wales and of Somerset are connected with the equally valuable coalfields of North France and of Belgium, some 1,200 square miles in extent, by a series of isolated fields or basins concealed by the newer rocks. The strata of the North French and Belgian carboniferous rocks, if carried westwards into South-eastern England, as Mr. Godwin Austen has shown, would bring them into the district between Hythe and Sandwich. The probability that the coal-measures will be struck in this district is rendered greater by the discovery of a mass of bituminous mineral in a fissure in the chalk north of Dover, that has probably, as Mr. Godwin Austen pointed out in his evidence before the Coal Commission, been derived from the coal-measures below. By the kindness of the council of the Geological Society the writer had been allowed to make a minute examination of Mr. Austen's specimens, and he found that the mineral is a pitch which has resulted from the distillation of coal. The interest attaching to the experimental boring undertaken by the Directors of the South-Eastern Railway is very great. If the coal-measures are proved, a discovery of vast importance will be made. If, on the other hand, rocks older than the carboniferous are struck, they will offer a basis for further borings, which will ultimately result in the discovery of the hidden coalfields of South-eastern England, and cause as great an economic revolution in that region as that which has been caused in France and Belgium by the discovery of the coalfields underneath the chalk.

A New Sunshine Recorder.

Mr. W. E. Wilson explained a new sunshine recorder. The instrument consists of two parts, one of which—the indicator—is affected by the sunshine, and the other registers the indications. The indicating apparatus was a differential metallic thermometer, made of a spiral of two metals (zinc and steel) soldered together. Half of the spiral is right-handed, and the other half is left-handed. The complete spiral is fixed at its upper end. At its lower end a lever or pointer is attached. The upper half, or right-handed portion, of the spiral projects through the roof of a ventilated box, and is exposed to the sunshine. The lower or left-handed half is in the shade. Any change in the temperature of the air does not cause the lever or pointer to move, as the upper half of the spiral tends to move it as much in one direction as the lower half tends to move it in the other. When the sun shines on the exposed upper half, the lever moves and completes an electric circuit, which passes through the recording part of the apparatus. The recorder consists of a drum, driven by a clock. The drum revolves once in 24 hours, and is mounted on an axis, with a screw of ten threads to an inch, which turns in a nut. This gives the drum a slight longitudinal motion, as well as its motion of rotation. The clock makes an electric contact once every minute, and the electric circuit is led through an eletro-magnet, which causes a pricker to strike the drum when the circuit is complete. The circuit is led through the lever, &c., of the bi-metallic indicator, and is only closed when the sunshine causes the lever to close it. When the circuit is complete the electro-magnet pricks off dots every minute, which represent so many minutes of sunshine. The drum is of such a length that it holds the daily record of sunshine for three months. The instrument is also made to give the total time during which the sun shone in the day.

Photometric Standards.

Mr. Stepney Rawson contributed a comparison of the "Harcourt and Methven Standards of Light." The author explained the growing necessity for a reliable Governmental standard of light, remarking that the time-honoured "Parliamentary candle" was the last standard which scientific men would dream of making compulsory. He showed two of the standards to which reference was made in the report of a committee appointed by the Board of Trade in 1881. These were the Harcourt air-gas lamp and the Methven screen. The improvements made in the former since the last meeting of the British Association consisted in an adjustable black background screen for protecting the eye from the light of all but the upper point of the flame when regulating the height, and thereby enabling the exact height to be determined more accurately; also in a rack and pinion movement, with a scale engraved in millimètres, for setting the height of the platinum wire. Besides these there was an entirely new method of preserving an accurately even rate of drop of pentane for feeding the lamp in the portable form exhibited. This device consists in producing a perfectly constant head by providing an overflow outlet from which the excess of pentane drops into a small bottle, which can be removed when necessary and emptied into the main reservoir, which is on the top of the lamp, the bottle forming a stopper to the reservoir to prevent evaporation. The rate of drop into the lamp is regulated with great delicacy by letting the pentane flow down a glass tube, in which there is a constricted passage which can be more or less closed by a fine platinum wire, which can be screwed in or out of it by means of a screw-thread working in a cap at the top of the tube. The method is due to Mr. W. F. Donkin. In other respects the lamp remains exactly as described by Mr. Vernon Harcourt at previous meetings of the Association. The Methven screen is one of the form as now constructed, but differing from that upon which the committee reported in 1881. The author showed by a diagram the errors intro-

duced by the alteration of form, amounting to fully 16 per cent. below its normal value. He gave the result of observations made by Mr. W. F. Donkin and himself, and showed that the errors may be determined theoretically, and were practically coincident with the result of observations.

Electric Illumination of Lighthouses.

The first paper was by Mr. Hopkinson, M.A., D.Sc., F.R.S., upon "Electric Illumination of Lighthouses." The paper related to the cost of the electric light in lighthouses, and suggested a method of reducing the same. It had hitherto been supposed, the writer said, that it was not possible to establish and maintain an electric lighthouse at anything like the expense of a first-class light in which paraffin-oil was used in the ordinary way. The high expense of the electric light arose in great measure from the fact that the machinery was placed at a distance from the lantern, so that two attendants were always required on duty. The writer's suggestion was that a small gas-engine and dynamo should be provided in a room immediately below the lantern for use in fairly clear weather, and much more powerful machinery, for use only in thick weather, be provided outside the tower. It would then only be necessary that two attendants should be on duty in thick weather. It was shown that, so arranged, an electric lighthouse would involve an expense, initial and annual, approximately the same as that of a first-order light of ordinary construction, with the advantage of enormously greater power in thick weather.—Mr. J. R. Wigham concurred with the writer of the paper with regard to the advantage of using large lenticular lights for the illumination of lighthouses. He had advocated long-focus lenses for many years. As to the question of cost, he said it was highly desirable that they should endeavour to bring down the cost of all powerful lights. Mr. Hopkinson's method of doing this seemed promising. There was a divergence of opinion as to the extent to which the electric light exceeded other lights in fogs. It would be well for the maritime public to withhold its judgment, and not to expect that the electric light was more powerful in fog than any other light. For his own part he had great doubts on the subject.—Sir William Thomson said that many people were under the impression that the electric light was less potent for penetrating fog than gas-light. He thought he was right in saying that there was no discoverable difference in penetrating power in either lights. When the fog was such as to redden the sun or moon, then for piercing power gas or oil would be found to be of superior quality, but when the fog left the sun white there was no sensible difference in either light.

Mr. J. R. Wigham read a paper on points connected with the illumination of lighthouses. He spoke, first, of a new method of burning oil, by surrounding the flames of the lamp with cylindrical walls of air instead of glass; and next of a new form of light for lighthouses. The new form of light was a group-flashing light of a different kind to those now in use. Instead of causing the lenses to revolve round a central light, he caused two, three, or more lights to revolve with the lenses, the relative positions of light and lenses being maintained. By this arrangement he was enabled to give the full power of each light to the mariner, and at the same time materially to reduce the cost of lenticular apparatus. He used two instead of eight or six lenses, while by intermitting the lights he had a combination of a striking and perfectly novel character. He also referred to a new illuminant for lighthouses, and remarked that in connection with his gas-light he used a solid carbonaceous body, converted into vapour, and made to produce intensely white light by compressed oxygen. He used the oxygen at a pressure of about 1,000lb. to the square inch. The naked light of a triform on this principle would have an illuminating power quite as great as the highest power of the most powerful electric light or combination of electric lights.

Delany's Multiplex Telegraph.

Mr. W. H. Preece explained "Delany's System of Multiplex Telegraphy." The growth of electricity, he said, thanks greatly to the introduction of the halfpenny-a-word tariff, had been so great that the Post Office had been compelled to adopt every possible contrivance that has been suggested or invented to improve the capacity of wires for the conveyance of messages. It was thought a very wonderful thing many years ago that two messages could be sent along a wire at the same time; but this was eclipsed when it was shown that it was quite possible to transmit four messages on one wire at the same time. This system has now been improved, and they were able to transmit messages at from 400 to 450 words per minute, and to send two, three, four, five, or six messages in one direction or another at the same time, by a method which they called the hexode. The new method was based on the principle of distribution. All the existing apparatus could be utilised. Synchronism was for the first time rendered almost perfect. It was quite possible to send 72 messages on one wire at the same time, but the rate at which they could be transmitted would be very slow. The maximum work which they got out of the wire now was when six messages were sent. A cause of disturbance in the working was due to electro-static induction, caused by the authorities being compelled to put wires underground. This was a matter of very serious consequence to the Telegraph Department. It slowed the rate at which currents passed; it diminished the capacity of the apparatus in question, and whilst they had no difficulty in sending six messages between Birmingham and London, they could only send four between London and Manchester, and places of an equal distance.—Sir William Thomson said the method was one of the most beautiful and practical realisations in telegraphy. [We described Delany's system in No. 992, p. 69.]

Stellar Spectra.

Prof. E. C. Pickering, in the course of a paper on this subject, said the spectra of ordinary stars, whether examined directly by the eye or indirectly by means of photography, presented little variety. The comparatively few cases of deviation, therefore, were particularly interesting, and the occurrence of bright lines in a stellar spectrum constituted, perhaps, the most singular exception to the general rule. The photographic observations which had been undertaken at Harvard College observatory, included a series of photographs of the spectra of all moderately-bright stars visible in that latitude, and four other spectra with bright lines had been brought to the knowledge of the observers.

Induction in Telegraph Wires.

Mr. W. H. Preece, F.R.S., gave an account of some experiments on electric induction between wire and wire. He prefaced his remarks by stating that along the Gray's Inn-road, London, the Post Office had a line of iron pipes buried underground, carrying many telegraph wires. The United Telephone Company had a line of open wires along the same route over the housetops, situate 80ft. from the underground wires. Considerable disturbances were experienced on the telephone circuits, and even Morse signals were read which were said to be caused by the continuous and parallel telegraph circuits. A very careful series of experiments proved unmistakably that it was so, and that the well-known pattering disturbances due to induction were experienced at a much greater distance than was anticipated. With a view of finding out how far these effects could be detected, experiments were conducted on the Newcastle Town Moor. The area of the disturbance was extended to a distance of 3,000ft., while the effects were detected on parallel lines of telegraph between Durham and Darlington at a distance of 10½ miles. But the greatest distance experimented upon was between the east and west coast of the border, where two lines of wire 40 miles apart were affected, the one by the other; sounds produced at Newcastle on the Jedburgh line being distinctly heard at Gretna, on a parallel line, though no wires connected the two places. Careful experiments had also been made to show that the effects were quite independent of the earth, and were probably inductive effects through the air. In one case a circuit of copper wire, sheathed with gutta-percha, was laid on the ground forming a quarter of a mile square. At a distance of a quarter of a mile another square of similar dimensions was formed. It was then found possible to hold distinct conversation by telephone through the air without any connecting wire between the two squares. This distance it was thought could probably be much exceeded. It was not even necessary that air should be the medium between the two wires. Since those experiments were made the English cable to the Scilly Islands was broken at a certain part. Half a mile from the damaged cable there was another belonging to one of the submarine companies, and extending to Brest. These two cables were half a mile apart in the water, and they did not approach each other on shore, yet signals on the Scilly cable were heard distinctly on the French one.—Prof. Thompson said he must enter a mild protest against the somewhat miscellaneous use of the word induction. In the experiments from square to square he did not doubt that the results were produced by genuine induction; but in the other experiments, notably the forty-miles one, he believed the greater portion of the effect was due to the earth returns.

Manufacture of Soft Steel.

Mr. W. Hutchinson, of the South Staffordshire Ingot Iron Company, Bilston, read a paper descriptive of "The Manufacture of Soft Steel by the Bessemer Basic Process in South Staffordshire." The plant consists of three Bessemer vessels of the ordinary description, and of about six tons capacity—one of which is lined with gannister bricks, and the other two with basic material. The converting process differs from that at other basic works in England, owing to the pig-iron used being more variable in its content of silicon. To meet this it has been found advantageous to use the acid-lined vessel as a refinery for desiliconising the metal, which is brought in a liquid state from the adjoining blast furnaces. From four to eight minutes' blowing in this vessel is sufficient to reduce the silicon to a point at which it can be dealt with in the basic vessel. The refined metal is then transferred to one of the basic vessels into which about 20 per cent. (of the charge of metal) of freshly burnt lime has previously been placed, and the charge is blown in the ordinary way until the carbon has disappeared, which is indicated by a sudden diminution or dropping of the flame. Up to this point very little of the phosphorus has been removed; but the blowing is continued for a few minutes longer, and dephosphorisation proceeds rapidly. After about five minutes of this so-called "after-blow" the converter is turned down, part of the slag poured off, and a sample of the metal taken, hammered out, quenched in water, and broken. From the fracture of this the blower judges if the phosphorus is sufficiently removed, and if not continues the blow for a few seconds longer. The finishing metal, consisting usually of rich ferro-manganese, is then added, and the charge poured in the ordinary way. The following is an average analysis of the soft steel usually produced: Carbon ·080, silicon ·004, phosphorus ·050, manganese ·430, sulphur ·045, and iron (by diff.) 99·391 per cent. The slag formed during the process bids fair to become an important manure, as experiments recently carried out by Prof. Wrightson and Dr. Munro have shown that on certain soils it is equal to the best superphosphates and other phosphatic manures.

Mr. George Hatton (Brighton) read a paper on the "Production of Soft Steel in a New Type of Fixed Converter," in which he said that the fixed converter was not a new invention: Sir Henry Bessemer conducted his early experiments in one, and it had been used somewhat extensively in Sweden for many years, making steel of very high quality. In using the old type of fixed converter a great difficulty experienced had been the necessity for keeping the full pressure of blast on during the tapping out of the metal after the process of conversion was completed, with the risk of more or less oxidation of the bath of metal, which oxidation would of necessity be continued till the last of the steel ran from the converter, owing to tuyeres being fixed on a level with the converter bottom. Mr. Hatton has designed a fixed converter with which twenty blows per shift of twelve hours have been done, but with more efficient casting-pit arrangements this output could be very considerably increased. The usual numbers of Bessemer hæmatite pig iron were used, the percentage of silicon preferred in the mixture being about 1¾ per cent. to 2 per cent. When working rapidly with surplus heat a considerable quantity of scrap was added during the blow. The steel produced by this process was of the highest quality, remarkably soft, and particularly adapted for welding, it being largely in demand for lap-welded boiler tubes and other similar purposes; it was also made into boiler plates, and was largely made into stamping sheets and tin plates for difficult work.

Electric Safety-Lamps.

Mr. J. W. Swan, M.A., read a paper on "Improvements in Electric Safety-Lamps," in which he stated that since last year he had improved his safety-lamp in various ways. The objects he had in view were:—(1) To reduce the weight as much as possible consistently with the giving of sufficient light; (2) to simplify the construction with a view to minimising the cost of manufacture, and the cost of keeping in order; (3) to make the lamp better able to resist a blow; (4) to seal in the liquid, so that the lamp could be held in any position; (5) to add a fire-damp indicator. The latter was a novel feature. By turning a switch the current from the battery could be sent through a fine platinum wire contained in a small glass tube. The presence of fire-damp was indicated by the heated wire becoming abnormally bright in one case, and in another by the rise of liquid in a gauge-tube (communicating with the hot wire tube) after the cooling of the hot wire. The total cost would not exceed 5d. per week where several hundred lamps were in use. He thought he had produced a lamp having the advantage of absolute safety.

Antarctic Explorations.

Dr. John Murray, of the *Challenger* expedition, made a few observations on "The Exploration of the Antarctic Regions." He said that the appointment of a committee at the Aberdeen meeting last year to consider what steps should be taken with the view of promoting further exploration in the Antarctic regions had had the effect of again directing much attention to those unexplored regions. In reviewing the existing state of our knowledge concerning the Antarctic regions, he said that five expeditions had been despatched from this and other countries to explore those regions. Only three navigators, however, succeeded in cross-

ing the parallel of 70deg. south, Ross crossing that parallel three times in three different years. No steam vessel had visited the Antarctic area except the *Challenger*, and she was quite unprotected for ice work. Ross and D'Urville were the only two navigators who had succeeded in setting foot on land within the Antarctic Circle, and neither remained longer on shore than was sufficient to allow them to gather a few specimens of rocks. With the exception of some off-lying islands, all the land was described as being completely ice-bound. Where the coast was low there was a line of perpendicular icy cliffs, 150ft. to 200ft. high, rendering hopeless any attempt at landing, and that was known as the ice-barrier. It had been conclusively proved that there was a great mass of continental land within the Antarctic Circle, but we had much more definite information about the Antarctic and Southern Ocean than about the Antarctic Continent, although fuller knowledge of those waters was very desirable. The committee appointed to consider this matter reported that before approaching the Government, a plan of operations should be carefully drawn up and submitted to the Association for the approval of the Council.

Capt. Ettrick W. Creak, R.N., F.R.S., contributed a paper on "The Advantages to the Science of Terrestrial Magnetism to be Obtained from an Expedition to the Region within the Antarctic Circle." He showed that at present we have data to make satisfactory charts of the earth's magnetism for all parts between 60 N. latitude and 50 S. except in some parts of North Africa and Central Asia. Farther south than the point mentioned we have practically had no observations since Ross's expeditions in 1840-43. Somewhat recent observations, especially those in connection with the *Challenger*, showed that at about 50 South latitude the magnetism in that neighbourhood had changed since the records were made by Ross, so that the data obtained then could not be relied upon at the present time.

American and English Railways.

Mr. W. P. Marshall, M.I.C.E., read a paper on "American and English Railways in reference to Couplings, Buffers, and Gauge, with a Suggested Improvement in Couplings." He said the railways of North America were of particular interest on account of their very great extent, amounting to nearly one-half of the total railway mileage of the world. Their standard gauge was the same as in England; but there were formerly five other gauges in extensive use in North America, three of them larger than the standard, 5ft., 5ft. 6in., and 6ft., and two smaller, 3ft. 6in. and 3ft. The standard gauge had now become so far universal as to include about 80 per cent. of all the railways of the world. In reference to buffers, on the American railways the striking difference was seen of single centre-buffers universally used instead of the double side-buffers of this country and the Continent; and this was a point that called for special consideration, because, although centre-buffers were so unfamiliar in this country, they were really in the majority as regarded the length of railways upon which they were used. In the English carriage couplings there was no provision against the telescoping of the carriages in a collision, which was the great source of injury in train collisions, the coupling being flexible vertically as well as horizontally; but the American carriage coupling most extensively used was rigid vertically, preventing displacement beyond the limited range required for variation in heights of carriage frames, and it formed a direct provision for preventing one frame mounting upon the next one in a collision, and the consequent telescoping of the carriage bodies. This coupling had a strong metal bar projecting from the end of each carriage frame under the next carriage, which must be broken away before either carriage could mount. This coupling was automatic, and was worked by bumping the carriages together; the coupling jaws are wedged apart horizontally by the striking together of the projecting tapered ends, and then engaged together by springing back to the central position. There was, however, no means of tightening up this coupling beyond the original compression of the buffers in bumping up; and although the carriages were usually held very steady in running, it happened not unfrequently, with the extra stretch of the draw-springs in a heavy train, that the buffer-faces got slack or even separated, allowing a side oscillation of the carriages, which could not be checked, and which was a serious defect in the coupling.

The Hardness of Metals.

Mr. Thomas Turner described an apparatus which he has invented for determining the hardness of metals. He said hitherto there had been few attempts to determine the relative hardness of metals. The method adopted by the United States Government in 1856 consisted in the punching of a hole by a tool in the form of a pyramid and under a constant pressure. The indentation was carefully measured, its capacity calculated, and in this way relative hardness was expressed. But it had been shown that the results obtained really depended upon combined tenacity and hardness, and so were not accurate representations of hardness. The apparatus recommended by the author was an adaptation of the method which had already been employed in determinations of the hardness of minerals, namely, by scratching the surface with a weighted diamond. The diamond is attached to a gradulated beam arranged so as to allow of motion in both a horizontal and a vertical plane. By means of a sliding weight sufficient pressure is applied to cause a distinct scratch on drawing the diamond over a smooth surface of the metal to be tested. The weight is then moved until the diamond just ceases to produce a visible scratch, when the position of the weight on the scale is observed. Some experience and care were necessary in observing the scratch; but when that had been obtained the apparatus gave uniform results. The author's experiments with cast iron had shown the common idea that hardness and tenacity necessarily accompanied each other was erroneous. Very soft cast iron could be obtained with a high tensile strength, while hard cast iron had very often a low tensile strength. When metal had to be worked unnecessary hardness led to useless expenditure of power and loss of tools, and in such circumstances a soft metal was much to be desired. The apparatus was intended to be used in connection with tensile tests of the metal, and in that way afforded valuable information as to the mechanical properties of the material.

Gilded Chrysalides.

Mr. E. B. Poulton read a paper in which he stated that for some years he had been working upon the colour of caterpillars in relation to the colour of their surroundings, and he had shown that the colour could be modified in one generation by the appropriate alterations of their surroundings. It seemed certain that through some sensory surface, possibly the eye, caterpillars were affected by their external relations, and a corresponding effect was produced in colour. It was probable that the colour was produced by the effect upon the caterpillar before it turned to the chrysalis. Experiments were therefore made by Mr. Poulton to put the fact itself beyond dispute. That was done first by the use of caterpillars of the peacock butterfly and the common tortoiseshell butterfly. It was found by allowing them to turn to chrysalides upon a white or black screen very different results were produced. Those upon white paper were often brilliantly golden, although the chrysalides of the tortoise-shell were not quite so golden. Gilded specimens were sometimes found, but their appearances seemed to be produced as a disease.

Preservation of Gases over Mercury.

Prof. H. B. Dixon, F.R.S., read an interesting note on the preservation of gases over mercury. In the life of Faraday, written by Dr. Bence Jones, an account is given of a dispute which arose between Faraday and Sir H. Davy as to whether gases could be preserved indefinitely over mercury without undergoing change. Faraday commenced his first experiments in this direction in 1823, examining the gases he had preserved in 1824, and concluded that gases could not be efficiently preserved over mercury. On the other hand, we find that the last entry in the laboratory note-book of the Royal Institution in the handwriting of Sir H. Davy stated that he had confined hydrogen over mercury for a considerable period, and on examination the gas was not contaminated by air. Faraday, however, collected gas in 1825, which was examined after fifteen months, and found that it was much contaminated by air; he, therefore, concluded that gases could not be kept over mercury. Mr. Dixon has examined various gases, including hydrogen, cyanogen, sulphur dioxide, and electrolytic gas, which had been kept over mercury for periods ranging from 2½ to 9½ years, and concludes that the gases when examined were in the same condition as when collected. Mr. Crookes considered these results somewhat startling, and suggested that the influence of the purity of mercury was very important. Sir H. Roscoe, F.R.S., said they were much indebted to Mr. Dixon for his researches into a subject of such practical value to chemists. He believed the effect observed depended on the formation of a film between the mercury and the glass in some cases. Mr. Dixon, by using clean vessels and hot, pure mercury had prevented this formation, and hence diffusion had been prevented. Prof. Vernon Harcourt, F.R.S., said it might have been supposed that dirty mercury, from its known property of adhering to glass, would have been most efficient in preventing diffusion. This, however, did not appear to be the case, but he suggested that experiments should be made in which dirty mercury should be employed. Mr. Turner said that the experience of Dr. Franklin confirmed the experiments of Mr. Dixon, and the opinions of Sir H. Roscoe that diffusion did or did not take place according to the state of the mercury and the containing vessel. After some remarks by Dr. Russell, Dr. Gladstone, F.R.S., stated that when talking of this matter some years ago to a friend, he was answered that if gas could not be retained without diffusion, then we could have no mercurial barometer. Prof. McLeod, F.R.S., said that in the case of dirty mercury the metal was not in contact with the glass, though it appeared to be so. The standard barometer at Kew was prepared with hot mercury, and though it was years since it was made it was still believed to be perfectly accurate. Dr. S. Young said his experience with barometers, which was pretty considerable, showed that some barometers remained perfectly correct, while others did not, though apparently prepared with equal care.

Waves and Bores.

Sir William Thomson, F.R.S., gave an account of some observations on stationary waves in flowing water. The subject, he explained, includes the beautiful wave-pattern produced by a steamer under way in smooth water. But the communication was limited to another interesting and well-known phenomenon, the rippling of the surface of a natural rivulet, or of water in a mill-stream or trough or conduit of any kind. It had been observed, for instance, that where there was a rise in the bottom there was a corresponding depression of the surface of the water immediately above, while where the bottom was depressed the surface of the water rose to a corresponding height above the mean level. Sir William explained the dynamical theory of the steady motion observed in all the cases mentioned above.—Some facts with relation to the phenomenon of the "bore," observed in the Severn and other streams, were detailed by Sir William Thomson. Observations made by Prof. Stokes, he said, had shown that it was almost certain that there was some proportion of broken water in a bore, and that the bore was not a phenomenon of steady motion of a perfect fluid. An apparatus, devised by the reader of the paper for producing artificially a standing bore, was exhibited in action, and excited much interest, its operation tending to prove the fact just alluded to.—In a paper on the velocity of advance of a natural bore, Sir William Thomson said that a natural bore consisted of a precipice of water advancing through water almost steady. Whenever a bore passed through the shallow water, the water deepened and flowed on behind the bore at a speed which was less than that of the bore. At present they had not been able to determine mathematically the relations of these two speeds and other problems suggested by these observations. Some graphical illustrations of deep-sea wave-groups were exhibited by Sir William Thomson, who explained how they bore also on the theory of light.

Distribution of Germs.

Dr. Percy Frankland contributed a paper on "The Distribution of Micro-organisms in the Air of Town, Country, and Buildings." It contained the results of a number of experiments which the author had made on the relative abundance of micro-organisms in the air of different places, and of the same place at different times. In these experiments the number of microbes contained in a given volume of air had been supplemented by the determination of the number falling upon a unit of horizontal surface (one square foot) in a unit of time (one minute). The air on the roof of the Science Schools was very considerably richer in micro-organisms than that collected in the London Parks, and this again than that of the country. The gradual attenuation of the microbes in ascending St. Paul's and the spire of Norwich Cathedral was also very striking. The figures obtained in museums, railway carriages, and hospitals for consumption showed how in confined spaces the number of micro-organisms present in the air was influenced by the number of persons moving about.

THE TREATMENT OF SECONDARY BATTERIES.*

THE possession of a reliable means of storing electrical power is now universally recognised. For electric lighting, whether temporary or permanent, whether domestic or public, it is almost an essential; for the commercial application of electricity to motive power it is a necessity. The theory of secondary batteries or accumulators, by means of which this storage is attained, has already been so ably dealt with, and is probably so well-known to all present, that it is unnecessary to enter into it in this short paper, the object of which is to bring to your notice some practical points of treatment which are essential, in order to render secondary batteries commercially reliable. The three main difficulties which we had to encounter were:—1. The destruction of the lead grid or con-

* Extracted from a paper by Messrs. BERNARD DRAKE and J. MARSHALL GORHAM, read in Section G, British Association.

ctor. 2. The buckling or warping of the plates. 3. The falling out of the active material. These three failings, principally affecting the peroxide plates, militated seriously against the commercial success of accumulators, of which durability forms so important a factor. We, therefore, carried out a large number of experiments, with a view to ascertain their various causes, and, by removing them, to render the secondary battery, with which we had to do, as reliable for durability as it already was in other respects.

Here I may mention that these failings, although common, were by no means universal. For instance, the E.P.S. accumulators in the Bank of England have been in use more than $2\frac{1}{2}$ years, and continue to give excellent results. That they do so confirms the conclusions to which experiment has led us. We will take first:—1. The destruction of the lead grid or conductor. This was the most serious difficulty to face, as on it depended the life of the battery.

The prevalent idea was that it was due to overcharging; that after the peroxide plate was fully charged any further charge caused an evolution of oxygen which rapidly destroyed the grid. We, therefore, proceeded to charge some cells without cessation, in order to ascertain the exact amount of current which would entirely destroy the lead conductor or grid. It was soon evident that the process was, at any rate, a slow one; but the experiment was continued, until the full prescribed current had been passed through, for more than two months. At the end of that time it was found that the lead conductor was practically as sound as before charging; the coating of fine peroxide formed on the surface was very thin; there was no sign whatever of buckling, and, further, the specific gravity of the solution, when the cells were left in their fully-charged condition, remained absolutely unaltered. The conclusion thence drawn was that the oxidisation of the grid caused by charging only penetrated to a very limited depth, and then ceased entirely, and that the coating of fine peroxide formed actually protected the grid, not only from deterioration by overcharging, but also from local action hitherto supposed to be unavoidable.

It was then established that the life of the grids was not proportional to the amount of charging—*i.e.*, to the number of ampère-hours put into a cell. Was it due to the number taken out? To ascertain this was the object of the next experiment. For this purpose a battery was divided into two halves, one of which (A) was repeatedly run out, and the other (B) was never discharged beyond the point at which the E.M.F. commenced to drop. This experiment also extended over a considerable time, but gave the instructive result that when exactly the same number of ampère-hours had been taken out of each half, the plates in the first half (A) showed signs of expansion or growing, whereas in those of the second half (B) no change could be detected. The life of the grid then was also not dependent on the amount of ampère-hours taken out, or on the work done, but on the treatment of the plates, first as to charging up, and afterwards as to total or partial exhaustion. Further, it was satisfactorily proved that there was no necessity to employ a conductor of unoxidisable material, providing the simple precautions were taken, first, to fully charge the cells; second, to avoid discharging them entirely.

The second point to be considered is:—2. The buckling of the plates.

This had hitherto been attributed to two or three causes — charging too rapidly, discharging too rapidly, impurities in the acid or oxides employed. Experiment soon showed that the real cause must be sought for elsewhere.

We found that the buckling was almost invariably accompanied by a hard white enamel (sulphate of lead) on the face of the plates, and, further, that where the extra cells in a battery had received more charging than the remainder, the plates in these cells were frequently quite free from sulphate, and the consequent tendency to buckle, while the rest of the battery had failed. This proved that the enamelling could be prevented by charging, and was not due to impurities in the oxides or acid used; further, that when the plates were free from sulphate there was no tendency to buckle. Experiment also showed that in the case of the first use of cells, when the acid was first put in, the specific gravity dropped in spite of the charging, indicating the formation of sulphate; by persevering in charging the sulphate disappeared, and with it the tendency to buckle. The conclusion was then that, in order to avoid buckling of the peroxide plates, cells on their first use (whether new or after long disuse) should be charged incessantly until they are considerably overcharged. Hence the radical change in the instructions issued to users of the E.P.S. batteries. Whereas, hitherto, they had been specially cautioned against overcharging, they are now urgently required to overcharge new cells, and to charge incessantly.

3. The separation of the active material. In almost every case where this occurred, the plugs of active material fell out of the plates in complete halves, and in a very hard condition; and analysis showed that they contained an excess of sulphate, due, as before explained, to insufficient charging. On the other hand, in a few instances, the active material was found to have become disintegrated and fallen off in a fine powder, and this was specially observable when, on account of a leak in the receiving vessel, and consequent frequent addition of water, the solution had become extremely weak. In this case, practically no sulphate was present, and the mass lost cohesiveness. The conclusion is then that a certain proportion of sulphate in the material is necessary to bind it together; but that excess must be avoided. This due proportion once ascertained, the third difficulty is overcome for all the ordinary work of secondary batteries.

It should be mentioned, however, that there is a constant demand for an accumulator which can be discharged without injury at an abnormal rate for special purposes. Such rapid discharge results at present in the scaling off of the oxides and destruction of the plates; but as it causes the formation of sulphate, which is the binding, not the disintegrating, agent, the cause of the scaling, and therefore its remedy, must be sought elsewhere, and on this point discussion is invited.

The conclusions to which our experiments have led us, are:—1. That the life of the leaden grids or conductors, and their freedom from buckling, are in no way dependent either on the amount of charging or discharging of the cells. 2. That cells on the occasion of their first use, and also after long intervals of idleness, should be very fully charged, and in the first case incessantly. 3. That they should never, under any circumstances, be entirely run out, and in fact should not be discharged below the point at which the E.M.F. begins to drop perceptibly. 4. That the coating of fine peroxide formed during charging is actually a protection to the plate against the injurious effect of overcharging, and against local action. 5. That a certain small proportion of sulphate is necessary to give cohesiveness to the active material, but an excess of it causes the oxide to separate bodily from the conductor. If the precautions here indicated be taken, we believe that the accumulators now made by the Company with which we are connected will answer every ordinary commercial requirement during a very considerable time; but an accumulator is not at present known which, without sacrificing capacity and efficiency, will stand the extraordinary rate of discharge sometimes demanded.

TOOL-POST GRINDER.

THE tool-post grinder shown in the annexed engravings has been in use for some time by Mr. F. H. Colvin, of Philadelphia, who sends it to the *American Machinist* for the benefit of all interested. Mr. Colvin says:—

Fig. 1 is a side view, Fig. 2 a front view, these

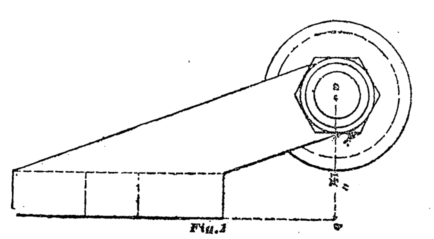


Fig. 1

being sufficient, I think, to give a clear idea of the attachment. I will give the sizes I used, though some of them may have to be altered to suit the lathe used. The height *a b*, Fig. 1, in my case $1\frac{3}{4}$in., should be made the same height as the lathe

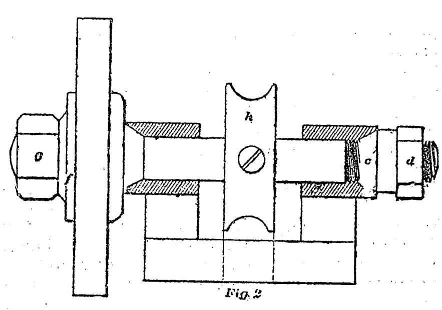

Fig. 2

centres. The cones *c c'*, Fig. 2, are bronze, *c'* being adjustable, as seen by drrwing; *e* is the emery wheel, *f* and *g* the collar and nut respectively, *h* the pulley, $1\frac{3}{4}$in. diameter, driven by $\frac{5}{16}$ round belts. The spindle can be reversed by taking off *c' d* and slacking the pulley screw. This is very convenient, as sometimes we wish to work close to either end. It is bolted in place of tool post; and with a "compound rest" on my lathe a great variety of work can be done, from grinding centres to backing off a fluted reamer. I hope I have made it clear, and that it will be of use to your readers in general.

18in. GLASS SPECULA.

THE following is an extract from a paper read before the Royal Society of N.S. Wales (Sydney) on July 7th entitled "Notes on the Process of Polishing and Figuring 18in. Glass Specula by Hand, and Experiments with Flat Surfaces," by Mr. H. F. Madsen. It is kindly forwarded by Mr. F. B. Kyngdon, the hon. sec. The author exhibited a silvered specula and the glass tool upon which it was ground. This glass tool was composed of three plates of rough glass 1in. thick by $18\frac{1}{2}$in. diam. These were ground together to fit one another, and then cemented into a solid block, the top being formed of a $\frac{1}{4}$ more convexity than the required concavity of the speculum, the latter being partly hollowed out by the use of a leaden weight and rough emery. The tool and the glass being ground together soon formed themselves into perfect spherical surfaces, and very nearly of the proper curvature; the mirror was bright enough to reflect the image of the sun at an almost perpendicular incidence, and the true and regular surface left nothing to be desired. The speculum at this stage having an absolutely true curve, the polishing was proceeded with, using rouge upon pitch, the speculum being uppermost, and continued until no emery holes or scratches could be seen. With the ordinary pitch polisher the surface is graduated into squares, and requires an extra side motion in working in order to avoid concentric grooves or rings. Mr. Madsen graduated his polisher in a wavy or volute manner, with the advantage of being able to polish for hours without side motion or the trace of a ring. The 18in. speculum took $5\frac{1}{2}$ hours to polish, no pressure being used—simply revolving it upon the tool. By Foucault's test the 1-millionth of an inch variation can be detected at the centre of curvature, and a true spherical surface having been obtained, the most delicate part of the process commences in changing it into a paraboloid of revolution—e.g., the correction of spherical aberration (Fig. 1). There are several methods of accomplishing this, Lassell's system of local polishing being perhaps the one most used. The author prefers the pitch polisher graduated in a correct system (Fig. 2), and figured his glass upon the plan of the parabolic curve coming into contact with the spherical surface at an intermediate point. Both polisher and glass having been regularly raised in temperature were left together until cool, after which the usual stroke for keeping the spherical form was proceeded with for about 10 minutes, when the correction was found sufficient. The glass was simply revolved on the polisher A perfectly even temperature must be maintained, and the polishing powder be evenly distributed with uniform contact at every point between the two surfaces. M. Foucault's artificial star or minute pinhole test at the centre of curvature was used to determine the exact time when the paraboloid had been developed. The rate of decrease required in the amount of correction is very rapid with the increase of radius of curvature, and supposing a theoretically perfect speculum to be obtained with from 20—40ft. focus, the slightest touch or variation in temperature would be sufficient to destroy its good definition. By decreasing the focal length, the rays cross at a less acute angle, and small variations in the reflecting surface have not so detrimental an effect. Mr. Madsen found that an extra thick film of silver deposited on the specula might impair the efficacy of the reflector. He, therefore, determined to measure the thickness of these films, and has confirmed Dr. Draper's calculation of $\frac{1}{200000}$in. obtained by depositing on a large surface, and estimating it by chemical methods. To compare the thickness of the silver film with a ray of light was the optical method used. To do this, two perfectly flat surfaces were required for Mr. Brashear's colour test, and monochromatic light falling at an angle of 65° upon two placed over each other produced straight dark and coloured bands (Fig. 3). If by reason of irregularity of pressure or form a deviation from theoretical flatness be produced, it can be rigidly calculated by measuring the curves or bends in the bands in comparison with the distance between them, which should be as large possibly as half an inch (Fig. 4). The equation for calculating these films is as follows:—

λ = ray of $\frac{1}{44000}$ wave length;
δ = thickness required;
Angle of light = ϕ.

The deviation in thickness between two dark bands is represented by x. $x = \frac{\lambda}{2}$ sec. ϕ, and the smallest displacement can be calculated so

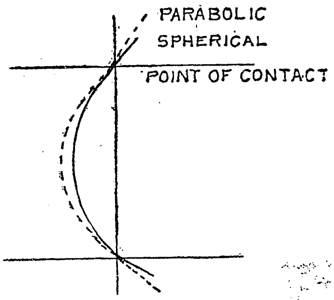

FIG. 1

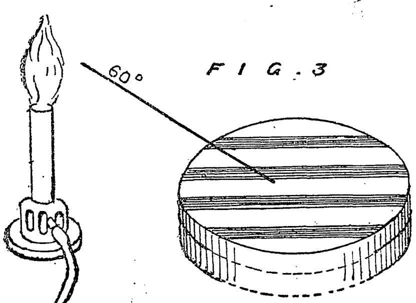
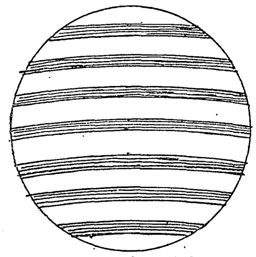
FIG. 2.

FIG. 3



FLAT

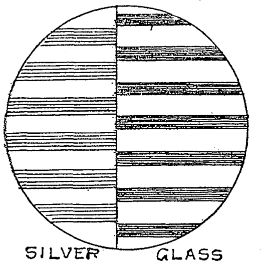
FIG. 4.



IRREGULAR

that defects of less than $\frac{1}{300000}$in. can be seen. By silvering half the upper surface of one of these glasses (Fig. 5), and letting light, say, at an angle of

FIG. 5.



SILVER GLASS

30° fall upon the whole glass, the bands were found to be broken or displaced at the edge of the silver a distance about $\frac{2}{5}x = \delta = \frac{\lambda}{5}$ sec. $30° = 0{\cdot}00000525$, a result nearly agreeing with Dr. Draper. Several single films gave results less than $\frac{1}{3000000}$in. To ascertain the effects of heat and pressure upon these glasses, they were placed upon a 2in. wooden chuck, and observed a uniform colour at 65°. When the finger was placed on the centre without pressure, the colour instantly changed to regular concentric rings, and by lowering the point of sight these rings travelled towards the centre, proving the glass to have become concave, and that by a measurable quantity. By substituting an iron support for the wooden one, the chill in less than one minute produced convexity in the middle surfaces to $\frac{1}{30000}$in. A pressure of 8lb. applied to the centre caused two wide bands of colour to cross in the middle, showing that the glasses had become strained in two directions, and their figure destroyed. These experiments prove that regularity of temperature is the most important factor in the production of any true glass surface, and that in finished specula the least irregularity of temperature at their sides will produce serious defects in their defining power.

THE SENSE OF HEARING.

THE Monday evening discourse before the British Association was delivered by Dr. W. Rutherford, F.R.S., who commenced by describing the vibrations which constitute sound, explaining the difference between simple and compound vibrations, the latter being illustrated by the simultaneous sounding of notes of different pitch. Infinitely more complex, he said, were the vibrations produced by an orchestra with a chorus of human voices and solo singers associated. The mind fails in the effort to grasp the wave-form of the flood of complex vibrations that pours into the ear at every movement. The highest and lowest tones were heard; the qualities of the notes produced by the strings, the wind instruments, and the voices are all discernible. The theory offered by Helmholtz in explanation of this wonderful property of hearing is that the terminations of the nerves in our ears can analyse complex vibrations. It was maintained by Helmholtz and others that in the ear every audible tone throws into sympathetic vibration one or more of the nerve terminations, and that all complex tones are analysed by them into simple pendular vibrations, which affect different nerve terminations according to their frequency of vibration. The lecturer, however, said that he would presently show good reason for doubting that theory. He then proceeded to deal with the organ of hearing, describing the peripheral mechanism which receives the sound vibrations and transforms them into nerve impulses, the nerve fibres that conduct the nerve impulse to the brain, and the sensory nerve cells in the brain which are thrown into action by the arrival of those impulses, giving rise to that state of consciousness termed sensation. They must add to this sensory mechanism other nerve cells in the brain concerned in perception—an intellectual fact far higher than mere sensation, whereby the consciousness examines the various sensations of sound, and attaches to them various significations, with which they are afterwards associated. Having described at length and with minuteness the structure of the ear of a vertebrate animal, the lecturer said that the basilar membrane is covered on both surfaces by epithelial cells. Very many of those on the upper surfaces are hair cells with ordinary or somewhat modified epithelial cells placed between them, to support them in their places. There is an immense number of these hair cells in the cochlea of the cat; four rows of them run the whole length of the cochlear canal in the human subject. There are five or six rows of them, and the total number of the cells is estimated at about 15,000. These hair cells of the cochlea seemed placed in a position of advantage, inasmuch as they are supported on a membrane that can vibrate with the sound wave. It is otherwise with the hair cells of the otolith sacs, which are planted on a membrane that is fixed in the periosteum lining the bony wall of the labyrinth. Immediately over the free ends of the hair cells there is a thin covering membrane, the use of which it is difficult to comprehend. The function of the covering membrane is quite obscure, and must remain so until we know its position with reference to the hairs. The sound waves come into the cochlean canal on the side of this covering membrane, and travel through it to reach the auditory hairs. The lecturer proceeded to criticise the generally accepted theory of the action of the cochlea in the reception of sound, to point out its shortcomings, and to offer for consideration a new theory. Helmholtz, in his great work on "The Sensations of Tone," supported the theory that the nerves terminated in the cochlea are affected by sound on the principle of sympathetic vibration—that is to say, there is a finely graduated series of nerve terminations that individually respond to tones of a pitch varying from 16 to many thousands of vibrations in a second. That theory is based on the analogy of the sympathetic vibration of tuning forks and strings. No doubt it had been shown by Professor Hensen, of Kiel, that the free auditory hairs of some crustaceans vary in length, and that, when he sounded different notes with a horn, some hairs vibrated more than others to particular notes. But Professor Henson admitted that when he sounded any note very loudly, all the hairs vibrated. But when we turn to the cochlean hair cells, especially those of mamals, we find that the hairs are all nearly of the same length, and all exceedingly short. It would take from 120 to 220 of them, placed end to end, to make the breadth of one millimètre. The shaft of an ordinary pin is just about the breadth of a millimètre. The variation in length of these hairs is so trivial that no one has ever suggested that the different hairs can be expected to make a selective response to sounds of different pitch. But in all animals auditory hairs are the recipients of sound vibrations. In the organ of taste also delicate hairs at the free ends of epithelial cells are the parts impressed by molecular motion. Why, then, the lecturer asked, is the theory still maintained, although the condition of the auditory hairs gives no countenance to it? Hensen had endeavoured to show that as the fibres of the basilar membrane slightly increased in length from the base to the apex of the cochlea, they answer the conditions required for that sympathetic response to the tones of different pitch. But the fibres are at most very short, and their variation in length very short. They vary from one-fifth to rather more than a third of a millimètre. That is to say, it would take from five to nearly three of them put end to end to make the breadth of a common pin, and yet within the limits of dimensions so minute we are expected to find a series of vibrating bodies, that with unfailing precision select particular vibrations, varying from 16,000 to 40,000 in a second. But the fibres of that basilar membrane were regarded by no one as the termination of nerves, and although an attempt had been made to show how the vibrations of particular fibres may be communicated to certain hair cells, the explanation was so far-fetched that he need not trouble his audience with it. The lecturer was convinced that this theory of sound analysis in the cochlea or in any other part of the peripheral mechanism of the ear must be abandoned. After illustrating the difficulties and inconsistencies of the accepted theory of sound sensation, he said, before he substituted another theory, he would pay a humble but sincere tribute to that genius of Helmholtz whose magnificent services to science had long since placed his name among those of the immortals. Some five years ago it struck the lecturer that the case of the telephone might throw light on these difficulties regarding the sense of hearing. When sound-waves fall on the plate of one of the telephones, it vibrates. The vibrations of the iron near the magnet affect the magnetism, and so induce in the wire currents of electricity, whose frequency and amplitude correspond to those of the vibrations of the iron produced by the sound. The currents travel to the second telephone, and induce oscillation of its magnetism, which in turn causes its iron plate to vibrate and produce sounds similar to those communicated to the first telephone. There is no analysis of the sound-waves. The transmitting telephone takes up simple or complex vibrations. The harmonies of an orchestra may fall upon it, and it does not fail to convert the complex sound vibrations into electrical vibrations, and these again into the complex sound of the orchestra in the receiving telephone. The theory which the lecturer had arrived at, and which he published that night for the first time, might be termed the telephone theory of the sense of hearing—the theory that the cochlea does not act on the principle of sympathetic vibration, but that the hairs of all its auditory cells vibrate to every tone just as the drum of the ear does, that there is no analysis of complex vibrations in the cochlea or elsewhere in the peripheral mechanism of the ear, that the hair cells transform sound-vibrations into nerve-vibrations, similar in frequency and amplitude to the sound-vibrations, that simple and complex vibrations of nerve energy arrive in the sensory cells of the brain, and there produce, not sound again, of course, but the sensation of sound, the nature of which depends not upon the stimulation of different sensory cells, but on the frequency, amplitude, and form of the vibrations coming into the cells, probably through the fibres of the auditory nerve. On such a theory the physical cause of harmony and discord is carried into the brain, and the mathematical principles of acoustics find an entrance into the obscure region of consciousness. Now, if nerve energy were only electricity, that theory would probably be accepted at once; but nerve motion is very sluggish when compared with electricity. The lecturer for five years had kept this theory back, because he felt that he had no evidence of the possibility of sending a rapid succession of vibrations along a nerve. It cost him a good deal of thought and experimental observation to find the evidence he required. If we give to a motor nerve of a frog or rabbit ten instantaneous shocks of induced electricity in a second, ten impulses will pass along the nerve to the muscle, and produce ten distinct contractions in the same period. If we send 40 impulses along the nerve, we get, not 40 contractions of the muscle, but a single continuous contraction, because the several contractions are fused together. Now, if

we listen to the muscle so stimulated one hears a musical note having the pitch of 40 vibrations per second. If we stimulate the nerve, say, 200 times per second, causing a tuning-fork to make and break the primary circuit of an induction machine, and so send 200 shocks per second into the nerve, the pitch of the note in the muscle exactly corresponds. It has the same pitch as the fork. The lecturer had experimented in this way, and eventually found that he could send as many as 352 impulses per second along the nerve, and get a note from the muscle of the pitch of 352 vibrations per second—that is to say, a note of the F on the lowest space of the treble clef. But when he tried by more rapid stimulation of the nerve to get a higher note from the muscle he failed. There was nothing but a noise heard. That a musical note is produced by a contracting muscle is known to every physiologist. One can hear it if he firmly clench the jaws during the stillness of night, when other sounds are hushed. It is the low note with a frequency of vibration less than 40 per second. There is, therefore, nothing new, the lecturer said, in the statement that a note may be heard in a muscle; the new point is that the pitch of the note may be increased by a more rapid stimulation of the nerves, and retain their individuality so sharply that they can produce a note in a muscle having a pitch number of 352. That new fact, he thought, would lend much support to a vibrational theory of nerve energy. Was he to conclude that because he failed to get a higher note than one of 352 vibrations from the muscle it was not possible to send more than 352 vibrations per second along a nerve? By no means, the lecturer said; the fibres of a muscle are very different from those of a nerve, and also very different from nerve cells. The molecules in both of them can probably vibrate far more rapidly than 352 times per second. He had, therefore, directly proved that vibrations of the same frequency as all the lower tones of the scale, from the lower F of the treble clef downwards, can be transmitted by a nerve. He had therefore a very significant piece of evidence in support of his telephone theory of sound sensation, and he could not but think that the evidence in favour of it would increase. In dealing with methods so difficult and obscure they must beware of dogmatism; but it was the duty of the scientist to frame theories which seemed to explain phenomena. One might, and often did, err in holding back a theory, lest it should give pain to the author of some theory which it was destined to oppose, forgetting that the suggestion of a new line of thought might, in some other mind, lead to ideas still further in advance. Should his theory of the sense of hearing find acceptance, it would lead to a reconstitution of theories regarding the other sense organs.

SCIENTIFIC NEWS.

THE death is announced of the distinguished African traveller, M. Paul Soleillet, at the age of 44 years. Latterly his journeys have been made to Shoa, his object being to open commercial intercourse between that kingdom and France.

Herr R. Flegel, formerly a purser on board one of the Liverpool Company's steamers on the Niger, but latterly a not undistinguished explorer of parts of tropical Africa, must be added to the list of those who have died in the attempt to open up the Dark Continent to civilisation.

Dr. Maywald, for many years one of the "calculators" of the "Berliner Astronomisches Jahrbuch," devoting his time more particularly to the orbits of the small planets, died recently in Berlin at the age of 70 years.

The income of the British Association for the past year amounted to £3,805, out of which £1,300 has been awarded for various purposes, e.g., in mathematics and physics, £280; in chemistry, £115; in geology, £210; in biology, £535; in geography £30; in economic science and statistics, £10; and in anthropology, £120. The sum devoted to Biology is mainly given to the "Zoological Record" and the Naples Zoological Station (£100 each), while the stations at Granton and Plymouth receive £75 and £50 respectively, and two sums of £75 are devoted to the Flora of China and the Flora and Fauna of the Cameroons. Ben Nevis observatory is awarded £75.

The American Association had no fewer than 252 papers before it; but, strange to say, separated without appointing the next place of meeting—a significant fact being that no invitation was received from any quarter. Prof. S. P. Langley was appointed president for next year. Amongst the papers read was one on the "Soaring Bird," by Mr. I. Lancaster, who had a number of diagrams to explain his paper, and was understood to have a model, which, however, was not forthcoming. The president of the association, Prof. Morse, attacked the principles and facts set out in the paper, moving a suspension of business that all might go out on the square and try a model. Great interest was excited, and many were willing to be spectators of the remarkable performance. But Prof. Lancaster finally disclaimed a knowledge of mechanics, saying that he had made his models fly in Florida, and that his theory was demonstrated. Some indignation was expressed by the audience, and 1,000 dollars was offered by members for a model that "would work."

Prof. T. C. Mendenhall read a paper on "Characteristic Curves of Composition," in which he described a method of analysis of authors by counting the number of words of different lengths employed by them. He finds that different writers employ a style of remarkable uniformity in the general average of words of different lengths used by them. By counting and tabulating the number of letters in 1,000 or 10,000 words in Dickens, Thackeray, and John Stuart Mill, he finds that the results may be graphically represented so as to give a characteristic curve for each author, differing from that for all others. The practical application of these researches might be in deciding the question of the authorship of Shakespeare, which Prof. Mendenhall thinks feasible at an expense of 1,000dols. or 2,000dols. In response to a query, he expressed the opinion that prose and poetry of the same author would contain words of the same average length.

The report of the Comptroller-General of Patents for 1885 states that the number of applications was 16,101. The number of applications communicated from abroad in 1884 amounted to 2,607, and in 1885 to 2,336. The largest number of applications on any one day in 1884 was 266 on the 1st of January, and the smallest 25, on the 26th of September in the same year. The corresponding numbers in 1885 were 109 on the 7th of April, and 24 on the 17th August. The total number of applications, including communications from abroad—viz., 12,461 in 1884 and 11,695 in 1885, made through agents, amounted to about 73 per cent. in both years, the remainder, or 27 per cent., being made directly to the Patent Office by applicants themselves. During the year 4,383 notices of similarity of inventions applied for were given in respect of 2,531 applications, and 49 applications previously included in prior applications were reported.

The new electrical launch *Volta* made a successful voyage to Calais from Dover last Monday. She is built of steel, is 37ft. long by nearly 7ft. broad, and is fitted with two Reckenzaun electro-motors, supplied with energy from 61 accumulators, some or all of which can be employed at will by means of switches. The power of the motor ranges from 4 to 12 horses, the motor shaft making from 600 to 1,000 revolutions per minute. The trip to Calais occupied 3 hours 51 minutes, the return trip 4 hours 15 minutes; but the trial was not one for speed, although, according to one account, during the last half-hour of the return trip a speed of "fourteen miles an hour" was reached. The quiet movement of the boat was well shown by the fact that a sleepy gull was caught by the hand and brought into Dover. That indicates the special value of the electrical utilisation of energy.

The salt industry at Port Clarence and Haverton Hill is progressing apace, and with cheap coal on the spot promises to become a formidable rival of the Cheshire trade. Altogether there are sixteen bore-holes down, and more are being made. The salt beds are in the form of a basin, the dip being apparently to the south and east, as the brine is reached nearest the surface at Haverton Hill, and at Eston Junction is found some 600ft. lower. It is stated that the product of salt will this year reach 200,000 tons. In connection with this matter we hear of a new boring apparatus which is said to be capable of sinking a 5in. borehole 800ft. in a fortnight. It is an American device, which has been often employed in making prospecting boreholes in the oil-regions of Pennsylvania.

The programme for the autumn meeting of the Iron and Steel Institute, which is to be held in London on the 6th, 7th, and 8th of October next, has been issued. The council of the Institute has arranged to hold the meeting in London this year, for the second time in the history of the society, with a view to affording members the opportunity of studying the mineral resources, &c., of the Colonies as illustrated by what is shown at the Exhibition, and of coming into contact with colonists and Indians who are interested in mineralogical operations. Perhaps the most interesting paper in the list is one on the ironmaking resources of our Colonies, prepared by Mr. Gilchrist (whose name is associated with the well-known basic process) and Mr. Edward Riley. Among other papers to be read there is one on the chemical composition and mechanical properties of chrome steel, by M. Brustlein; another on combustion, with special reference to its application in the arts, by Mr. F. Siemens; another on the treatment of high-class tool steel, by Mr. A. Jacobs, of Sheffield; and one on modifications of Bessemer converters for several charges, by Mr. John Hardisty, of Derby.

The master of the steamer *Thessaly*, belonging to the Houston Line, writing to the owners of that vessel, notes a strange experience on his last voyage from Liverpool to Montevideo. On Thursday, July 1, at 11.35 p.m., the ship, which at the time was in lat. 0 55 N., long. 29 34 W., was suddenly and violently shaken and bumped, the shaking being accompanied by a loud, rumbling, metallic kind of noise. The first impression was that the ship was tearing the bottom out over hard rock, but knowing there was nothing in the neighbourhood she could touch, save St. Paul's rocks, and as they could not see land, the captain concluded the machinery was going to pieces. About eight minutes after the first shock, a second, not quite so severe, stopped the ship, which in the meantime had been going slowly. Subsequently they experienced a third shock—a slight one. The lead indicated 60 fathoms with no bottom. Being now satisfied that the shocks were caused by some submarine disturbance, the captain proceeded on his course. After steaming about fifteen minutes, he experienced a fourth shock, only inferior to the first in severity and duration. After this all was quiet. During the shocks the compass cards were much agitated.

Prince Albert of Monaco has been on a voyage of scientific investigation in his yacht *Hirondelle*, his object being to study the influence of the Gulf Stream on the French coasts. Altogether 179 floats were thrown out at various spots north-west of the Azores, forming a line about 170 miles in length, and the conclusion arrived is that as far as 300 miles to the N.N.W. of the Azores the Gulf Stream shows no tendency to flow N.E., and even its tendency E. is not definite.

Prof. A. A. Church will deliver in November and December, at the Royal Academy of Arts, Burlington House, a course of lectures on the chemistry of paints, of painting methods, and of pictures.

Before the Royal Scottish Society of Arts, Mr. G. R. Primrose read last Monday a paper describing his Electric Meteorological Scale Reader, an instrument which transmits by one wire readings of a distant barometer, &c. It is intended for use between mountain tops and captive balloons.

M. Camille Koechlin has recently brought before the Academy of Sciences a paper "On the Purple of the Solar Spectrum." He contends that the solar spectrum yields only two simple colours, blue and yellow. It is not easy to describe within a limited space M. Koechlin's views; they must be carefully studied to be properly understood. He contends that the spectrum contains the elements of all shades, by mixture, or by diluting with white, or extinction with black. In the last case the colours containing blue preserve their tint, while those on the opposite side of the yellow become changed in character. The whole question of colour radiations is opened anew by these statements, and it demands a most thorough and exhaustive examination from M. Koechlin's point of view.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only but in all other subjects; For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

NOTES ON TELESCOPIC DEFINITION AS AFFECTED BY THE DIRECTION OF THE WIND.

[26247.]—IT has long been a subject for remark with astronomers that the east wind exerts some curious influence upon the definition of their telescopes. Almost every practical observer, from the time of Sir W. Herschel to the present, has noticed —in this country, at least—the tendency that star discs have to assume a more or less triangular appearance under such atmospheric condition. Some time ago I had occasion to mention this peculiarity before the Liverpool Astronomical Society (*cf* "Abstracts of Proceedings," Vol. I., p. 37; Vol. II., pp. 7, 10), where it provoked a little discussion. With a view to obtain further information on the point, I sent a request to observers through the ENGLISH MECHANIC (Vol. XXXVII., p. 336). By way of reply, I received copious notes from Mr. A. S. Williams, of Brighton, and from the late Prebendary Webb, at Hardwick. Want of leisure has hitherto prevented me from making use of their results; but, now that the lamented author of "Celestial Objects" has passed away, it seems scarcely fair to withhold them longer, so I send a brief abstract, in the hope that it may interest your readers. Mr. Webb's notes relate to lunar, planetary, and stellar objects; Mr. Williams's to lunar and stellar—the *stellar* records only being here quoted. In the earlier observations by Mr. Webb a $3\frac{7}{10}$in. achr. telescope was used: a $5\frac{1}{2}$in. Alvan Clark achr. from 1861: and a $9\frac{1}{3}$in. With reflector, from 1869. The instrument used by Mr. Williams was a $5\frac{1}{4}$in. Calver reflector. The precise dates are omitted from the abstract, for the sake of brevity; but they can be furnished to anyone who cares to investigate the subject further.

NOTES ON DEFINITION AS AFFECTED BY WIND, &C.

By Rev. T. W. WEBB.

1850—Very fine, warm, haze, strong N.E.; very fine, occasionally blotty, warm N.; fine, very cold N.E.; very beautiful, after falling of cold N.E.; good, strong cold N.E.; splendid, S.W.

1851—Excellent, N.E.; in part very fine, high and cold N.E.; remarkably fine, N (4 dates).

1855—Very nice, severe frost, cold N.E.; very pleasant, mild, transparent, calm below, W. above, but "villainous D."

1856—Above average, severe frost, piercing E.N.E. or N.E.; good, not superior, N.E.; fine, N.E. (2 dates); not quite so good, S. or S.E.

1861—Sometimes sharp, at others flaring or distorted, severe frost, N.E. or E.

1862—Strong flare, cold N.E.; exceedingly high and cold W.S.W., "all kinds of definition"; very fine, strong cool W.

1863—Fine, a little flutter, W.N.W.; discs small, much rippled, focus very changeable, haze, E.; worse, clearer, E.; bad, perfectly clear, N.E.; fine, thick haze, warm N.E.

1864—Really fine, N.E., causing very chilly, ungenial weather; very fine, though frequently blotted, much haze, cool E.

1865—Extraordinary weather, warm, not hot, nearly cloudless after morning fog, very gentle, warm S., beautiful D. (5 dates); brilliant sky, very gentle N., D. fluttering with high powers.

1869—Very severe frost, snow on ground, N., D. especially bad, disturbance plane very near earth; sharp frost, N.E. changed to N.W., disturbance region lowered, D. not good.

1870—Unusually good, severe frost, calm, N.E.; before sunrise, therm. 16°, D. almost perfect, N.E.; a good deal of haze and flutter, severe frost, N.E.; good, but flaring and very unsteady, N.E.

1871—Quite calm below, rapid upper current, W., D. very blotty; bad, small discs, much false light, chilly, N.E.; good, stars dull, haze, N.E.; moderate, therm. 26°, N.E.

1873—Marvellously bad, wind, if any, E (2 dates).

1877—Fine, strong W.

1878—Exceptionally fine, N.E., not cold.

1881—Bad, a little white haze, cold N.E.

1883—Blotty, high and miserably cold S.W.

(The immediate proximity of the Welsh hills might give rise to some peculiarities in the atmospheric conditions noted by Mr. Webb, as this was a point frequently alluded to in private letters from him.)

NOTES BY A. S. WILLIAMS, BRIGHTON.

1st Series (from double star obs.)

1880—Bad, strong N.E.; moderately fine, slight N.E.; decreasing from pretty good to bad, E.; ditto, N.W.; moderate, strong N.; bad to moderate, N.E.; bad, very misty, N; moderate, pretty fresh N. to N.W.; moderate, E.; good, light N.E.; indifferent, strong N; ditto, strong W.N.W.; bad, half gale from N.E.; moderate, misty, strong N.E.; very indifferent, half gale from S.W.

1881—Indifferent, misty, E. (two dates); very indifferent, fresh N.E.; very poor, fresh N.E.; moderate, E.—better later on, when wind veered to N.W.; moderate to good, N.E., light generally; bad, very strong N.E; indifferent, misty, much dew, slight E.; fair to indifferent, fresh N. to light N.W.; indifferent to fair, light N.; bad, very strong N.; fair, rather misty, strong N.E.; very good, strong S.; good, fresh W.; bad, strong N.; fairly good, strong S.E.

2nd Series (from double star measures).

1880—Not good, unsteady, strong N.E.; moderate, N.E.; fair, N.W.; moderate, E.; not first rate, light N.; moderate, fresh N.; moderate, calm to N.E.; moderate to indifferent, light W.

1881—Moderate, heavy dew, light E.; pretty good but a little unsteady, N.W. to light W.; very indifferent, fresh W.; moderate to indifferent, N.E.; good, hazy, calm to light N.; good, light S.E.; indifferent, occasional puffs from N.W.; moderate to indifferent, heavy dew, N.W. light to fresh; not good, rather misty, light N.E.; fair, fresh N.E. (two dates).

In the lunar observations, Mr. Williams uses numerals to denote the quality of definition, according to the following scale:—

0 = the worst possible state of atmosphere.
1 = a very disturbed atmosphere.
2 = fluttering and unsteady definition.
3 = fair definition.
4 = good definition.
5 = finest possible definition.

Mr. J. E. Gore, of Ballisodare, in a private letter, dated June 17, 1883, says:—"In the Punjab summer, when the air is *extremely* dry and hot (sometimes over 100° F. several hours after sunset), it is generally so laden with dust that telescopic observation is out of the question—stars below 4 mag. being invisible to naked eye. This state of things is at its worst with a west wind." (The wind from this quarter would traverse the arid countries of Arabia, Persia, and Afghanistan —the western desert region of Asia.) Whatever may be the peculiar characteristic of the east wind in the British Isles, which causes this phenomenon of a triangular star disc, it is a matter that deserves rigid investigation.

That such winds have an effect upon the human economy is a fact with which many persons are only too well acquainted; and it does not seem strange, therefore, that the same winds should exhibit anomalous optical effects. Of course, local conditions may undoubtedly modify the peculiarity already mentioned; but I think it will be found that the consensus of opinion will corroborate it. At any rate, most observers that I have met with in this country have expressed themselves in accord with my own opinion. I shall be very glad to learn what others have to say in regard to this curious point. **W. S. Franks.**

METEORIC.

[26248.]—FURTHER particulars respecting the fire-ball of August 4th are as follows:—As seen at Bristol, Mr. Denning writes me, saying, "The path was R.A. 129°, Dec. 60° N., to R.A. 83° Dec. 40° N. . . . Estimated brightness equal to or brighter than Jupiter." The meteor was also observed by a correspondent of *Nature*. Writing from Ramsey, Isle of Man, he says the path was a little E. of η Aquarii, and seemed to be in the direction of a line joining η and δ Aquarii. The path seen at Leeds, put into R.A. and Dec., at the request of Mr. Denning, three weeks after the meteor was seen, reads from $\pm$ R.A. 265°, Dec. 25° N. to R.A. 287° $\pm$ Dec. 0°. I took my magnitude from a cottage chimney over which the meteor passed, as seen here; the chimney just eclipses the full moon. A Mr. W. Gaunt, of Leeds (three miles W. of centre), says: "It lit up the country like the full moon." Is Mr. Davenport sure the meteor appeared to take the path indicated by him in letter 26142? —namely, "parallel with α and β Ophiuchi."

D. Booth.

5, Rownsley-street, Leeds.

ORIGINAL ELECTRICAL EXPERIMENTS.—No. VIII.

[26249.]—I WILL now take what I conceive to be a new departure in Electrics, and will describe an experiment or two with a Wimshurst machine, in order to give those interested some brain friction during the fast approaching winter evenings. We will take this machine with 24in. discs, and, say, any equal number by preference, of sectors upon each, from, say, 16 up to 128, have I tried, and have introduced odd numbers without any noticeable difference, and for the Bunsen's I substitute, say, 2in. of the wired bass string of a violin, unwinding, say, an inch of the wire as required at the end, which, if bent into a small ring, will not damage the tinfoil sectors for a considerable time; the other end is pegged into the short piece of tube on ends of what are termed the neutralising rods. It will now be found that although the machine will not start in all weathers, that, on being started, it will continue to work with only three brushes, or, as I prefer to term these, three electric conductors, because a careful investigation will reveal the fact that electricity is going "on" to the discs at "all" times, whether three or four are used. Next, I remove these brushes or conductors, and set up each one upon a separate stand, and the machine will work just as well as in the original arrangement, it being understood that there are merely in operation the discs and brushes. I now arrange four Leyden jars, easily prepared by filling champagne bottles with the numerous scraps of waste foil resulting from varied experiments, coating outside up to spring of neck, then a length of $\frac{1}{8}$in. brass wire passed through a cork, the top end bent to a rounded right-angle, a small hole drilled therein, and a piece of aforesaid wire pegged in same; each jar has a piece of foil pasted on it reaching from the rod down the neck until it is, say, $\frac{1}{8}$in. from the outside foil. Now we can substitute these four jars for the four brushes, by having the rods of suitable lengths to touch the sectors at the proper places upon the opposite diameters of the discs, thus we can have a succession of shocks as long as the machine is kept going. We can also take a large jar with a jumping place of, say, $1\frac{1}{2}$in.; arrange a fork with two pieces of the fine wire, as explained, so that the jar being placed opposite to the circumference of the discs, these wires all but touch the sectors; it will give in favourable states of the atmosphere tremendous shocks, and it will be found that the action is as though the sectors were pumping from the inside foil of said jar, and the discharge can be plainly seen to take place "from" the earth "to" the inside foil. Now, during all these experiments, it may be proved that "all" the electricity is coming on to the discs, and also, if the knuckles be brought near, it is undoubtedly clear that, although a careless observer might imagine otherwise, that these sparks are "from" the knuckles "to" the discs. Thus we find that all the electricity visible is going on and none whatever coming off, and if further proof be desired I will take a jar, arrange a jumping place of, say, $\frac{1}{8}$in. or so, place said jar upon a sheet of thick glass. Now, if the knuckles be approached to the outside foil when the machine is set in motion, the sensation will be found to be very powerful and painful. It will also be observed that the outside foil takes a charge in proportion to the jumping distance, and when sufficient has accumulated upon its surface there will be the jump. If, instead of the knuckles, we arrange a chain lying along the table, and within, say, $\frac{1}{4}$in. from the outside foil, on approaching a knuckle to any part of said chain we will experience a sensation similar to a very powerful electro-magnetic machine.

In these experiments it will be found that the electricity is in a state of great tension, as, if any connections from the rod to the jumping place be made by pasting tinfoil around said rod, across the varnished mahogany or other cover, and down the side of the glass, or of one piece of foil to another, it will be observed that each spark punches a small hole in said foils through the resistance of the damp paste.

Thus, it would seem as though the Wimshurst machine is virtually an electric pump, as thus arranged, of tensional electricity; but also one differing from all other pumps in the fact that, as thus arranged, it swallows in its insatiable maw all that undefinable "something" that it produces.

We can also obtain a continuous current from the machine by arranging the rod leading into any Leyden jar, so that it does not touch the inside foil, and shortening the jump to a suitable distance proportionate to the power of the apparatus; thus for this size machine I use a jar of, say, 9in. by 4in. Thus it would appear, as a result of these experiments, that when + electricity is produced by any means upon any substance capable of partly retaining it, that said substance becomes possessed of the property of attraction for all bodies and — flows on to the opposite side (not to the opposite diameter) of, say, in this case the discs, from both

the air and the earth, just in proportion to the quantity of + developed, and thus the circuit is complete when the one joins the other; in proof of which I am ready to take the largest Leyden jar in my hands whilst another discharges it, so long as I am not included in the circuit, as the instant the shock takes place there is an end of the matter, such as a return to air or earth of the combined forces. It thus appears possible to me that the electric theory may be formulated thus. This earth is a magnet, and everything upon it is saturated with electricity of the quality termed, which, by the way, is a misnomer, because it is so subtle that nothing is able to retain it save in comparatively small quantity; and I hazard the opinion that all attraction is due to it, because when developed upon any substance capable of retaining even a small quantity of it, that body exhibits strong attractive properties. Therefore, it seems evident that the true action of all electric machines consists in the removal of some of this—what shall I term it?—say, form of energy, from its usual habitation, thus reducing its tension or force, and causing an instantaneous rush from surrounding matter in order to restore its balance. In proof thereof, any person possessing a Wimshurst machine will find that if he places a light balanced wire at the base of insulated conductors, say, as I have, of glass tube 2ft. long, then the instant that the machine shows any electricity the said needle will be attracted to the glass, and experiment will show that it is – which is ascending, not any kind coming down. A., Liverpool.

THE LARGEST DYNAMO IN THE WORLD.

[26250.]—YOU have already mentioned that the Brush Co., of Cleveland, Ohio, were building for the Cowles Electrical Furnace Company the largest dynamo in the world, and your readers may possibly be interested in the following, which I extract from an article in the *Scientific American* by a Mr. H. C. Hovey: it is remarkable in more ways than one:—" It is related (says Mr. Hovey) that about nine years ago Mr. Charles F. Brush, then a professional chemist in the city of Cleveland, intimated to his friend, G. W. Stockley, at that time President of the Telegraph Supply Company in the same city, his purpose to make a dynamo that should excel the French and German machines. Without further ado, Mr. Brush completed his dynamo in about two months, brought it to the factory, set it to work, and found it to work successfully on the very first trial. It was purchased by other parties, and has been running constantly ever since without needing repairs. This illustrates the quietness and thoroughness with which this distinguished inventor works. A peculiarity of his method is that he wholly discards empirical experiments; but when he sees that some new machine is demanded, he proceeds to meet the demand. In this he is greatly aided by his remarkable powers of vision. He will draw his original designs, send them to the pattern-maker, and when the model is returned will, by his unassisted eye, detect any deviation to within the sixty-fifth part of an inch. He can also, it is said, subdivide an inch into hundredths, using only a common pocket-ruler, and do it so accurately that on testing his work by the vernier it shall be found correct to within two one-thousandths of an inch. Last spring Mr. Brush contracted with the Cowles Electric Smelting Company (then of Cleveland, but now removed to Lockport, N.Y.) to build and deliver a 500 horse-power dynamo within three months, under forfeit. He made no model nor experimental machinery, although the mechanical design was new, and the electrical proportions had to be worked out entirely *de novo*. He simply made his working drawings and placed them in the hands of Mr. Possons, the company's superintendent. The patterns, of course, had all to be made new. The machine was built exactly according to the original drawing: its parts were duly assembled; it was set in place and tested for ten days with a 500 horse-power engine under all varying conditions of load, and it was found to realise all expectations, not only in the output of current, but in all mechanical and electrical details. The problem of the commutating arrangement for currents of 3,800 ampères at 100 volts would alone have been enough to discourage ordinary electricians. The commutator of Brush's 'Colossus' performed its functions perfectly on the first trial, and no difficulty whatever was experienced in this respect. In order to avoid attacking this very problem, Mr. Gordon, in making his great dynamo, was obliged to make the field-magnets revolve, the armature remaining stationary. Gordon's dynamo, built several years ago in England, was the bulkiest machine of the kind ever constructed, being two or three times as heavy as Brush's 'Colossus.' It had nearly as great electrical capacity, but did not work for any great length of time, when, as we understand, it went all to pieces on account of mechanical imperfections. The 'Colossus' represents the latest advance in dynamo building, having the greatest electrical capacity of any machine ever hitherto made—having, perhaps, five times the capacity of Edison's famous 'Jumbo.' Indeed, the Brush Company itself, a few years ago, would have had to build a dynamo of double the size to get the same capacity. But this dynamo embodies all Mr. Brush's latest improvements, and may safely be pronounced the foremost achievement of its kind. The work to be required of it at the Cowles Smelting Works will be the reduction of refractory ores. This company has for some time past been using a Brush dynamo of 125 H.P., and the results attained have been so remarkable as to justify the expectation of still more wonderful triumphs by the means now placed at their command. Precisely what these may be, however, is as yet a matter of conjecture. Those already familiar with the dimensions and powers of other dynamos will be specially interested in the following data, given by Mr. Brush, concerning the 'Colossus': The whole machine is 14ft. long, 5ft. 2in. high, 4ft. 2in. wide, and weighs in all 22,000lb. The weight of the copper wire used on the machine is 6,250lb. The diameter of the pulley is 40in., and of its face 45in. The normal speed of the dynamo 430 revolutions per minute. The electrical capacity is 300,000 watts, or the equivalent of 5,000 incandescent lamps of 16c.p. each."

There is no doubt about Mr. Brush's dynamo being a monster, but it is simply nonsense to suggest that because Mr. Brush can divide an inch into hundredths by means of a pocket ruler that he can also build the best dynamo per saltum. If Mr. Hovey's knowledge of the "Colossus" is to be gauged by his acquaintance with the history of the Gordon dynamo we shall know what to think; but at present one may hope that he knows more about Brush's machine than he does about Gordon's, which is running very well indeed at Paddington station. **Nun. Dor.**

LIGHT — THE COLOUR DISPERSION. —III.

[26251.]—IN attempting to explain this matter, which has always caused perplexity, it will be necessary to introduce the undulatory theory. Now, in explaining refraction generally, we have to take into account the fact that light is not propagated instantaneously, but takes time to advance; so also in explaining dispersion, which is nothing else than the unequal refraction, we must also suppose that this, too, depends, therefore, upon time; and the only question is, How does time enter into the calculation? It must be thus:—

The fact of there being refraction shows that the velocity is not the same in one medium as in another, and we shall try to show that the entire change is not instantaneous, but goes on all the time that the wave is passing from one medium to another, and this depends upon the length of the wave. Let us see how this happens.

As long as a wave is moving in a homogeneous medium, the action of the forces which act upon the particles is such as to maintain an equal and uniform speed of both ends; but while the wave is in passage, this can no longer be the case, for it becomes a *composite* wave, with a different force acting in one part to what acts in the other, and having a tendency, therefore, to produce a different velocity in the advancing end to what it would have had if either of the forces had acted singly, so that we must regard the force in the following part as a *disturbing* force, which disturbs the uniformity which the motion of the advancing front would otherwise have had, so that the motion is no longer uniform, but keeps increasing or diminishing; that is, the velocity of the front having been interrupted by entrance, the initial velocity in the second medium is not maintained uniform; but continually increases or diminishes, and does not attain its final value till the wave has completely entered, after which there will no longer be any difference between the forces in one part to those in another. And this is what we proposed to show—that the change of velocity was not complete till the whole wave had passed. Now, the tendency of the force in the advancing end being always to assimilate the velocity of the advancing end to that of the following, the assimilation becomes more complete, the longer the process is going on—that is, the longer the wave is; or, in other words, $\frac{v}{v_1}$, upon which refraction depends, is always nearer to unity for long waves than for short ones, which quite agrees with observation.

It may be objected that we ought not to have treated it as a case of force, but as a case of the conservation of momentum. But if forces *are* really acting, as they certainly are—to wit, the force of elasticity, it seems, to begin with, to be simply a contradiction to say that forces are acting, yet it is not a case of force. However, let us see what would follow from looking upon it as a case of momentum. Let m be the mass of the particles in a given portion of the wave which has not entered, v the velocity, m_1 and v_1 corresponding quantities for the other part. It would then follow that $\frac{v}{v_1} = \frac{m_1}{m}$; but this is utterly untenable, for suppose the wave to be moving from vacuum, or from ether, into glass. To institute any comparison between the mass of ether and that of glass cannot be; moreover, if it could, since $\frac{v}{v_1} = \frac{m_1}{m} = \mu = \frac{3}{2}$, it would make out that the mass of a wave of ether would be two-thirds that of one of glass.

And this confirms, or even may be said to demonstrate, the truth of the supposition that the undulation going on in glass is not an undulation of the particles of the glass itself, but of the same ether which is outside, only having its density and elasticity, one or both, modified by being in the glass; or, at least, we may suppose the effect of the glass upon it to be the making of the vibrations the same as those of ether thus modified. This being so, since it is not the glass itself, but the ether, which undulates, we might, if convenient, omit all further reference to the glass, and might simply treat the medium as ether in its altered state.

If, then, we avail ourselves of this, our liberty, the whole question becomes much simplified. For, according to Newton (Lib. 2, Prop. 48), the velocity of a wave in an elastic medium varies as $\frac{e}{d}$ the elasticity and density, but is independent of the length of the wave; so that $\frac{v}{v_1}$ would be the same for all waves had no change in v_1 been made by the passage from one medium to the other. But the fact of there being dispersion shows that the ratio is not constant for all waves when there has been a passage, so that the alteration can only have taken place during the passage. The manner of its doing so has been indicated above, and it has been brought about by the difference of the elastic forces in the two media.

We might illustrate the case by comparing the effect which the length of a wave has with that of the length of a gunbarrel upon the velocity of the projectile.

Two things following from this may be mentioned, first, that $\mu = \frac{v}{v_1}$, will be only an approximate value; its more correct is $\frac{\lambda}{\lambda_1}$. These values would be identical if v_1 were constant during the passage; however, as v and λ both increase together, we were correct in saying above that μ depended upon $\frac{v}{v_1}$ and increases or diminishes with it.

Another consequence, and a very curious one, of v_1 not being constant during the passage, is this: it may easily be shown that the waves, after passing from a rarer to a denser medium, become detached, and proceed singly, and that they are somewhat jammed together when they move from a denser to a rarer. This may seem a great objection; but it is one which appeals to imagination rather than to reason, for a wave which has been once set in motion, goes on quite independently of any that may follow it; moreover, after being refracted again through the second face of the prism, they will be reunited as before.

On account of the importance of the subject, I shall ask leave to give in another letter a summary of what Newton says on the subject, with some remarks as to how it bears upon the theory of light generally. **W. G. Penny.**

(*To be continued.*)

IS VIOLET A PRIMARY COLOUR?

[26252.]—BEFORE proceeding to reply to Mr. Hardie's criticisms (letter 26121) on my first letter under this heading, I must point out an error in his explanation of the fact that blue and red mixed make violet. He writes: "The red simply neutralises the green constituent of the blue, and leaves its violet outstanding." Red, however, does not neutralise green, since they are not complementary colours; so a portion of the violet constituent of the blue would also be required in order to effect that result. Moreover, since the proportion of red required to be mixed with blue to form violet is so small, it is not clear even then that all the green would be neutralised. Mr. Hardie is right in saying that "if the red and blue are at all bright, the result is rather lilac than violet." But it should be borne in mind that violet is the least luminous of all colours; and it is unreasonable to expect to obtain a colour of such low intensity as violet from blues and reds of a high degree of luminosity. It would be scarcely more unreasonable to expect to obtain dark blue by mixing two light blues. Nevertheless, the violet of the spectrum can be perfectly imitated if a deep, rich blue be used and not too much red.

The next paragraph of Mr. Hardie's letter shows that he does not understand the nature of the coloured spectral images which are seen after staring at coloured objects—a fact illustrated by

the well-known advertisement of Pears' soap. Mr. Hardie regards the effect as existing in the eye independently of any light which it (the eye) may receive from without; and asserts, as proof of his statements, that the spectral image may be seen projected upon a black surface. To determine that point I laid a sheet of white paper on black velvet, and then proceeded to gaze attentively at a small piece of coloured paper placed on the white. When this coloured paper was removed I saw in its place a faint image of it, having a colour complementary to that which I had been staring at. But when this spectral image was caused by a movement of the eye to overstep the limits of the white paper, it disappeared, and reappeared when the eye returned to the white ground. The following is Helmholtz's explanation of the phenomenon. Suppose the eye to have been gazing intently at a small piece of green paper placed on a white ground. Then if the green paper be suddenly jerked or blown away, the light which enters the eye will be white; but since the nerves of the eye—which are sensitive to green light—have been fatigued by staring at the green paper, they act but feebly, whereas the two other sets of colour nerves, having retained their freshness, act with their usual vigour. Consequently, the colour due to the combined action of these latter nerves predominates, and so a faint rose-coloured image is formed, that being the colour due to simultaneous action of the red and blue (or violet) nerves. In effect it is the same as if one of the seven colours composing white light were to be partially withdrawn, in which case the combined action of the remaining six would produce that colour which is complementary to the one withdrawn. In the case we have just considered the green nerves do, of course, act to some extent, and so produce white light, rendering the rose-coloured spectral image paler than it would otherwise be. If the green paper be now placed on a yellow instead of a white ground, then it is clear that after it has been removed certain of the rays of light necessary to form the rose-coloured spectral image will be wanting. Since the light which in this case enters the eye is yellow, it stimulates chiefly the green and red nerves; and since the former have been fatiged by staring at the green paper, the effect of the latter predominates, and so we see an orange-coloured ghost where the green paper lay. For a similar reason, if red paper be used instead of the green, the spectral image is a greener yellow than the ground. Applying these explanations to the fact that red paper on a violet ground produces a blue ghost, I draw the natural inference that violet contains red light, the blue spectral image being due to the temporary withdrawal of the red constituent of the violet owing to the fatigued state of the red nerves. Mr. Hardie's explanation clearly cannot be right, for chiefly violet light enters the eye, and this would be incapable of producing a green spectral image (green-blue he should have said) to combine with the violet in forming blue. To believe that the feeble spectral yellow resulting from exposure of the eye to pure blue light could so modify violet as to cause it to appear more red, requires an undue stretch of imagination. According to the theory which Mr. Hardie is advocating, its green and red constituents should mostly combine with the violet to form white.

Mr. Hardie only objects to my explanation of the fact that violet and green make a pale blue on the ground that it assumes the existence of blue and red in violet. I may, with equal reason, object to his explanation that blue and red make violet, because it assumes the existence of green and violet in blue, the proofs of which are far from convincing.

I will now endeavour to make clearer the objection which Mr. Hardie found incomprehensible, but may remark in passing that since, on his own confession, he failed to understand it, it was at least premature to pronounce it irrelevant. The difficulty briefly stated is this: to account for the fact that blue, a colour by hypothesis containing green, still remains blue when much more green is mixed with it; in other words, to explain why blue and green mixed in certain proportions (nearly equal) produce a beautiful light blue in which no trace of green can be detected by the unaided eye. If we mix red and green we obtain yellow, and if we mix red and yellow we get orange, because we are then mixing two parts of red to one of green. Therefore, analogy would lead us to expect a very green blue to result from a mixture of blue with only a moderate amount of green. When we further reflect that the blue thus produced is equally pure and brilliant in appearance, if not superior (which I think it is) to the blue obtained by mixing green and violet, the fact is calculated to shake one's faith in the hypothesis that blue is a secondary colour containing green.

I certainly do not insist that white light must contain equal proportions of the primary colours; but failing positive information on the point, it seems a safer assumption than the contrary. Therefore, I think that a theory which is apparently consistent with such a supposition is more probable than one which compels us, as I have pointed out, to assume inequality of proportions in order to reconcile it with facts relating to the complementary colours. Until it is agreed which are the primary colours the question cannot be settled; and in any case must be very difficult to decide. However, it is not quite so obvious as Mr. Hardie seems to think that "white light contains a far larger amount of green than of the other constituents, as anyone who looks at the spectrum may see at a glance." Obviously, green occupies a larger space than red; but Mr. Hardie takes no account of the relative intensities of the colours. I have by me two diagrams by Clerk-Maxwell which represent by curved lines the relative intensities of his three primary colours, red, green, and blue, in different parts of the spectrum. The diagrams were obtained from observations on two different persons, the intensities differing slightly for different eyes. In one the maximum intensity of the red is shown to be one-third greater than that of the green, and in the other one half greater. Therefore, it is clear that if the proportions of red and green in the spectrum were equal, the red would occupy considerably less space. Moreover, according to Maxwell's theory, there is red at the violet end of the spectrum, which must be taken into account if we accept that theory.

Mr. Hardie treats with scorn the last objection I advanced, which was virtually an appeal to our sense of colour; but his criticism is hardly fair. On the contrary, to class together as of the same kind the popular beliefs that violet contains blue and red, and that green is composed of blue and yellow, is manifestly unfair. The former is based on the evidence of our colour sense, the latter solely upon the fact that blue and yellow pigments make green. The most ardent supporter of the latter would not seriously maintain that he can perceive both blue and yellow in green. But if it be admitted that the unaided sense can discern the presence of both yellow and red in orange, or of blue and green in certain mixtures of those two colours, then it must also be admitted that the evidence of the same sense is not wholly devoid of weight when it pronounces violet to be merely a reddish blue.

Before closing this letter, I must state that I have observed a green ghost on a blue ground after gazing at violet, which I accept as conclusive evidence that the blue paper which I used reflects green rays, but not necessarily as evidence against blue being a primary colour. This particular blue I examined with a spectroscope, and found it to reflect an abundance of green. My belief that this is the cause of the green ghost above mentioned is confirmed by the fact that I failed to obtain a violet ghost after gazing at green unless I used a pale blue; on a medium blue the ghost appeared merely as a darker blue. The violet ghost on pale blue may be due to the presence of white light, from which a rose-coloured spectral image would be formed after staring at green. However, since pigment colours are never pure, experiments of this kind made upon them are not conclusive, and it is to the colours of the spectrum themselves we must appeal for more positive evidence. I detailed at length in my first letter how the violet of the spectrum could be made to assume a bluer or redder tint by exposing one eye to red or blue light; but numerous attempts to modify the appearance of blue either towards green or violet have failed. No length of exposure of the eye to violet light (I used a combination of green and violet-blue glass, which, it so happens, cuts off all colours of the spectrum except violet) sufficed to produce the slightest appearance of green in the blue of the spectrum; nor was exposure to green light any more successful in developing a violet tint. I leave these facts without further comment to the consideration of your readers, hoping they will try the experiments for themselves.

F. W. Reynolds, B.A.

RAILWAY SIGNALS.

[26253.]—BEING very much interested in the correspondence on signalling in your valuable paper, I venture to offer a few remarks which I think will be of service to your readers and the public as coming from a driver of thirty years' standing, who is well known to you, but who is in the position of one of Mr. G. L. Watkinson's (p. 555) "up jumps" for the first time on this question. Who he is I do not know, nor do I care very much; the logic he lays down is not very much. I say that were I to sign my name, my situation would not be worth this paper that I am writing on. Now, as to Mr. Watkinson's remarks, it is very well known among railway servants that Mr. Stretton's name is a great bugbear to railway officials, and whatever he says is poo-poohed by them if they possibly can do it; some of them have coossed swords with Mr. Stretton on railway matters, but they have always come off second best, and it would be the very essence of ingratitude on the part of railwaymen were they not to defend their disinterested champion when they know that he is in the right. Such champions as Mr. Stretton is on behalf of all classes of railway servants are very scarce. Mr. Watkinson says that signals are not fixed at random. I say that they are not fixed by thorough practical men on all lines, and the London and North-Western is one of them, or why should new signals have to be so repeatedly altered after they have been fixed? No one acquainted with signalling will say that the London and North-Western does not pay any attention to the signalling of its own line, but it is the way it is done, and the men they employ to do it, who do not know their business and won't be told, or who will not do it properly—I do not know which; but the fact is, they do not do it properly. There are a number of cases on this line, as I believe there are on others, where what is a signal at one place for one line, on a similar post is a signal at other places for another line. A fortnight ago a Leeds driver was discharged for mistaking one for the other at Huddersfield, and he had not twenty yards' sight at the time of the signal. A collision occurred through the mistake, the man was not allowed to be heard, although his regular work was over a district where the signals are for the other line at other places. There are scores of places where signals are fixed where there is not fifty yards' sight of them. Are they fixed up by practical men? Where the line is as level as a billiard table and as straight as a pikestaff, distant, home, and starting signals are fixed on the right-hand side of the line. What does Mr. Watkinson think of such practical work as that? Mr. Watkinson's remarks about drivers asking for signals to be shifted to the right side of the line may be quite true; but in such cases as these there ought to be a repeating signal placed on the other side of the line (or "proper" side, *vide* Mr. Stretton), so that a driver would have a more extended view, and when he came to the repeater he could make no mistake. There is not a driver on any line in the world who would object to that, because it would meet Mr. Stretton's and all drivers' ideas of proper signalling, to suit all weathers, and foggy weather most of all. That is why Mr. Stretton and drivers wish all signals to be placed on the left-hand side of the line. There are repeaters fixed on some parts of the line now where there are bad places. What is good for one place surely ought to be good for other places. Mr. Watkinson says that when drivers make a complaint that signals are not in a proper position to be seen it is inquired into and remedied if possible. I flatly deny this statement, and say it is not so in all cases, and should any one driver report a few cases a way will soon be found to make him understand that he is making himself too officious. Nothing short of some practical drivers being appointed by Government as signal inspectors will ever make signalling safe and easily understood by all in the service;—that such wanted there cannot be any doubt, more especially is now than ever; what with the speed they have to run, and the weight of the trains, and the engine they have to do it with, it has become a very harassing life; they are buffeted about from pillar to post by everybody, both men and boys, who do not know their duty, but whom they have to obey, right or wrong; and should anything go wrong the drivers are told that they ought to have known better.

A Lancashire Driver.

HIGH-PRESSURE v. COMPOUND-CONDENSING ENGINES.

[26254.]—I APOLOGISE to "Engineering, Manchester," if I have fallen into error; but I construed the meaning of the letter to infer that the engines with the 7in. cylinder were converted into surface-condensing engines, although such is not directly mentioned in his letter (26042, July 30th). I will not dispute the fact that the simple high-pressure engine will always find favour in small launches, where the question of cost is the first consideration and it is a secondary consideration the cost of coal. I quite agree with G. D. Seaton on that question, but I was led by the wording of "Engineering's" letter to think that in using the term yacht he was referring to sea-going vessels. Now in respect to compound non-condensing engines, I do not see how such great economy can be claimed for them, because we have the back-pressure, radiation, and extra friction to contend with without the benefit of a vacuum, which would give at least 14lb. on the square inch more pressure on the large cylinder. This is the text of "Tube Plate's" communication in the Query column of Sept. 3rd, No. 60310.

Now, it is a well-known fact that where steam is used expansively great economy is the result, and I can only reason the matter thus. When the steam is cut off early, say at $\frac{1}{4}$ stroke, the crank is approaching its most favourable position for receiving the full sweep of the pressure, and when at $\frac{1}{2}$ stroke the maximum position, at which the crank develops the greatest effect, is reached. To apply the full pressure after reaching this point can only result in loss. When using steam in stationary

engines working expansively a flywheel is used, which is inadmissible in a yacht. No benefit can result from expanding in two cylinders placed tandem fashion, because the expansion could be carried out equally as well in one cylinder; but in the case of applying the power to another crank placed at right angles to the high-pressure cylinder crank the case is different, because the pressure is applied on a crank in a more favourable position to receive the power, thus giving greater regularity of motion, and this is even more marked in using three cylinders.

Pressure of business compels me to defer writing more on this subject at present, but in the course of a week or so I hope to place my ideas on this subject more clearly before the readers of this paper.

London, Sept. 6th. **Ingeniero.**

NOTES ON THE CHAMBER ORGAN.

[26255.]—I HAVE very great pleasure in submitting to Mr. Audsley the information he asked for with regard to the dimensions of the organ I gave a specification of, as also of the room in which it is erected:—

Room.—Length, 39ft.; width, 14ft. 6in.; height, 11ft. 6in. Organ.—Depth, 10ft.; width, 14ft. 6in.; height, 11ft. 6in. Each manual has a separate reservoir supplied with wind by a large main bellows placed in a kitchen below, and worked by a hydraulic motor. The console stands a few feet in front of the instrument.

I now append the specification of another chamber organ constructed by Mr. Gern on a new principle, as shown by him at the Inventions Exhibition, and for which he obtained a medal. The great advantage of this system is that any stop can be transferred from one manual to all of the others, and made to sound separately on either manual or on all at the same time; thus a choir or solo organ may be obtained without the use of any additional pipes.

GREAT ORGAN CC TO C. 61 NOTES.

(Inclosed in a Swell Box.)

1. Lieblich Bourdon ...	16ft. tone	61	pipes
2. Open diapason	8	61	"
3. Dulciana	8	61	"
4. Stopped diapason ...	8ft. tone	61	"
5. Harmonic flute	4	61	"
6. Principal	4	61	"
7. Flautina	2	61	"
8. Clarionet (Ten. C)	8	49	"

Three combination pistons to great, acting on pedal stops as well.

SWELL ORGAN. CC TO C. 61 NOTES.

1. Open Diapason	8ft.	61	pipes.
2. Hohl Flute	8	61	"
3. Viole de Gambe	8	61	"
4. Voix Celestes (Ten. C).	8	49	"
5. Flanto traverso	4	61	"
6. Gemshorn	4	61	"
7. Oboe	8	61	"

Three combination pistons to Swell Organ.

CHOIR ORGAN CC TO C. 61 NOTES.

Borrowed from the Great, but acting independently as separate ranks of pipes.

1. Dulciana.
2. Stopped Diapason.
3. Harmonic Flute.
4. Clarionet.

Two combination pistons to Choir Organ.

PEDAL ORGAN. CCC TO F. 30 NOTES.

1. Bourdon .... 16ft. tone 30 pipes.
2. Sub-bass, composed of Quint 10⅔ft., borrowed from Bourdon, with the extra 8 pipes in the upper part, which, when drawn, speaks with the Bourdon, thus forming an acoustic Sub-bass of 32ft. tone.
3. Violoncello .... 8ft. 30 pipes.

COUPLERS.

1. Swell to Great.
2. Swell Octave.
3. Great to Pedals.
4. Swell to Pedals.
5. Tremulant.

A self-recovering pedal to take "Great to Pedals" in and out. A self-recovering pedal to take Tremulant in and out.

It will be seen from the above specification that the builder has studied his work well, for while he has only a limited space to contain the organ, he has so arranged it that it is full of variety and pleasing combinations.

The whole is inclosed in a handsome oak case, beautifully carved in Gothic design, with burnished tin front pipes. **Organist.**

EXTEMPORISING A STRAIGHT-EDGE.

[26256.]—IT is often necessary in the workshop, or when engaged at a distance from the tool-room, to extemporise a straight-edge, and the following method, though doubtless well known to many of your readers, may still be news to many others. A straight edge, then, may be extemporised by jointing one edge of a board, then marking in centre of board a line parallel with the jointed edge. Get out a strip of board and nail or screw to the straight edge in such a manner that the upper edge of the strip coincides with the mark before mentioned. The level may be placed upon this nailed-on strip, and the levelling job finished long before a straight-edge could have been finished. In fact, quite a long distance may be accurately levelled with any board or plank that may chance to come to hand, no matter whether it be straight, crooked, or taper. The only points are to place the level on top of the board in exactly the same place every time the level board is used, and the board must also be turned "end for end" also, and the last levelling must be made with the board turned in an opposite direction from what it was when the first length was levelled. **E. A. M.**

HAS ENGLAND GONE UP-HILL OR DOWN DURING THE LAST FIFTY YEARS?

[26257.]—THE population of England, Ireland, Scotland, and Wales was, in 1831, 24 millions; 1871, 31½ millions; 1881, 35¾ millions. The poor's-rates in England and Wales in 1832, £9,683,420; in 1869, £9,100,244; in 1884, £8,432,409. The paupers in 1869, 995,346; in 1884, 779,038. The number of convictions in England and Wales in 1837, 17,000; 1858, 13,236; 1883, 11,347; 1884, 11,134; ditto in Ireland, 1838, 11,036; 1858, 3,350; 1874, 2,567; 1883, 1,740; 1884, 1,546. The pig-iron produced in 1850, 2¼ million tons; in 1870, 6 million tons. The clearing-house passed in 1869 £3,626,000,000; in 1883, £5,929,000,000. Coal raised in 1850, £40,000,000; in 1871, £115,000,000. Cotton and other fabrics enormously increased. The whole country has been covered with railways and telegraphs. London and all large towns have very superior hotels and public institutions. Buildings of every description are better lighted—gas *versus* candles. Places of amusement more than ever supported. Ten times more people have pianofortes, watches, and jewellery. Such tradesmen as used to live over their shops now have suburban residences. Four times more people take long summer holidays. More employment for females. All classes have better houses, better clothing, better food, and more ornamental articles. All classes are better educated, better paid for labour, and work shorter hours. Nearly all provisions are much cheaper. Domestic servants are very scarce, at double the former wages. Shipping has increased more than in any other country. Manufactories all over the country increased enormously. Books, newspapers, postage, and travelling are much cheaper. Tenfold more subscriptions to churches and charities of all kinds, the deposits in the savings and all other banks very much increased. One penny Income tax produces nearly double what it did at first. The imports in 1839, £61,250,000; in 1883, £426,750,000. The exports in 1839, £105 millions; in 1883, £305,000,000. It is easier now to raise four million pounds for public works than one million in 1840. Consols and all other Government securities are much higher, showing a bountiful supply of capital—in fact, millionaires, which were very scarce articles, are now almost as plentiful as blackberries. **B. R.**

A WAVE OF HEAT.

[26258.]—THE following is an abstract from a letter recently received from Manitoba, Canada:—One Sunday night, early in July last, a hot atmospheric wave swept over the town of Portage la Prairie. The sudden increase of temperature was so great that the inhabitants left their beds and rushed into the street, expecting to find that the town was on fire. During the hot blast, thermometers in some of the houses indicated the temperature of 95° Fahr. The summer has been unusually dry, and the farmers were loudly complaining of want of rain. The letter does not contain information as to the direction from whence the hot wind came, or the length of its duration. I have reasons for believing that the phenomenon occurred on Sunday night, the 4th of July last; probably an account of it may have appeared in some of the Canadian newspapers at the time.

Greenheys, Manchester. **J. B. Dancer.**

MIXED TRAINS.—ENGINE COUPLINGS.

[26259.]—"ANTI-VAC" (26237) gives a curious reason for placing the passengers at the end of the train. But suppose another train ran into the mixed train, or the passenger carriages became disconnected, and then run into. How about the passengers then? Or some of the ancient rolling stock between the passenger coaches and the engine comes to grief? This latter is, I think, the usual cause of accidents to mixed trains.

The couplings, wheels, and axles of goods waggons do not seem to be so carefully looked after as those on the passenger carriages. Perhaps Mr. Stretton or others could give a few of the chief causes of accidents to mixed trains?

I believe that nearly all the railway companies attach the engine to the train with the screw coupling only. If I am wrong, perhaps someone will kindly correct me. This manner of attaching the engine with only one coupling seems to me to be a source of danger. Suppose the engine breaks away and nothing more serious happens—are spare couplings carried? And how is the train to be taken to its destination.

Wm. Rowland Hart.

THE "ADVANTAGES" OF STEAM DOMES AND DRUMS.

[26260.]—IF some of your readers, whose existence seems to be passed in timing trains and in making lists of locomotives with their stations, would but condescend to think over matters connected with the construction and working of those engines, they could, no doubt, enlighten the world, which, after all, is not much interested in the speeds of rival trains or in the performances of rival brakes. As a contribution to the subject of domes and drums, I send the following with the hope that some of your contributors will kindly criticise and let in a little light from their experience. Mr. Stirling on the Great Northern dispenses with domes, but the majority of locomotive superintendents seem to prefer them. Still, the storage capacity for steam which a dome adds to a steam boiler, sometimes adduced as an argument in favour of their use, is insignificant, and can be obtained many times cheaper by making the boiler shell slightly larger. For example, take a 48in. boiler with tubes 15ft. long, and provided with a dome 27in. in diameter and 27in. high. The dome would have a storage capacity of about 9 cubic feet, while the shell would have, with the water at its usual height, a steam-room of 52 cubic feet; 52 + 9 = 61, and retaining the same number and arrangement of tubes we can get the extra 9 cubic feet of steam-room by simply making the boiler shell 2in. larger in diameter. The cost of this extra two inches added to the shell of the boiler would be much less than that of adding a dome to the smaller boiler, while the extra surface presented to the air for the radiation of heat and consequent condensation of steam would be very much less. Steam-drums are a nuisance, pure and simple, in ninety-nine cases in a hundred where they are used. Why steam should be generated, conducted outside of the boilers, and stored up in a drum whose only possible function is to furnish cooling surface for the condensation of the steam, passes comprehension. Steam, the instant it passes out of the boiler, away from the influence of the furnace heat, begins to part with its heat; no matter how well the surfaces of the containing pipes or drums may be protected, there will always be some loss, which is continuous and irrevocable. This radiation of heat means condensation of steam, therefore it is evident that the steam should be retained in the boiler so far as it can be done until it is ready to be used. Do away as far as possible with storage domes and drums, and make the body of water in the boiler the reservoir of heat. The steam supply will be much steadier, and its quality will be better in this case than it will be if the conversion into steam has taken place and an attempt has been made to bottle it up outside of the boiler. These are points worthy of debate; but while writing I should like to ask "Kappa" (p. 41) what there is wonderful in a light engine running a mile in 40sec. that he should think there are beings conversant with railway work who would doubt it. It is quite possible for an engine to run at the rate of 100 miles an hour, but can any of your readers supply authentic records of a train having been taken 60 miles in one hour?

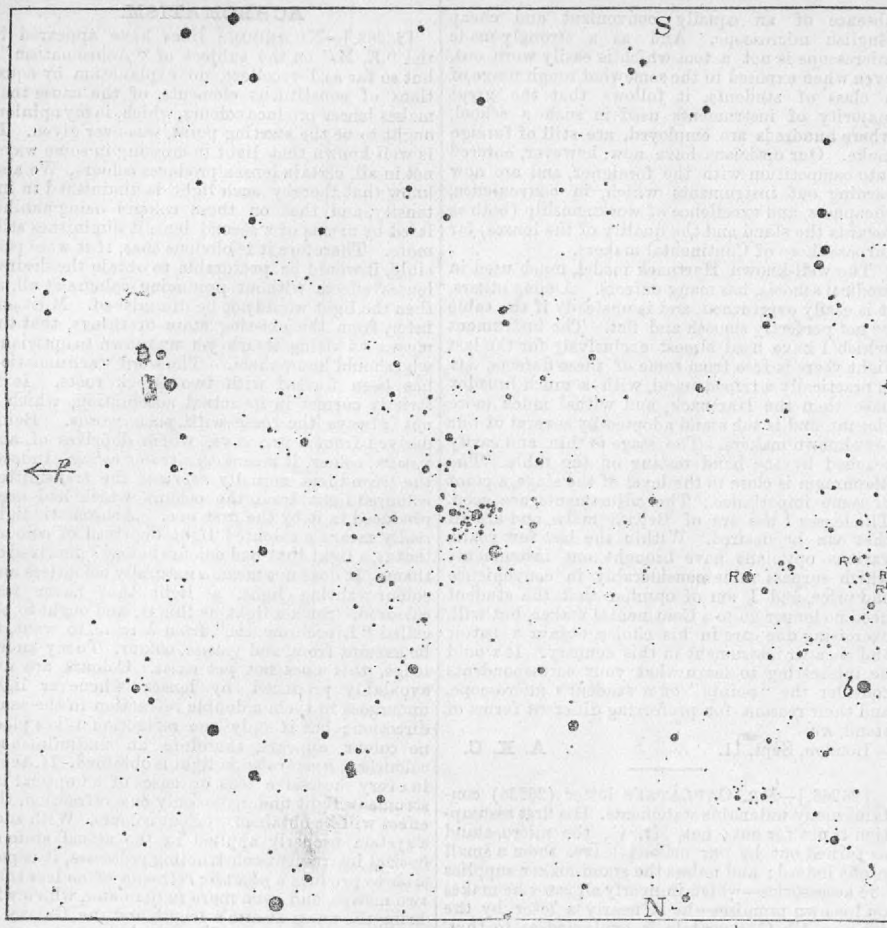
J. T. M.

CLEFTS WANTED.

[26261.]—FOR some time past I have been looking in vain for clefts where, it seems to me, we should find them so far not recorded; but my telescope is too small (3·5 o.g.) to show such delicate detail, and I appeal to the fortunate possessors of larger instruments to help me if they will.

The belief seems to be very general that clefts are really huge cracks or "crevasses" in the lunar surface, and that they are not the beds of old rivers, as at one time suggested. The way in which they hold their courses along plains, inclines, and right through mountain ranges, shows clearly enough that they are not due to erosion.

A study of their arrangement in relation to surrounding features seems to indicate that they are



CLUSTERS IN PERSEUS.

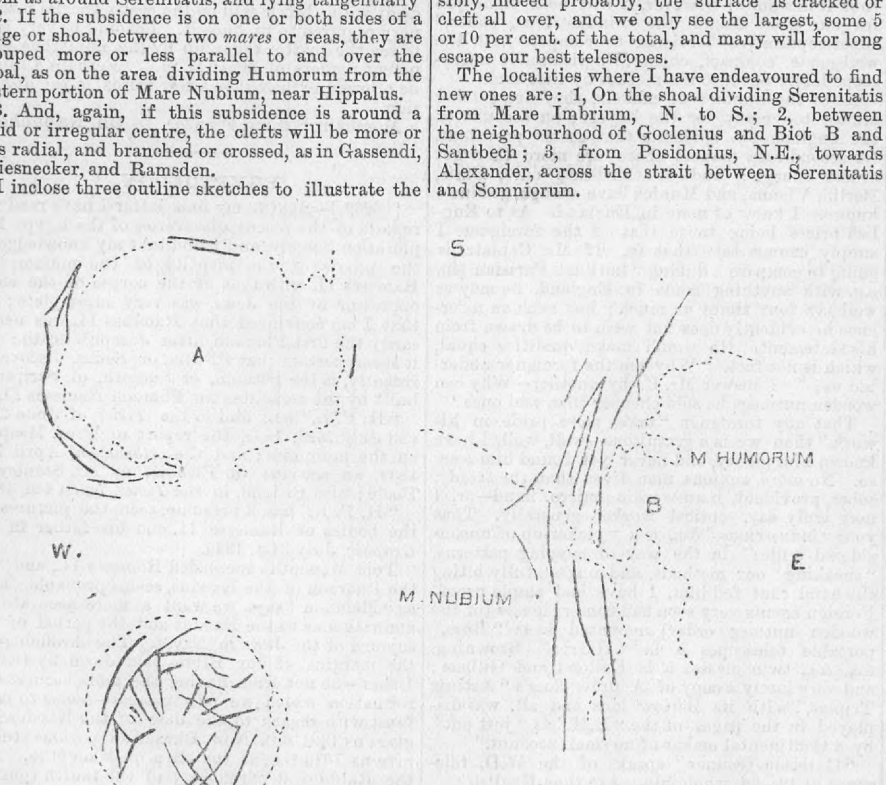
due to subsidence of an adjoining area, and that they can be, as it were, classified thus:—

1. If the area of subsidence is large, and surrounded by a presumably rigid margin, we see them as around Serenitatis, and lying tangentially

2. If the subsidence is on one or both sides of a ridge or shoal, between two *mares* or seas, they are grouped more or less parallel to and over the shoal, as on the area dividing Humorum from the eastern portion of Mare Nubium, near Hippalus.

3. And, again, if this subsidence is around a rigid or irregular centre, the clefts will be more or less radial, and branched or crossed, as in Gassendi, Triesnecker, and Ramsden.

I inclose three outline sketches to illustrate the



above: A of the tangential arrangement, as around Serenitatis; B of the parallel or linear, as over a shoal dividing two seas; C of the radial or crossed, as seen inside Gassendi.

At first sight it may seem that the great series of clefts, extending from Hyginus past Sabine to Magelhaens does not fall into the above groupings; but if all are plotted in red ink on the map in "Webb's Celestial Objects," their relation is at once seen as bordering a *series of mares*, i.e., Fecunditatis, Tranquilitatis, and Vaporum. Possibly, indeed probably, the surface is cracked or cleft all over, and we only see the largest, some 5 or 10 per cent. of the total, and many will for long escape our best telescopes.

The localities where I have endeavoured to find new ones are: 1, On the shoal dividing Serenitatis from Mare Imbrium, N. to S.; 2, between the neighbourhood of Goclenius and Biot B and Santbech; 3, from Posidonius, N.E., towards Alexander, across the strait between Serenitatis and Somniorum.

Where there is any decided and extensive fall in the surface we may look for clefts transversely, as on the S.W. boundary of Nectaris, from southern extremity of the Pyrenees to the west horn of Fracastorius, parallel to the Bohnenberger cleft. Or, again, where there seems to be a possibility of prolongation of a shoal, as from Agatharchides to the Riparian highlands, or under sea cliffs, as th eastern border of Crisium.

If the above relating to A B is correct, we find that lunar seas and terrestrial have one feature in common, i.e., permanent and slow subsidence of the floors—a singular feature, when we consider that they have absolutely less weight on them than land surfaces at similar depths.

If the *mares*—at one time seas of water—subsequently dried up and became semi-solid mud (see Neison's "Moon," p.50, lines 4 and 5), we should surely expect to find the parts solidified last, in the centre, full of clefts?

Instead of this, they are at such places conspicuously absent. There can hardly be a doubt that the *mares* solidified first around the edges, by zones; not only are the margins marked out by wide belts of a different and darker tint, but they are at a higher level, and often bordered by long, low ridges.

The central portion of Imbrium is well marked out by great ridges, and is closely spotted with small craterlets. Why these so-called *volcanoes* (?) should be specially grouped over the portion that was *last liquid* I leave advocates of igneous surfacing to explain. It seems the same kind of anomaly as that presented by volcanic cones in the centres of large walled plains allied to marine formations. Indeed, the crowding of small "craterlets," especially over that portion of the *mare* that was last liquid seems to me an argument of some weight as against their *volcanic* origin, and a really good one in favour of "surfacing by glaciation," where craterlets are simply rings of snow—i.e., condensed aqueous vapour—piled around small orifices in the ice crust at temperature of, say, minus 60° or 80° C., at which ice does not vaporise, even in vacuo. **S. E. Peal.**

Sibsagar, Asam, Aug. 4.

CLUSTERS IN PERSEUS.

[26262.]—DRAWINGS of star clusters in popular works on astronomy are, as a rule, not very satisfactory from a scientific point of view. Many of them are taken from Smyth, whose renderings of such objects are unsurpassed as purely imaginative sketches, but which leave something to be desired as representations of the actual objects as seen in the heavens. Take, for instance, the clusters in the sword hand of Perseus, "affording together," Smyth observes, "one of the most brilliant telescopic objects in the heavens." His drawing of the preceding of the two clusters, Ḩ vi. 33 = h 207 = G.C. 512, is, perhaps, less unlike the actual star-group than his sketch of M 11 Antinoi is, for example; but it is, nevertheless, wrongly orientated, and conveys but a very faint idea of the actual

appearance of the cluster as viewed with a telescope of moderate power. Most of the figures of this cluster in popular works are copied from Smyth's on page 58 of the second volume of the "Celestial Cycle," while professedly original ones—*e.g.*, the one in Nichol's "Architecture of the Heavens," last edition—are equally unlike the real object.

Nearly all the stars on the annexed diagram are traced from a photograph by MM. Henry, taken with a 6·3in. photographic telescope on October 10th, 1884. The exposure was fifty minutes, and over 500 stars down to the 13th magnitude are shown on the original negative. I have not traced all the photograph, and have omitted some of the faintest stars, as the visual and photographic magnitudes differed considerably in some cases. I have given the magnitudes for 43 of the chief stars of the preceding cluster assigned by Krueger in his measures with the Bonn heliometer ("Der Sternhaufen *h* Persei," Fennicæ Soc. Sci. Acta., Vol. VIII.), and for the magnitudes of the stars in the following cluster, which is Ḫ. vi. 34 = *h* 212 = G.C. 521, I have followed Vogel ("Der Sternhaufen χ Persei") while I have given the *Durchmusterung* magnitudes for the bright stars outside the clusters. Vogel shows 176 stars seen in Ḫ. vi. 34 with the 8½in. refractor at Leipzig. The stars marked A and B are P. II., 21, 22; OΣΣ 25. The magnitudes of this pair, according to Dembowski, are 6·1, 7·1., the angle being 204·2°, and the distance 102·91″. The pair has two small *comites* between the bright stars which have not been previously noted. Krueger gives the magnitude of A as 6.6 and B 7.1, both being white, according to De.; in the *Durchmusterung* A is 6·6 and B 7·0. The star marked *b* in the cluster G.C. 521 is 6·6 mag. according to Vogel, 6·7 Argelander, δ being 8·5 mag. Vogel, and 8·9 Argelander; the distance between them being 203·7″, and the angle 58·5°. The star lettered *c* is 7·7 mag. Vogel, 7·5 Argelander, and *x* is 8·0 mag. Vogel, 8·5 Argelander, its photographic magnitude being about 10.0. The position angle of these two stars is 138·3°, and the distance 218·0″, while ζ 9·2 mag. is 347·2″ from *c* in 105·7°. Anyone desirous of observing the cluster can construct a rough scale from these measures. The stars lettered R are those called red or orange by Vogel and at the Dunsink Observatory.

Sept. 9. **H. Sadler.**

FOREIGN MICRO-OBJECTIVES.

[26263.]—I AM not going to enter upon any controversy with "Prismatique"; but his condemnation of all except English optical work is too strong. I have used both English and foreign for many years, and can say, without hesitation, that Seibert's and Zeiss's lenses are equalled by few English, and if they are surpassed by any, I have yet to see them, while they cost less than half equal quality English. The brasswork is not of the stuff he describes. Indeed, he must be as innocent of knowledge on these points as he is loud in denunciation, and as he has often proved himself on other matters. I say nothing of the taste which allows such remarks under a *nom de plume* from an interested party. I shall not say a word more on this matter. **E. Holmes.**

ENGLISH VERSUS FOREIGN MICROSCOPES.—TO "PRISMATIQUE."

[26264.]—WHILE agreeing with many things adduced by our friend, I cannot endorse all he has written, for I *know* that objectives as good as English ones are made by Continental and American makers. I must, however, point out that I am not, as "Prismatique" seems to think, "interested in pushing foreign stuff." The only thing that interests me is the advancement of *truth*. As to the claptrap which passes current under the name of *patriotism*, if "Prismatique" wishes to have my opinion on it, I must beg him to peruse an article by my brother, which he will find at p. 19, of No. 3, Vol. XII. of the *Republican* for June, 1886, and which embodies *my* notions. **S. Bottone.**

ENGLISH v. FOREIGN MICROSCOPES.

[26265.]—AS one who has worked in one of the largest science schools in Britain, I have been much interested in the correspondence on the relative merits of English and foreign microscopes. Some ten or twelve years ago it was a matter of some difficulty to procure a really suitable "student's" microscope for histological work. Opticians were slow to discard the tall, imposing-looking stand, with its mechanical stage and other costly complications, and consequently the English-made instrument, though of undoubted excellence in workmanship, was placed beyond the reach of the average student, who was obliged to fall back upon the cheaper and smaller instruments of Continental make, which, after all, he found much more suited to the nature of his work. His teacher also, who had probably "gone to Germany" to complete his histological studies, introduced the Continental model into the laboratories, in the absence of an equally convenient and cheap English microscope. And as a strongly-made microscope is not a tool which is easily worn out, even when exposed to the somewhat rough usage of a class of students, it follows that the great majority of instruments used in such a school, where hundreds are employed, are still of foreign make. Our opticians have now, however, entered into competition with the foreigner, and are now turning out instruments which, in convenience, cheapness, and excellence of workmanship (both as regards the stand and the quality of the lenses) far surpass those of Continental makers.

The well-known Hartnack model, much used in medical schools, has many defects. Among others, it is easily overturned, and is unsteady if the table be not perfectly smooth and flat. The instrument which I have used almost exclusively for the last eight years is free from some of these defects. It is practically a tripod stand, with a much broader base than the Hartnack, and withal much more elegant, and is the stand adopted by several of our best-known makers. The stage is thin, and easily reached by the hand resting on the table. The diaphragm is close to the level of the stage, a point of some importance. The adjustments are good. The lenses I use are of British make, and are all that can be desired. Within the last few years, various opticians have brought out instruments which surpass mine considerably in convenience and price, and I am of opinion that the student need no longer go to a Continental maker, but will, exercising due care in his choice, obtain a better and cheaper instrument in this country. It would be interesting to learn what your correspondents consider the "points" of a student's microscope, and their reasons for preferring different forms of stand, &c.

London, Sept. 11. **A. K. C.**

[26266.]—MR. CAPLATZI'S letter (26234) contains many untenable statements. His first assumption is not far out; but, Mr. C., the micro.-stand as turned out by our makers leaves them a small profit indeed; and unless the stand-maker supplies the accessories—which in nearly all cases he makes on his own premises—he is nearly a loser by the job; so, Mr. C., your tale is explained as to that. "Could they (the English makers) supply one-fourth the demand?" Yes, one of our works, now in my mind, once busily engaged in micro. work, full of bustle, and turning out A1 work too, has almost lain idle for some years, and is capable of supplying ten times the number of microscopes that it has done; however, it will be a tight job for our good friend the "industrious, sober," super-superlative foreigner to compete with the well-made, compact, cheap, English-made microscope lately put into the market by that firm.

As to the number of makers, they are getting almost too many for the buyers; on account of the Anglophobia epidemic that seems prevalent. Of second-rate makers there are more than get orders enough; and of third-rate ones, Paris, Berlin, Vienna, and Munich have enough, goodness knows. I know of none in England. As to English prices being twice that of the foreigner, I simply cannot take that in. If Mr. Caplatzi is going to compare a duffing "button" Parisian ¼in. o.g. with anything made in England, he may as well say four times as much; but such an inference he evidently does not wish to be drawn from his statement. He would make qualities equal, which is not fact. "Why can the foreigner underbid us?" I answer Mr. C. by another—Why can wooden nutmegs be sold cheaper than real ones?

That any foreigner "takes *more* pride in his work" than we is a gratuitous—well, well, I have known him plenty, and never yet found him *more* so. No more anxious man lives than the steady, sober, provident, hard-working micro. hand—or, I may truly say, optical worker generally. That your "industrious," &c., is a "picker-up of unconsidered trifles" in the way of copying patterns, "sneaking" our methods, and ungratefully biting the hand that fed him, I have had ample proof. Foreign agents very soon had camera lenses (of the wooden nutmeg order) mounted à la "Ross," portable telescopes à la "Harris," Browning, &c., &c., twin glasses à la Dollond and Gilbert; and very lately a copy of Andrew Ross's "Actinic Triplet," with its Barlow lens and all, was displayed in the pages of the "E.M." as "just out" by a Continental maker of no small account.

"Garrison Gunner" speaks of the W.D. telescope at 19s. 6d. wholesale. Are they English?

Prismatique.

ATTRACTION.

[26267.]—WOULD you allow me two, or three lines to request any of your competent authorities if they can to furnish me with any demonstrable evidence that there is such a principle as attraction of any kind in all nature—solar, lunar, polar, or central? I would gladly pay for any information on the subject.

Balham, Surrey. **John Hampden.**

ACHROMATISM.

[26268.]—NUMEROUS lines have appeared in the "E. M." on the subject of "Achromatism"; but so far as I recollect, no explanation by equations of constituent elements, of the cause that makes lenses produce colours, which, in my opinion, ought to be the starting point, was ever given. It is well known that light in crossing in some ways, not in all, certain lenses, produces colours. We also know that thereby such light is diminished in intensity, and that on these colours being annihilated by means of a second lens, it diminishes still more. Therefore it is obvious that, if it were possible, it would be preferable to obtain the desired lenses' effects without producing colours at all, as then the light would not be diminished. Must one infer, from the existing state of things, that the means of doing it are yet unknown to opticians, who should know them. The word "achromatic" has been formed with two Greek roots. It is strictly correct in its actual acceptation, which is not always the case with such words. Being derived from a privative, which deprives of, and χρωμα, colour, it means *deprived of colour*. Indeed, the second lens actually *deprived* the transmitted coloured light from the colours which had been produced in it by the first one. Achromatic light really means a coloured light deprived of colour; that is, a light that had colours but was deprived of them. It does not mean a naturally colourless and colour-wanting light, a light that never was coloured. Such a light as this is, and ought to be, called "Lipochromatic," from λειπειν, to want, to be exempt from, and χρωμα, colour. To my knowledge, this does not yet exist. Colours are unavoidably produced by lenses whenever light undergoes in them a double refraction in the same direction; but if only one refraction takes place no colour appears, therefore an undiminished, colourless, *lipochromatic* light is obtained. If, then, in every successive lens or lenses of an optical instrument light undergoes only one refraction, the effect will be obtained without colours. With such a system properly applied in the actual state of optical instrument constructing processes, it is possible to produce a *gigantic refractor* of no less than two mètres, and even more in diameter, which will bring the moon at arm's length and the Galaxy in a neighbour's garden. Most likely such an instrument, which I have now been suggesting for more than fifteen years, will not be constructed in my country. I feel impressed that English, or rather American, opticians will realise it. The main difficulty is not the cost price of the instrument when made nowadays. Such matters are easily dealt with; but it will be the costly special machinery required to produce it. I should be very glad to see the matter taken up by the numerous competent readers of the "E. M." Perhaps I might be allowed to introduce a few words in the discussion.

Morchain, Somme, France. **Ch. Rabache.**

EGYPTOLOGY.

[26269.]—SINCE my first letter I have read the reports of the recent discoveries of the Egypt Exploration Society, and I find that my knowledge of the proofs of the identity of the mummy of Rameses II. with that of the corpse of the chief oppressor of the Jews, was very incomplete; not that I am convinced that Rameses II. was necessarily the first Pharaoh after Joseph's death; but it seems certain that Pi-tum, or Sekut, discovered recently, is the Pithom, or Succoth, of Scripture, built by the Israelites for Pharaoh Rameses II.

"H. F. L." will find in the *Times* of June 25th and July 23rd, 1885, the report of Prof. Maspero on the mummies; and the *Athenæum*, April 7th, 1883, an account of Pithom, by Mr. Stanley L. Poole; also Pithom, in the *Times*, April 4th, 1885.

"H. F. L." has, I presume, seen the pictures of the bodies of Rameses II. and his father in the *Graphic*, July 31st, 1886.

That Maneptha succeeded Rameses II., and was the Pharaoh of the Exodus, seems probable; and, as "Memnon" says, we want a more accurate examination as to the Exodus and the period of the sojourn of the Jews in Egypt. The chronology in the margins of our Bibles laid down by Bishop Usher—he not then having the more accurate information which we now possess—seems to be at fault with regard to the date of the Exodus; he gives us 1491 B.C. Now, Bunsen's laborious studies give us 1313 B.C. as the date of Maneptha. And the Rabbinical chronology of the fourth century, the result of learned comparison of the most ancient and trustworthy Hebrew texts then existing, curiously gives exactly the same date, 1313 B.C., as the date of the Exodus.

These are two authorities which we must respect, and in which we may have great confidence, and an examination of the tribes and generations, from Jacob's entry into Egypt down to the Exodus, results in further proof of the probable accuracy of this date—1313 B.C.—as that of the Exodus under Maneptha.

That Josephus is more correct with his 215 years

from Jacob's entry to the Exodus, than is the more generally accepted 430 years (exactly double) seems also to go along with the results of this study.

In Genesis xxxviii. 29, we have the birth of Pharez, the son of Judah, not long before the events leading to the arrival of Jacob in Egypt.

In Ruth iv. we have the generations from Pharez to Nahshon, four generations. In Numbers i. 7, we have the assertion that Nahshon was a prince of Judah just after the Exodus.

Is it probable that each of these four men handed down the stream of life from father to son, having each their first sons born to them at about the age of 107 years?—this would be necessitated by the supposition that 430 years elapsed during these four generations.

Is it not more probable that Josephus's 215 years, giving fifty-three years or so to each, is correct?

Further examination, allowing this lesser average to each generation, gives us for the six generations following Nahshon down to Solomon—a further 318 years. Solomon reigned 1,000 years B.C.; this is generally accepted as proved.

Adding this 318 from the Exodus to Solomon to the 1,000 B.C. of Solomon, we get 1318 B.C. as the date of the Exodus, not very far off the 1313 B.C. of Bunsen's calculation for Maneptha, and the same date of the Rabbinical chronology for the Exodus.

The request of "H. F. L." for me to give my impressions of the Pyramids, would lead me to cover too much space; but as I have seen, inside and out, the Great Pyramid, if "H. F. L." will kindly state what reported details he has seen reason to doubt, I will do my best to help him, from my own experience.

Gerard Smith, M.R.C.S.

Upper Clapton, E.

A PSYCHOLOGICAL PROBLEM.

[26270.]—"GARRISON GUNNER'S" very interesting letter (26230, p. 38), is merely an amplification of his former one. I would respectfully suggest to him that he has not met my particular arguments, which were offered from a metaphysical point of view.

Substantially, I am more in accord with him than would appear at first sight. What is rather incomprehensible to me is the way in which he seeks distinctively to separate the reason, the will, and the imagination. Will he kindly explain his use of the phrase "reasoning faculty"? I would have agreed with him had he simply said that the will is *potentially the ruling factor*.

The will seems to me to represent the only tangible element known to us. It is on account of this belief that I have insisted on the essential *unity* of the reason, the will, and the imagination. This position enables me to endorse in a large measure the ideas of "Garrison Gunner" in relation to religious truth.

He strangely asks—"Was any act of *true* heroism ever done to please the reason or the imagination?" The answer must be an affirmative one, if the will cannot come into operation without the alliance of the reason. "In "Garrison Gunner's" hypothetical case of the courageous soldier, the reason—more correctly, the judgment or comprehensive reason—has its proper share in determining the man's conduct. Not that the judgment is always right. It may err in company with the collective will. The whole issue, indeed, appears to me to rest on the question of ratio.

Two things are necessary for the true comprehension of the kaleidoscopic phenomena of dreaming.

There must be shown, in the first place, the precise external correlation existing between the reason, the will, and the imagination. Further, the origin of the function of sleep requires to be closely studied.

Surely very pregnant would be the answer to the question—What is sleep? **H. W.**

REMOVAL OF WARTS.

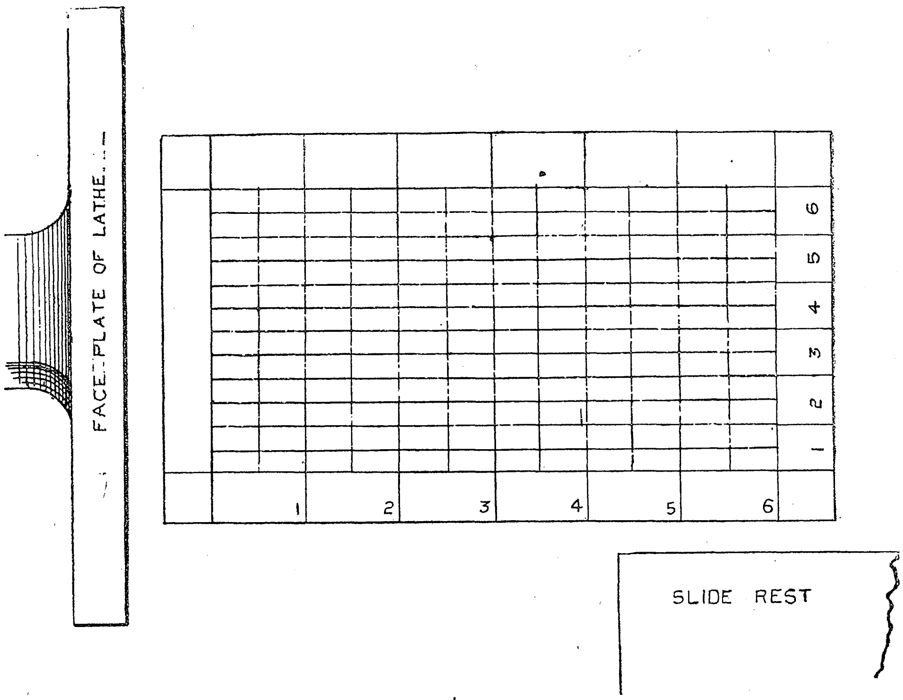
[26271.]—I RECENTLY observed in the "E.M." an article recommending the use of castor-oil for removing warts. A much simpler and more pleasant method is to rub the head of the wart frequently with a piece of common washing-soda, which should be carried in the pocket for that purpose. I have never had occasion to use it myself, but those to whom I recommended it have informed me that this treatment requires only to be continued for a week or ten days, as then the wart will have entirely disappeared.

James M'Cash Govan.

SETTING SLIDE-REST TAPER.

[26272.]—I HAVE seen several queries in "Ours" as to setting the slide-rest taper. I have invented a gauge which I am unable to patent, so I give it to the readers of the "E. M." The sketch is half-size. I have one myself which I use, and find it answers many purposes to my entire satisfaction. **W. Cooper.**

10, Harrow-street, London-road, Derby.



DRY-PLATE PHOTOGRAPHY.

[26273.]—THE appeal of "Punch," p. 580, is not in vain. I will do my best to give him his answers. I do not know how or in what form to apologise for my absence for a period from the pages of "Ours"; but it is simply through having too much, far too much, work to do—an increasing business, a seat in our Town Council, connection with some score of societies of all kinds—that I have been unable to spare a moment to write. But the visit of the British Association to Birmingham, and the shaking by the hand of so many, many readers of "Ours" who came to Birmingham, has made me snatch a few moments from rest, and I again will do my best towards helping the earnest mechanic in his endeavours to accomplish his desired work. Page 515 I cannot find. Will you please repeat queries 1 to 6 inclusive? (7) The focus is $10\frac{1}{2}$in. (8) The stops are F-12, F-16, F-24, F-30. (9) Make up two solutions—(*a*) bromide of potassium 40 grains, water $\frac{1}{2}$oz.; (*b*) ammonia $\frac{1}{2}$oz., water $\frac{1}{2}$oz—then mix them in ordinary proportions for developing—thus, 10 drops each *a* and *b* to each oz. of A solution. (10) Use a retouching pencil for small holes, and for large holes a little sepia. (11) You have not hurt the vignette glass. Simply wash it and use it for its ordinary work. (12) Don't trouble about any form of sensitometer, trust rather to experience. *Experientia docet*, and have method in your work. Make a note, both mental and pencil, of every photo you take, both as to light and amount of exposure, and in a very little time you will be astonished at your own success.

W. J. Lancaster.

STEERING OCEAN STEAMERS.

[26274.]—IT was only by the merest chance that I saw "Nun. Dor.'s" letter (26055) commenting upon my statement that "If an ordinary Transatlantic steamer were traversing the ocean at a speed of 20 knots per hour and an obstruction were suddenly sighted 500 yards ahead, she would inevitably collide with it, as there would not be time to alter her course in the time it would take her to reach it," and stating that if the rudder were put hard over in 10 seconds the 40 seconds remaining would be sufficient to clear the obstacle. When I made the calculation as to how long a vessel would require to clear an obstruction I certainly allowed more than 10 seconds from the time the man on the look-out saw the obstruction till the rudder was put over; but assuming that it was put over in 10 seconds, I could name more than one Atlantic "liner" that would not clear such an obstruction in 40 seconds, nor would they do so in the proportionally increased time which they would have, as they do not steam at the rate of 20 knots per hour.

When the s.s. *Oregon* was sunk, the captain stated that *after* the helm was put over she would steam 1,800ft. before her course was altered *one single point*, or, roughly speaking, nearly double the time I allowed. "Nun. Dor." speaks of the captain's statement as being absurd; but I really do not think that any captain placed in a similar position would make a statement which could so easily be disproved.

I know but too well that most collisions are caused by "sheer carelessness"; but I certainly do not understand what "Nun. Dor." means by saying, "It is not always that the truth is elicited before boards of inquiry when the counsel employed are incapable of seeing the absurdity of statements made by experts"; or, in other words, that Board of Trade inquiries are a mere farce. Moreover, "Nun. Dor." knows, or ought to know, that the "counsel" have nothing to do with the finding of the inquiry: they are employed by the officers and owners simply to look after their interests, and to see that their conduct is represented in as favourable a manner as possible. The inquiry rests in the hands of trained and competent men.

James M'Cash Govan.

MIDLAND EXPRESSES.

[26275.]—AS "P." still sticks to his statement that "the Midland trains are timed so fast that they cannot even now and then keep time," I will ask him how, if this be the case, he accounts for the fact that they *do* not only now and then, but frequently, keep time, as has been shown by various accounts of runs in previous numbers.

I see no more reason to doubt "Q.'s" run when he gained 25 minutes between Nottingham and St. Pancras, than "P.'s" own statement that "Avon" ran from Rugby to Willesden in 80 minutes, which is a performance more wonderful still, and which I can scarcely bring myself to credit. I have myself frequently gained time on the road with the Leeds expresses.

I should like "P." to note the arrival of the morning Scotchmen at Euston, and I think he would scarcely find them such a model of punctuality as the other trains on this line are according to him. There are many trains on the Midland (for instance, the up Leeds express due into St. Pancras at 5.50) which are delayed by connections with other lines.

I may inform "P." that I do not base my assertions on observations of the Midland main line traffic made at Rugby, which would be rather a difficult matter, to say the least of it; but upon the experience of myself and numerous friends who are in the habit of travelling by the Midland, and upon a series of observations made by myself during part of the past six weeks at Nottingham Station, through which, I believe, most of the Leeds expresses pass.

I find that the down trains are very punctual, and also certain of the up trains; but some up trains are late owing to constant delays, and though not timed as fast as the down trains, are not nearly so punctual.

I understand that the 1738 class of M.R. engines which work between London and Nottingham do not take water at Kettering. This looks as if they meant to run that distance without the stop at Kettering.

This ought to be productive of some grand running. I believe that the distance could comfortably be covered in 2 hours 20 minutes. I think also that, with a better arrangement of the traffic, they might quicken between Nottingham and Leeds. **E. A. Speed.**

RAILWAY SIGNALS.

[26276.]—DURING the recent correspondence on Signals "Libra" and others have told us what they *think* are the opinions of the *men*. There has been a very large and important meeting of signalmen at Leeds, and the report shows what the men do want:—

"RAILWAY SIGNALS AND SIGNALMEN.

"At a meeting of signalmen, held at Leeds recently, the question of signalmen and signals was discussed. The opinion of the meeting was that it is most essential that a uniform system of signal lights should be adopted—that red should be 'danger,' green 'all right,' and that white be a back light when the signals are at 'danger,' but when the signal is off it should show a blank. Shorter signal posts should be provided where possible. When tall signal posts are necessary, duplicate arms should be connected, so that the driver might have something to show him the position of the signal in foggy weather. All distant signals should be fitted with repeaters. All semaphores should lead distant signals—namely, the semaphore should be pulled off before the distant can be. All siding signals should be ground discs. All signals should be placed on the left-hand side of the road. Nor should signalmen be on duty more than eight hours, at busy junctions only six hours."

With regard to the question of *proper* side, you will note the resolution, that all signals should be on left-hand side of line. **Signalman.**

MIXED TRAINS.

[26277.]—"ANTI-VAC" says (26238, page 39), "Suppose the carriages are in front, and there is a collision?" Well, let us take a case with carriages in the rear—Suppose a following train runs into them; is not that surely as bad?

Railwayman.

ON A MODIFIED METHOD OF PRODUCING OZONE COMMERCIALLY.

[26278.]—SEEING in the queries, p. 23, an inquiry (60313) for a method of manufacturing ozone on a large and commercial scale, I give my experience in the matter of manufacturing it in large volume by a special process discovered jointly by the late Wm. Spottiswoode, P.R.S., and myself.

I will preface my description of the special apparatus by pointing out the necessary conditions for its successful production, whether on a large or on a small scale, and afterwards refer to the diagrams for explanation of the same. Nearly every one interested in science knows that ozone is oxygen in a peculiar state, produced by the packing, or grouping together, of the ultimate atoms of the gas, and this grouping occurs under two familiar conditions —i.e., when a disruptive electric discharge takes place in air, and in the decomposition of water by electricity, and by the oxidisation of crystalline phosphorus. It is necessary to employ dry air in its production, and, better still, *cold* dry air. Heat transforms *ozone* into ordinary oxygen. The silent or inductive electric discharged is the most preferable form in which to use the force for producing it.

Having, then, indicated the most favourable conditions for its production, I will go on to describe the apparatus. We will first consider the *ozone generator* which, though not new, may be unknown to many readers. Fig. 1: B is wooden box, 1ft. by 6in. by 2in. inside measurement. It has a tightly-fitting cover and a round hole about 1in. in diameter at each end, into which fit short lengths of ebonite tube about 2in. long for connecting it to the aspirator or pump for forcing the air through the box.

In the interior of the box, which is well varnished with shellac, and then paraffined, is a series of celluloid plates about $\frac{1}{16}$in. thick, P P P, and kept apart (by fillets of the same material) $\frac{1}{16}$in. thick. These sheets do not reach from end to end of the box, but are about 1in. short of each end. Each sheet has a piece of tinfoil attached to its upper surface, as shown at Fig. 2, S, with a small "lug" attached at one corner. The celluloid is now coated (tinfoil and all) with a *thin* coat of paraffin wax. This is to protect the foil from the chemical action of the ozone. It will be seen that if air is forced into one end of the box, it will go out at the other end, having to pass in thin "slices" between the tinfoil-armed sheets of celluloid.

Now every sheet of even number—i.e., 2, 4, 6, &c., has its "lug" of foil connected to a common binding screw P, and the "lugs" from the uneven numbers are all connected to binding screw N. Presuming that the box with its contents is air-tight, with the exception of the ingress I and the outlet O, we have our generator; but the only features I claim to be novel in such an apparatus are the use of *celluloid* plates, as being in every way superior to glass or ebonite, both for physical superiority and cheapness, and on the protection of the foil by paraffin wax.

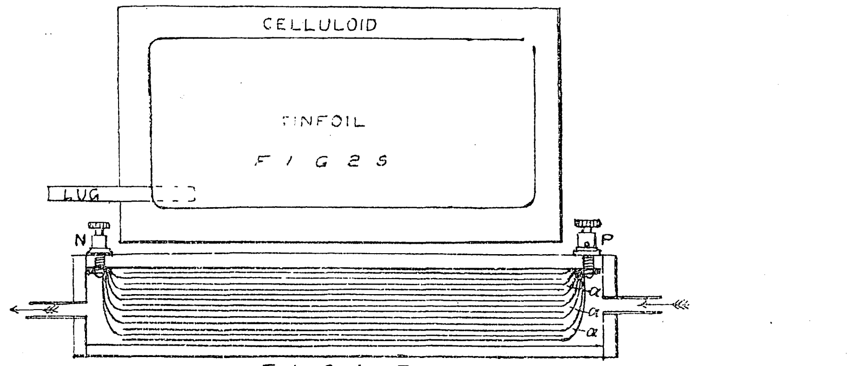


FIG. 1 B.

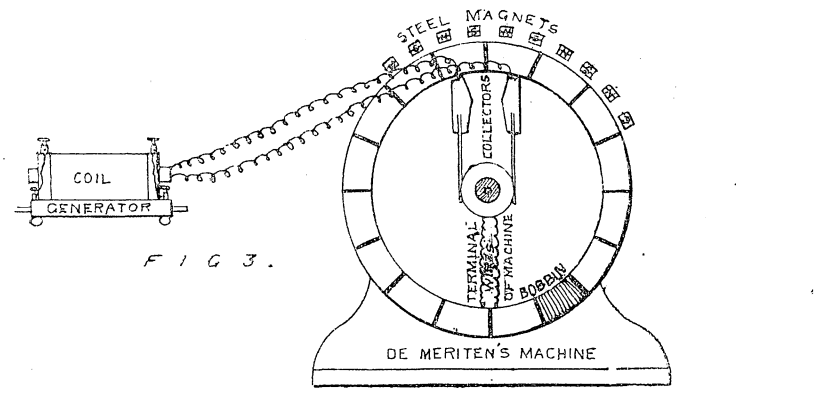

FIG. 3.

We now come to the feature for which I claim absolute novelty, simplicity, and cheapness. I allude to the apparatus for and means of generating the inductive silent discharge. It has hitherto been necessary to utilise a powerful induction coil with its complications of contact breaker, condensers, springs, switches, commutators, &c., and at best these sometimes fail, and it is only an experienced person who can "set" the contact-breaker to work evenly, and then he is not sure at what moment it is going to "stick," and thereby either burn up his primary or throw the belt off his dynamo.

Supposing none of these disagreeables happen, the operator can only get, at most, 4,000 currents per minute, and therefore he cannot drive his air through his generator beyond a certain limit of speed, in case he gets a "slice" through which has never been subjected to the inductive discharge from his secondary at all.

Our improvement consists in doing away with all complications of contact-breaker, condenser, &c., and employing a simple primary and secondary, and that is all, and delivering into the generator not 4,000 currents per minute, but 40,000 or more. This we effect by simply connecting up the primary of our inducing bobbin to the terminals of a De Meritens machine of single-ring type, absorbing about 2 H.P. when giving a current of 300 volts. and 5 ampères.

The current I ought to point out for the information of any who are not conversant with the De Meritens machine, is an alternating one; hence the fact of no condenser or contact-breaker being required. A reference to the accompanying diagram (Fig. 3) will show the simple disposition of the whole connections.

It will be seen at what an enormous speed air can be forced through the generator when we take into consideration that one discharge, for the contained air in the chamber, is sufficient to materially ozonise it. It means that, taking the air bulk to be $\frac{1}{3}$ the cubic contents of the box, we can drive through 48 cubic inches of air 40,000 times in one minute, or roughly speaking, 1,111 cubic feet in one minute; or supposing we gave the air four electrifications instead of only one, we should still get 277 cubic feet of well ozonised air per minute.

I have made gigantic experiments in this direction in the laboratories of the late Dr. Spottiswoode, and have had as much as 12,000 watts running through the primary of one of his large induction coils; but there is a limit to the use of ordinary big coils on account of the fact that the core, when it exceeds a certain mass, cannot follow the magnetising and demagnetising effects of the current sent through the primary at such vastly quick alternations.

Therefore it will be seen that by our methods *ozone* can be produced for any commercial purpose at very little trouble and at a moderate cost. I may mention that there is only one make of coil which will stand the enormous and continued strain put upon it—viz., the "Apps Inductorium."

57, Chancery-lane. **Paul Ward.**

USEFUL AND SCIENTIFIC NOTES.

University College, Bristol.—The session 1886-87 will begin on October 5th. Lectures and classes are held every day and evening throughout the session. In the chemical department, lectures and classes are given in all branches of theoretical chemistry, and instruction in practical chemistry is given daily in the chemical laboratory. Excursions to some of the mines, manufactories, and chemical works of the neighbourhood are occasionally made. The department of experimental physics includes various courses of lectures arranged progressively, and practical instruction is given in the physical and electrical laboratory. The department of engineering and the constructive professions is designed to afford a thorough scientific education to students intending to become engineers, or to enter any of the allied professions, and to supplement the ordinary professional training by systematic technical teaching. The engineering laboratory is provided with a powerful testing machine, and instruction in the use of tools is given in the workshop. Special courses in surveying are given, and excursions for field practice are frequently made. The department for geology, biology, and zoology includes various courses of lectures in all branches of those subjects, together with laboratory instruction. In the botanical department practical instruction is given by means of the botanical gardens, which contain upwards of 1,000 specimens. Several scolarships are tenable at the college.

City of London College.—The Engineering Department of this college is under the care of Mr. Henry Adams, M.Inst.C.E., whose list of successful students for 1885 must be gratifying to himself and the college. The instruction, which includes practical work, is given in evening classes in technical drawing with drawing-office practice, building construction, machine construction, carpentry and joinery, mechanical engineering, quantity surveying, and land surveying. The classes commence the first week in October.

Miniature Battery for Neuralgia, &c.—Mr. G. Lichtenfeld, court hair dresser and wig maker, of Regent-street, has devised a very small chloride of silver battery for fixing in the hat or a wig, which is intended as a remedy for neuralgia, irritation of the scalp, &c. The battery, which is inclosed in rubber and an envelope of silk ribbon, has two thin silver sheet terminals, which are passed through the hat band and made to press against the forehead or other parts of the head. A battery, weighing less than three drachms, which occupies very little room in the waistcoat pocket, will ring a bell or excite a coil quite as strongly as most people care about, and we understand that some are made which weigh no more than one drachm.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[59842.]—**Mathematical Probabilities.**—Reading hurriedly through "Alioth's" query (No. 1118 p. 582), I did not observe that the odds were to be "against" and not "for," and the rule I gave applies only when the required odds are "for." His query can be solved, however, by the same method as I gave on p. 444 of last volume. The equation becomes $\left(\frac{20}{21}\right)^x = \frac{10}{11}$, $x = \frac{\log. 1{\cdot}1}{\log. 21 - \log. 20}$ = 1·95, that is to say, the odds 20 to 1 are reduced to 10 to 1 in two throws. It is interesting to notice that if the odds be n to 1 in one throw, in r throws they are reduced to $(n \div r)$ to 1, if n be a large, and r a small number. Thus, if the odds be 20 to 1, in two throws they are 9·8 to 1, the theory requiring 20 ÷ 2 or 10 to 1. In three throws the theory gives 6·6 to 1 (6·3 to 1 calculated); in four throws 5 to 1 by theory (4·7 calculated); in five throws 4 to 1 by theory (3·7 calculated); which are pretty close approximations. I have just completed calculating the data for the table "Alioth" requires, and find that the following formula holds good for adverse odds:—Tabular No. $= \frac{\log. (n+1) - \log. n}{434{\cdot}3}$ where n is the odds required. The rule is the same as before—viz., Multiply the tabular No. for the odds required by the original odds, and the result is the number of throws necessary. The tabular number with odds "for" is $\frac{\log. (n+1)}{434{\cdot}3}$, which is very similar to the preceding. I give a solution of "Alioth's" last query (p. 41), by means of the table. The tabular number for odds 5 to 1 is ·184, which, multiplied by 100 (the original odds), gives 18·4, or in about nineteen throws the odds 100 to 1 are reduced to 5 to 1. Only one multiplication is needed, as "Alioth" stipulated for.—R. E. F.

[59842.]—**Space Filled with Spheres.**—On further examination, I do understand "E. L. G.'s" chess-board arrangement in a box; and he is right to this extent, that it does generally waste less space than alternate layers of n^2 and $(n-1)^2$ balls. But he is as wrong, as I said before, in applying it to an infinite mass, as he did in answer to "J. K. P.'s" question, which was limited thereto. An infinite mass can only be considered internally. Also, I had better inform experimenters that it is difficult, if not impossible, to lay the first layer in that way without the floor being grooved to hold the balls steady. And yet further, the floor of the box must not quite be divided chess-wise, but must have a margin, nearly a quarter of a square or a seventh of a ball wide, all round the chess-board divisions, the diameter of a ball being the diameter of one of the squares. It is a very small matter, but neither my observation nor other people's agrees with his appropriation of the square pyramid to cannon balls and the triangular one to oranges.—G.

[59842.]—**Effect of Time on Chances.**—The process by which "R. E. F." would have his table made (p. 17) is a very needlessly operose way of getting the natural or Napier's logarithms from common ones. Dividing each common tabular logarithm by ·434, or (what is much easier) multiplying by 2·3026, would give two or three figures of the Napier logarithm. He directs us, opposite each number n, to put this Nap. log. of $(n+1)$; and then, if it be asked in how many throws, each having the odds of m to 1 *against* an event, the odds will become n to 1 *for* that event, I gather him to say we shall roundly approximate this by multiplying the tabular figure opposite n by m. But this is not the kind of question that either "J. M. pro Alioth" put in p. 582, or "Alioth" puts in p. 41. The former supposed it "20 to 1 against a certain event," and asked "in how many throws will the odds be 10 to 1 against?" while the latter asks, "If the odds against success in one trial be 100 to 1, in how many trials will the odds be only 5 to 1 against?" Neither speaks, like "R. E. F.," of a reversal of odds, or change from improbability to probability. Whether "R. E. F.'s" table will tolerably approximate the solutions he speaks of, wherever the original odds are large—say, larger than 20 to 1—I cannot tell; but it certainly will not with smaller original odds. Thus, the top figure of middle column of my table, p. 12, it would make 1·4, whereas it is certainly over 1·71. "Alioth" would come nearer if, after multiplying by m, he added the fraction $\frac{1}{m+1}$.—E. L. G.

[59854.]—**Box Filled with Spheres.**—The arrangement of the interior of a mass of spheres of equal size is always the same, for these reasons: A ball cannot touch more than 12 others of its own diameter. It can touch 12 larger than itself, and therefore the 12 of its own size need not mutually touch. If they repelled each other and had none beyond them, the centre of each would be 63° 26′ from those of its five neighbours, and their 12 centres would form 20 equal triangles, with their planes in 10 directions. But the masses outside prevent this, and compel each to touch 4 of its fellows and form the junction of two triangles and two squares (so that there are but 8 triangles and 6 squares, all their 24 lines subtending but 60° from the middle), because the 14-faced solid thus formed is of less bulk than the icosahedron they would form if repelling each other. Now as only each opposite pair of faces can be parallel, "J. K. P." has here at once the 7 cleavage directions, whose consideration is, as he suspected, the key to the whole matter. (It is the same with crystals. They have but 7 cleavages, not 10, and the regular icosahedron is unknown among them, because their particles are held by attraction, not repulsion.) Thus there can be but 4 directions of honeycomb planes, and 3 of chequer planes. Now between any 2 of the former he finds the angle 70° 32′, and between any 2 unlike planes (viz., a honeycomb and a chequer one) 54° 44′. It follows that any planes to be perpendicular must have nothing to do with honeycomb ones. But any 2 of the 3 chequer planes are perpendicular, so that a box can always fit them all three. Not, however, if bordered with any close row, because he will find the meeting line of any 2 such planes is an open row, whose balls' centres (calling their diameter 1) are $\sqrt{2}$ apart. But as he considers only space, apart from any particular form, he may ask whether the cube wastes least or the octahedron (both having the same number of edges, and of faces and corners together). This may be settled by the cube's edges being the blunter; but, at any rate, by comparing the numbers of inclosed and outer balls. All those in a cube, we have seen, must be half of an even cube number, or half of an odd one + 1. An octahedron with root a contains $\frac{2a^3 + a}{3}$ balls. The smallest cube to have as many balls within as on the surface (and 12 more) he will find to have 500; but the smallest octahedron to have as many within as without (and only 18 more) has 670. So, then, 6-faced boxes excel any with less than 14 faces.—E. L. G.

[59995.]—**Excavations in the Hill of Tara.**—With reference to my former reply to this query (Vol. XLIII. p. 512), I have now heard from my friend in the Royal Irish Academy, and he informs me that the gentleman I alluded to has since died, and, he adds, "As far as I know, no excavations have been made at Tara up to the present time."—J. E. GORE.

[60050.]—**Space Filled with Spheres.**—Does "J. K. P." really know what he wants? The original question has been answered several times, and, indeed, he said afterwards that he had found the answer to it himself—viz., that the vacant space in an infinite mass of equal spheres close packed is ·269 the whole. He did not say which of the two modes of closest packing he had calculated on, nor did "E. L. G."; and then I told him that they both give the same result, though, probably, one would have guessed that the triangular plan was the closest, because all adjacent balls in every direction are in contact; while in the square pyramid no diagonally-adjacent balls in any horizontal plane touch. The note which he has several times referred to in Lord Grimthorpe's "Book on Building" said the same, though with a small error in the figure for the ratio of the sum of the balls to the volume of the whole mass—viz., ·707 for ·740, through a slip, of which I can guess the cause, though that is immaterial. The ·707 is practically right, within an insignificant fraction, either for a square or a triangular pyramid containing as a box, not an infinite, but a great, number of balls, such as 100 in each edge, the result varying somewhat with the number. ·707 is also quite right for the proportion of a mass so large that the margins may be neglected, of balls close packed in either way, to that of the same number set cubically all over. "J. K. P." now professes to wish to ascertain whether those who have given these results (evidently meaning me) are aware of the reason for them. So far as a reason for a mere geometrical fact means anything, I had told him the reason with the fact; and as he has not attended to it, he probably would not if I told him again. He has now discovered a genuine paradox of his own (to justify his persisting in speaking of the "shot paradox, I suppose") —viz., "by means of a drawing-board, that the arrangement of"—not the vacant space in—"the interior of a mass of spheres is the same in whichever of the two ways you commence laying them, and he is not sure that either 'G.' or 'E. L. G.' is aware of this." I am quite sure that I am not; but I do not presume to answer for "E. L. G.," whose games of chess I (like "J. K. P.") now understand less than ever. If "J. K. P." will drop his drawing-board and buy some marbles, and build up a triangular and a square pyramid with them, and observe their internal arrangement as he goes on, he will see that their interiors are different in every way. And if he will then put them into a box as wide both ways as any integral number of the marbles, he will appreciate "E. L. G.'s" last assertion that he was right about beginning with the alternate squares of a chessboard. For the box plainly holds n^2 balls in the first layer, and $(n-1)^2$ in the second; and so, with an odd number of layers you get one more n^2 layer than $(n-1)^2$; whereas, if you begin on the alternate chess-square plan you cannot get near so many. And when you go to infinity there is no initial layer at all, and you can only look at internal arrangement, of which there can be but one in rectangular close packing. "J. K. P." fancies we cannot be sure that either the triangular or rectangular pile is the closest without the differential calculus. Yes we can; for it is easy to prove that any other that can be invented is wider; and anyhow, the calculus could not invent one for us. It is not a question of degrees as in the honeycomb problem, as may be seen at once from the fact that the two modes give the same result; and also, because the balls absolutely fix the angles of the piles, which in honeycombs may be called discretionary.—G.

[60055.]—**House Boat.**—TO E. CONRY.—Thanks for your suggestions in No. 23 last volume. Accepting your measurements of 16ft. length and 18in. draught, will you kindly give me width of pontoon in widest part, and also how much of the 18in. I may expect to be submerged with the weight given? May I ask the reason why you suggest the principle of a boat cut in half rather than that of two distinct boats.—PONTOON.

[60076.]—**Frictional Electricity.**—One answer to this question is: Charge the ball with sparks from a machine; but I suppose that is not the answer desired. Still, I do not think it possible to charge the pots without a supply of the electricity. —W. A.

[60083.]—**Clematis.**—Cuttings of these plants are not readily struck without heat; but the plan most likely to insure success is to peg down shoots in August, just wounding them at a joint which is buried in the soil by cutting slightly into the surface, so as to raise a little tongue. As to pruning, you can do almost as you like; but they bloom all the better for being cut back severely. If you want to train them, cut out the summer growth, and shorten the main stems until you get it into shape. The Jackman only flowers on the new growth.—C. K.

[60087.]—**Leclanche Cell.**—"A special Leclanché" are the words used; but they cannot mean anything more than a large size and several cells of the agglomerate pattern.—W. A.

[60097.]—**Vacuum Brakes.**—This cannot be answered without examination. The sticking is only occasional.—S. W. R.

[60106.]—**Chamber Organ.**—"Young Amateur" should look up the back volumes for scales of pipes, unless he can wait for Mr. Audsley to reach that part of his subject, in which I presume he will give specifications and scales.—J. T.

[60121.]—**Prime Cost.**—"Prime cost" is the price to be paid for the work done; "cost price" is what is actually paid for the materials and labour.—SAML. RAY.

[60123.]—**Boiler for Yacht.**—An engine of the size mentioned would do; but a boiler of the locomotive type would be best at such a working pressure.—J. T.

[60128.]—**Photo Lenses.**—Wide angle lenses are most useful lenses when used for their special purpose. In confined situations, in churches, rooms, &c., where space to use an ordinary lens is unobtainable, then the wide angle lens is of great value. You can have lenses so wide in their angle as to enable you to stand in one corner of a drawing-room and obtain a photograph of almost the whole of the contents of the room. You may get a photograph of the whole of the front of a house in a narrow street; but you must make many experimental trials before being successful. You must master the swing back, rising and falling fronts, then you will be able to get straight lines, good proportions, and a photo worth all your trouble. S. Bottone's reply, p. 561, is ambiguous, and apt to be misleading. To get roughly the angle of the lens, you mnst have a camera so large (not of merely sufficient size only) that the lens gives a perfect circle on the ground glass; then you may measure to get roughly the angle of lens. Shall be pleased to give you any further information you may require.—W. J. LANCASTER.

[60185.]—**L. and S. W. Locos.**—Here is all the information I have at hand:—2 Tartar, 14 Mercury, 25 Reindeer (Mar. 1873), 27 Eagle (Dec. 1862), 39 Wizard (Feb. 1874), 71 Alaric—four-coupled passenger engines; cylinders outside; bearings inside, except to leading wheels; large dome on firebox, with valves on top; Gooch's safety-valve on boiler; designed, I believe, by Beattie. 149 (no name)—goods tank, six-coupled;

built by Beyer, Peacock, and Co., Manchester, in 1882. 348 (no name)—bogie four-coupled express; outside cylinders; designed by Beattie; built by Sharp, Stewart, and Co., Manchester in 1877 (No. 2657). Similar to Nos. 349—366. L. B. and S. C.—4 Mickleham—passenger tank; 1873. 85 Cannes, and 86 Geneva—goods tanks; 1883.—V. J. B.

[60190.]—**Leclanche for Quantity.**—For the information of "M.M.I.Sc.S." I have performed the desired experiment with a "quantity" galvanometer having a resistance of ·01 ohm. Upon connecting it to the cell, having an ordinary ⅜in. diameter zinc rod, the needle was deflected to the full extent of the scale. Instead of inserting a resistance, I put a shunt wire between the terminals until the needle stood at 25°; I then changed the zinc rod for a plate 6in. by 3½in., and another 9in. by 4in.; but the needle would not move, showing clearly increasing zinc surface is useless, as stated by me on page 585, Aug. 26, when I used a galvanometer having 126 ohms resistance. May I ask the attention of E. Conry to this?—for replying to query 60073 in to-day's issue, he states "that zinc plates give a larger current at any particular time than rods." How would he prove this in the face of these experiments? I shall be very glad to hear the opinions of others, for a "quantity" Leclanché is what I have been aiming at for years.—AN A.S.T.E., Sept. 10.

[60197.]—**"Take a Postage Stamp."**—At the railway stations in several of the large Scotch towns there is a mechanical apparatus for supplying travellers with stamps, &c.; these machines are divided into two parts, one of which supplies a postcard when a penny is dropped into a slit; the other, which requires two pennies, supplies a sheet of paper, envelope, and stamp. I cannot give a drawing, but suppose it would be of little use, as these appliances are the property of a private company, and are, I believe, patented. There are also several on many English piers for supplying cigarettes.—JAMES MCCASH GOVAN.

[60205.]—**Compound Engines.**—In reply to "H. R. W.," page 43, the diameter of l.p. cylinder —viz., 3¾in.—will be quite correct for steam at 80lb., which gives a ratio of 3½ to 1. If you intend placing the cylinders tandem, a receiver will not be required, as the exhaust may be taken direct to the l.p. valve box. The one eccentric works both valves; but in large engines it is better to have an expansion valve on the h.p. cylinder. Set the valves to cut off steam at about five-eighths of the stroke.—ENGINEERING, MANCHESTER.

[60241.]—**The Vanishing Lady.**—By simple reasoning, founded on observation, I have arrived at the following conclusion with regard to this trick, which, I believe, is certainly correct in the main, though possibly not so in some minor details. The carpet and newspaper placed on the stage conceal a trap door, the position of which is indicated to the conjurer by the folds of the newspaper. Upon this he places a specially constructed chair, having *no cross rails*, and, to give an idea of transparency, painted to resemble cane. The lady is now seated in this chair, and some moments before the *dénouement* (and after the audience have been repeatedly assured that she is still there) wire arms are brought into proper position for holding the covering cloth exactly as though a person were seated in the chair, the seat drops on its hinges, and the lady passes downward through the trap, of course concealed from view by the cloth. To accomplish this, squares must be cut out of the carpet and newspaper. The first is, no doubt, done beforehand; the latter presents more of difficulty; but, even if the paper is not also previously prepared (as it might well be), I assume that it could be cut by the lady herself. The trap is then restored to its original position, bringing the carpet and paper to their places, the seat of the chair slips up, and the conjurer is ready to throw off the covering cloth, and reveal the empty chair. When the cloth also disappears, it is doubtless carried behind the chair by the wire arms flying back to their concealments at the moment of *dénouement*. —W. A. COOPER.

[60243.]—**Electro-Magnetism.**—The question seems to be badly put. In point of fact, you would not have any trace of magnetism in the dry pile you refer to. You could, and would, obtain a slight electrical effect from simply building the foils as directed, and you could increase this somewhat by sending a current through the whole; but the effect would be very small indeed, as from your query it is evident you would have metallic contact from end to end of the pile. No doubt the original question has been somewhat modified, or was intended as a catch question.—W. J. LANCASTER.

[60246.]—**Heating Small Conservatory.**—I have used, with a fair degree of success, a gas-stove to heat a fernery throughout the past winter, and as this fernery faces north-east, it received more than its share of last winter's chill. I have been unable to trace any deaths of ferns, of which I have a large number of varieties. The stove is Ritchie's Patent "Lux Calor Hygienic Condensing Gas Stove." There is a very large condensation, the water falling in a tray beneath the stove, and I place in a metal dish on the top of the stove sufficient water, which, as it evaporates, compensates for any loss, and really keeps plenty of watery vapour in the fernery. I have tried the makeshift petroleum lamp and T-tubes, &c., but with me they have all been failures.—W. J. LANCASTER.

[60252.]—**Gravity.**—If the earth were homogeneous, and a well were dug at one pole through the centre of the earth, a stone falling down the well would be always attracted by a force proportional to its distance from the centre, because the attraction of that part of the body of the earth outside the stone, or the whole outer shell whose thickness had been traversed by the stone, would cancel its own attraction on the stone, according to a well-known principle. The stone would reach the centre in 21 minutes of time, with a velocity of five miles per second. The earth, however, is not homogeneous, but increases in density downwards. In consequence of this the actual time of falling to the centre would be less than that mentioned, and the velocity greater.—DUBLINIENSIS.

[60252.]—**Gravity.**—When a body has fallen lower than the level of the ground the matter behind certainly does retard it, in the sense of making its weight less, and its velocity no longer increases by the same law as while it was above ground, but slower and slower, though still so increasing that its maximum would only be reached at the centre. It is true the earth acts on all bodies outside her as if her mass were all concentrated, but not so on anything within her. If her density were uniform up to the surface, gravity would here be at its maximum, and a pound taken a mile down would be a 3,960th lighter, or 1,980 miles down only half a pound; but, owing to the lightness of all the surface material compared to the mean density, the level where gravity is greatest, though not many miles down, is lower than probably experiment will ever reach.—E. L. G.

[60252.]—**Gravity.**—"Angulus's" query is one of the most serious that ever was inserted in the "E.M.," as it involves the famous principle of attraction. A proper answer would require a large space, and the arguments—cosmogonal laws —to be set forth would have no chance of being admitted by the Editor, as being absolutely opposed to the hypotheses now admitted as truth by all scientists, although false. But, even in admitting the hypothetical principle, the so-called force (?) which increases until the falling body reaches the surface, decreases to zero from the surface to the centre, so that there is none there, and that inertia —which is a nonentity—is the consequence. A centre is a point where there is, where there can be, nothing; therefore, attraction to or by a centre is attraction to or by nothing, which is absurd. The reverse can be said of centrifugal force (?) which, by the bye, is not centrifugal, but axifugal, which, should it exist there, continually flying away, but constantly remaining in place, as asserted by scientists, would repel all bodies and prevent their fall, since that force is said to have been sufficient to enlarge the earth at the equator. If "Angulus" writes to me, I will give him some information.—CH. RABACHE, Morchain, Somme, France.

[60254.]—**Tricycle Driving Gear.**—I am afraid gut-bands will prove most unsuitable for the purpose you wish to use them. Now I have long had an idea, but have never found the time to work the idea into practical shape, and as my time is more limited than ever, and every moment is of value, I will give the idea to you to do what you like with it. It is this: Having years ago done my share in tricycle riding, having treadled to Land's End and treadled back again, I have over and over again wished for something to take the place of the chain gear, and to neutralise the two dead points in every revolution of the wheel, and my idea is this: Instead of the two wheels and chains, I should use cranks and treadles; but in place of steel rods connecting crank to treadle, I should use thick indiarubber rod or spiral steel wire. A stretch of 1in. or 1½in. would be ample. With such an arrangement you could have no dead point, no jarring or jerking caused by a loose chain, and I believe a machine built upon this plan would be one of the best goers ever made, and for hill climbing it would be excellent; by means of an adjustable lever the length of stroke could be altered in an instant, and so either low or high gearing could be used at will. I shall be interested in hearing that you have made the machine, and that it does more than I have given it credit to perform.—W. J. LANCASTER.

[60255.] — **Hydrostatic Pressure.** — To "ALIOTH."—Very sorry, I am sure, to have hurt your feelings, but your present addition to your query makes it more clear to me, however clear it may have been to your own mind before. The moment formed by the weight of the rod by its distance from the point of support is exactly balanced by the weight of water displaced by the distance of its c.g. from same point, the latter being upward and the other downward. The downward pressure on supporting point is the difference of the two weights. All this you probably know, and you also probably know that it is a very pretty little problem to work out—volume displaced, and its centre of gravity, and so on—which I, for one, have neither the time, and perhaps not the knowledge, to work out for you; as I believe you will find it requires the calculus. Try and get "M.I.C.E." to help you out, if no one else does.—T. C., Bristol.

[60259.]—**Electro-magnet.**—The pole-piece, or so-called keeper, should bear some relation to the size of core. About half the volume in cross section I have found to work best; thus with your magnet a bar 1in. by ½in. would answer every purpose, using, of course, the softest iron you can get.—W. J. LANCASTER.

[60260.]—**The Aneroid.**—With reference to reply contained in your last number respecting the aneroid as an instrument for measuring elevations, I may say that I thought the lines ruled on the dial were all spaced at equal distances apart. As, or if, this is not the case, what is the use of the vernier? I fancied its purpose was to subdivide the fiftieths into tenths. Within the limits of, say, 30·269 and 29·610, would it be correct to reckon the movement of the index across each fiftieth as the measure of a rise of 19ft.? And if when I have reached the top of a hill I find that the index has moved from 30·110 to 30·073, then to what height have I climbed? What I ask for is information respecting the aneroid and vernier, or reference to some book explaining those things.—X.

[60260.]—**Aneroid Barometer.**—Are you quite sure you have a vernier on your aneroid? I have never seen one fitted to an aneroid. I have, of course, seen thousands with an altitude scale, and I have an idea yours must have this, from the fact that the inch of the aneroid should show 100 parts, while that of the vernier (?) should show 930 for the inch between 30in. and 29in. That is, let the barometric inch 30in. to 29in. be divided into 1,000 parts; then the elevation scale in same space should read 930ft. Of course 930 is not the mean from bottom to top of atmosphere, but is really the lowest number of feet per inch; thus, between 29in. and 28in. you would have 960ft. This is, of course, at a definite temperature—about 56° F.; but there are so many circumstances to be taken into account that your best plan will be to spend 6d. in purchasing "The Aneroid Barometer: How to Buy and how to Use It," by a F.M.S. You will have all your necessary tables in this.—W. J. LANCASTER.

[60262.]—**Photo. Enlarging Lantern.**—The lens you have would make an excellent front objective for an enlarging lantern. You would require a pair of 5in. or 6in. condensers, a triple-wick paraffin lamp, and then you would have to make a chamber to hold lamp and condenser, &c. If you are a mechanic and can make the apparatus, I shall be pleased to tell you how to do it. You could get an enlargement up to 36 by 30, and a lantern disc probably 10ft. in diameter. I am assuming that your lens is a good one.—W. J. LANCASTER.

[60266.]—**Sun Dial.**—The simplest form of apparatus you can construct is a large hoop, say 2ft. in diameter, and 4in. or 6in. broad; in one side of this cut out a hole, into which fit a double convex lens, exactly 2ft. solar focus; the ring must be suspended in trunnions, so that it may be moved from or to the zenith. The inside of the ring opposite to the lens should have a piece of silvered metal, or pieces of white paper with a metal back, to conduct away heat, will answer. Exactly opposite the centre of the lens a line must be marked perpendicular to the ring; this line is the meridian line, and your difficulty will be to set the ring exactly in the meridian. When so set the image of the sun must be watched as it nears the line, and when the sun is bisected by the line then table your time; of course, you must have tables as to sun fast, sun slow, &c., and with care in making and setting you will have a fairly reliable time-teller. This is useless for any other time but when the sun crosses the meridian—that is, at or about 12 o'clock.—W. J. LANCASTER.

[60267.]—**Thermometer Tube.**— Your query contains its own answer; by working slowly, you admit that you get on quickly. Now glass will not allow you to heat it rapidly without some sign of temper, generally hard and ill-temper; this goes from the glass to the hasty blower. Better make one good tube in ten minutes than spoil half a dozen in twenty minutes. Co-efficients of expansion have a most unaccountable way of suiting themselves to a particular substance, and if two substances having different co-efficients are blended together it is then necessary to use every caution

when using them; but you can easily arrange a model furnace, into which you can place ten or a dozen tubes, and get them heated, say, to 600° or 700° Fahr.; then take them out as you want them, and you will save a lot of time.—W. J. LANCASTER.

[60268.]—**C.G.S. Units.**—If the gentleman who gratuitously advertises himself as "Mr. Wm. John Grey, F.C.S., Analytical Chemist, Newcastle-on-Tyne," will be good enough to look up the subject of C.G.S. units in any textbook, it may dawn upon his gigantic intellect that there are often more ways of stating a case than one. His correction simply amounts to this: "It is absolutely incorrect to say that two things added to four things make half-a-dozen things: they make six things!" It is a pity this gentleman does not utilise some of the energy he expends in rude and incorrect contradictions in answering the constant queries that go unanswered in "Ours," simply because many of our contributors are in the same position as myself, and have not the time to hunt up information on the various subjects, if they do not happen to have it by them.—E. CONRY.

[60274.]—**Mushrooms and Salt.**—Being interested in an article on salting meadow land, and the growth of mushrooms, and the answer to query, does it not appear the salt sown in spring would during the summer months penetrate the soil by autumn, creating and maintaining agreeable moisture, favourable to the growth of mushrooms, of course attracting the dew to the soil earlier and before the summer heat is spent. The mushroom seems to revel between drought and humidity. Although salt may be somewhat unfavourable in any great quantity, neither contained in its composition, it seems reasonable to believe, the moisture created thereby is beneficial to the ramification of the spawn in the soil. Should this, as it appears, be reasonable inference, it would be highly interesting to experiment on some fairly-drained fertile old sheep pasture. Other experiment is hereby suggested, too long to be now entertained. The mushroom seems to revel between drought and humidity—*any* meadow taken indiscriminately would likely prove futile.—W. F. DARK, Gardener.

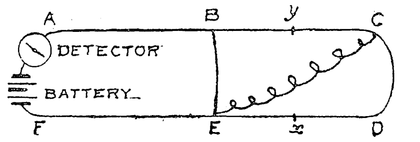
[60283.]—**Eyepieces.**—I should advise you to make two lower power eyepieces than you suggest, and you should use for the lower power $\frac{1}{2}$in. and $1\frac{1}{2}$in. lenses, these will give you a power of 40; then for the present high power use $\frac{1}{4}$in. and $\frac{3}{8}$in. lenses, power 80. The first pair must be mounted 1in. apart, and the last pair $\frac{1}{2}$in. apart, all plane surfaces to be mounted towards the eye. The dark head is a sun-cap to go over each eyepiece.—W. J. LANCASTER.

[60284.]—**Portrait Lens.**—You have nothing as yet towards a half-plate portrait lens, and I am afraid the making of such a lens would be an impossibility. Still, this is only an assumption on my part, as I do not know what you can do. Let me have this information. What have you done in optical glass grinding? Tell me what tools you have, then I will give you the information you require. Reading glasses are generally made of crown glass.—W. J. LANCASTER.

[60285.]—**Polarised Light.**—The arrangement as described on p. 550 appears primitive, and does not at all seem calculated to produce a good image. I should prefer two ordinary A eyepieces, with a cap fitting over eye lens carrying an achromatic plane of $\frac{3}{8}$in. focus. The opposite eyepiece I should make up in a precisely similar manner. The arrangement of Nicol does very well mounted as in drawing. For polariser, a single piece of $\frac{1}{8}$in. plate, roughened or smoothed on the back and blackened, answers almost as well as the bundle of plates, and is much more easily made. I do not just at the moment remember any experiments in circular polarisation with the microscope; but I see no reason why a quarter more plates might not be used with your Nicols to obtain circular polarisation.—W. J. LANCASTER.

[60186.]—**Mathematical.**—Thanks to "T. C.," "Toodles," and "E. L. G." for taking notice of my question. They had evidently overlooked the question of placing the three balls into a box "cube in shape." "T. C." and "E. L. G." give the side of the cube as $10\frac{1}{4}$in. (about) arranged diagonally in the box. Are they quite certain that by arranging them as a triangle in this way will give the size of the smallest cube. Will they kindly show the calculations for it?—ADAM.

[60297.]—**Testing for Faults.**—The question is one which can hardly be fully answered within the limits of a reply to a query, but the following may be of service. If you cannot get a current through A C D F, join the lines about midway, as Fig. 1, B E. This joint need only be temporary, as by scraping or cutting the insulation off both lines, and twisting a bit of wire round each; if, then, you get a deflection of the galvanometer needle (showing there is a current passing round A B E F) you will know the break of one or both lines is between B and C, or E and D. If you have a loose coil of wire of sufficient length handy, you can then tell in which wire the break is by joining one end of the loose coil to C, and taking the other end

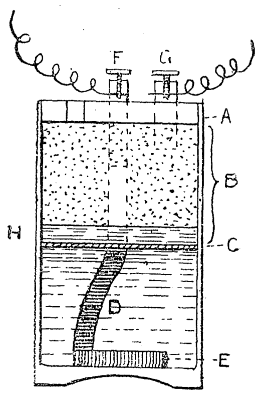


to E, up to which you have already found the wire F E D is all right. If no deflection, it shows that the break is in B C; if there is the deflection, it shows that A B C E F is all right, and you must then join the E end of the loose coil on for a moment at X, and see in the same way if A B C X E F gives a deflection, when the fault will be between X and D, and so on. If you have a loose coil and circumstances admit of your applying it as above, you can dispense with joining B E at all. If you have no coil or cannot use it, then you must, after having, by joining B E, "localised" the fault, as it is called, to the right half of the circuit, divide this half into half again by a temporary joint at X Y, and see whether the fault is right or left of you, in the same way. In the case of short circuits, which are much more frequent than breaks, and much more troublesome, you can trace them down in a similar way by keeping the extreme end of the circuit open between C and D, by cutting the wire if necessary, and working on the reverse principle—that a deflection on the galvanometer is wrong. A "deflection" is the sharp twitch of the needle that occurs when a current passes. The detector, or galvanometer, as it is generally called, is connected up in series with the battery, as shown. Dynamo testing and some other matters I must leave for the present—E. CONRY.

[60298.]—**Norway and Sweden.**—Heat of summer upon Arctic circle in Norway sometimes outstrips any summer in the south of England. Sultry, oppressive, and in many parts relaxing. Porridge-eaters fare happily. Do as natives do; and eat their mild white cheese, with flat bread. Spent all summer just on spot, 1884; fared well, independent of meat. Recommend route Newcastle—Bergen. Language: Bennett's "Norwegian Conversation," published at Christiania. Detailed information direct, if desired.—WEALD.

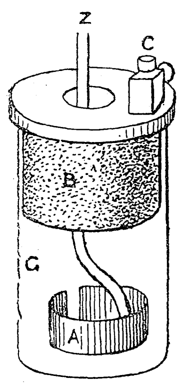
[60303.]—**Captive Balloons.**—As you kindly inserted a previous letter giving some particulars of my apparatus, and as this query contains several misstatements which, if not contradicted, might be calculated to give the public false impressions, I shall feel much obliged if you will allow me the opportunity of answering "Palace." "Palace" states he understands that the balloon was withdrawn because it proved a failure, and asks me the cause of the failure. He adds that it never was lit up with electric light: also, his whole query is full of inaccuracies as to dates, not one being near the mark. In reply, I beg to inform him that my balloon was not a failure, my patent apparatus working without a hitch. Further, my balloon was lit up with electric light most brilliantly, and witnessed by thousands. I withdrew the balloon from the Crystal Palace owing to circumstances which compelled me to commence a legal action against the Crystal Palace Company. Those circumstances I leave to reveal themselves in the fitting place. I thank "Palace" for the extreme interest he takes in my invention; but I think it is a pity that, before he wrote on the subject, he did not take care to be rightly informed in at least one particular. I am not surprised he did not see the electric light in the balloon on July 6th, as for some days previous to that date the balloon had been quartered some hundred miles away. If "Palace" requires further assurance of the success of my electric balloon, I refer him to the unanimous opinion of the London press, and to the fact that I have supplied my apparatus by order of the War Office to the English Government, and that I am now negotiating for its adoption by various foreign Powers.—ERIC STUART BRUCE, M.A. Oxon, Pangbourne House, Tunbridge Wells, September 8.

[60314.]—**Pollak's Battery.**—This battery consists of a cylindrical glass jar of suitable dimensions, the exciting fluid being salammoniac, as in the ordinary Leclanché cell. A is a wooden cover, having in it three perforations—two for binding-screws and one for filling purposes. B is a carbon block occupying about half the cell, having on its under surface a layer of copper (C), which has been electrolytically deposited. E is a strip of zinc bent into a cylindrical form, and connected by means of a strip of the same metal (D) passing through the carbon block to the binding-screw F. The other binding-screw is in connection with the carbon block B; H shows the height to which the liquid reaches, though it is only necessary that the copper should be wetted in order to give a current when the circuit is completed. As the battery depends a good deal upon gravitation, it should be moved as little as possible. Local currents are set up between the carbon and the copper, which decompose the NH_4Cl, forming chloride of copper. The nascent hydrogen liberated at the copper reduces the cupric compounds, which are formed again by the copper, the battery thus constantly charging itself anew. It maintains a current of $\frac{1}{80}$ ampère for six months, consuming $6\frac{1}{2}$oz. of salammoniac and $2\frac{3}{4}$oz. of zinc, at a cost of about 3d., the carbon block being said "to last for ever." E is given as



0·932 volt. For lighting purposes it would be about as efficient as a Leclanché; but for bells a simpler or cheaper battery could not be desired.—R. E. F.

[60314.]—**Pollak's Battery.**—The peculiarity of this battery consists in the ingenious arrangement whereby not only the depolarisation of the plate, but also the regeneration of the electrolyte, is effected. It consists of a vessel, in the bottom of which is placed a strip of zinc (A, Fig. 1) rolled



up into a cylinder $1\frac{1}{4}$in. in height and 3in. in diameter, which forms one of the electrodes. The other electrode consists of a porous, coarse-grained carbon cylinder, B, its upper part being formed of agglomerated carbon. The lower part is covered with an electrolytic deposit of copper. This cylinder is $3\frac{3}{4}$in. in diameter and $3\frac{1}{2}$in. in height. It is supported on the edge of the vessel by means of three projections. From 200 to 250 grammes of salammoniac are placed in the vessel, which is then filled with water until its level reaches from $1\frac{1}{4}$in. to $1\frac{1}{2}$in. above the lower edge of the carbon. This at once sets up a local action between the carbon and the deposited copper, which has the effect of decomposing the salt, and of producing other combinations with the copper; in other words, the carbon forms with the copper a couple, of which the metal is the positive element. A portion of the copper forms a soluble compound, whilst the hydrogen is burnt by the oxygen, which is condensed in the pores of the carbon. This local action is termed the formation of the element. It is this secondary copper carbon couple, or rather the metal of this couple, which really constitutes the negative electrode of the cell. The hydrogen disengaged upon the electrode thus composed is employed to reduce the salt, from which it precipitates metallic copper, but which is again formed afresh in the presence of the carbon, and so indefinitely. The cell furnishes a constant current, and has the advantage that the depolariser constantly renews itself. The E.M.F. is 1·3 volt, with an internal resistance of 0·5 ohm to 0·8 ohm. Trials recently made with this battery tend to show that it is well adapted for domestic lighting. By modifying its form and dimensions, the battery may be made to yield a constant current of ·5 to ·75 amp.,

which is sufficient for maintaining a small glow lamp. For instance, six cells 14½in. long, 9in. wide by 4in. high, are sufficient to supply the current necessary for a 2-candle lamp of 6 volts burning for ten hours daily. During the fourteen hours of repose the battery becomes entirely regenerated, so as to be ready for a fresh period of lighting. The work thus distributed may continue for about a month without its being necessary to disarrange the apparatus, and it is only when the solution is quite exhausted that it requires to be renewed.—W. HABGOOD.

[60320.]—**Fossils.**—The fern-like markings found by "Spes" in the cleavage division of the slate was not organic, but the phenomenon called *dendrites*, from "dendron," a tree. It is purely physical, in some cases the result of a kind of crystallisation, and quite common.—DUBLINIENSIS.

[60324.]—**Terrestrial Telescope.**—Having given a large amount of attention to this subject, my experience may possibly be of use to "D. G.," especially as I am acquainted with and have used the "International Code." At Dover there are two reporting stations, "Lloyd's" on the Admiralty pier, and another one to the east of it. Lloyd's use two telescopes, which I should estimate of 2½ aperture and about 3ft. focus. The other station uses a larger glass mounted on an altazimuth stand about 3½in. aperture. I had two telescopes, one 1⅜in. aperture, 14in. focus, power, 10; another 1⅓ aperture, 11in. focus, power, 14½. These reporting stations both send up an answering pennant when they have read a ship's letters, and then repeat the signal. As many as 60 ships signalled one morning. I read all those with the exception of four or five with the low-power glass; one ship I read with my little 1⅓in. was hull down from my window (first floor). This signal was not answered by either of the signal stations. For my own part, I would prefer a glass moderate in power with plenty of light for flag reading, as a high-power dark glass does not show the colours well. I make a point of examining all the telescopes I can get hold of, consequently see a good number in the course of the year. It is quite exceptional to find one that is not a dummy—*i.e.*, has its object-glass stopped down. The last glass I came across was the property of the Commissioners for Northern Lighthouses. Object-glass, 2in., of long focus; body of telescope, 2½ or 2¾; far larger than neecssary, to give it an imposing look. Object-glass stopped down to 1¼ or 1⅜, definition, notwithstanding the stop, was woolly; my little 1⅓, though of less power, beat it hollow. My last achievement with this little 1⅓ was to see a stick, 7ft. 6in. long and 2⅞in. thick, on the top of a cairn on a hill 700ft. high at a distance of 25 miles. If "D. G." wants to get the maximum amount of light he must, as I have before stated in these columns, have an emergent pencil of ·11in. In other words, for a power of 50 he ought to have at least an effective aperture of 5½in. A power of 50, however, is only suited for exceptional weather. A 3in. glass cannot be called portable, and could not be used without a rest. The glass I should recommend for "D. G.'s" purpose would be a 2in. of 18in. focus; three draws, pancratic eyepiece, power 20 and 30. Mine weighs 2lb. 11oz., is 11in. when closed, and 28½in. when focussed. I have never seen this glass equalled; it may interest our astronomical friends that it shows the *comes* to "Polaris" with the 20 power. If I had only one telescope I should not have such a large one, but would prefer my 1⅓ as above or a 1½ of 14in. focus, and pancratic eyepiece with power of 15 to 25, if such a thing is made. Finally, let me urge "D. G." to take warning from the glass supplied to the Commissioners of the Northern Lighthouses, and paid for by the Board of Trade, and 'ware makers to the Admiralty!—EDWARD M. NELSON.

[60330.]—**Engine Filling.**—As none of "Ours" gave "Coach Painter" the information he required last week, I may tell him that if he is a practical hand, the proper thing to fill up an engine with is "hard stopping," as used in the coach trade. I am surprised that he should attempt to rub anything with glue in it with water; if he had rubbed it with any stone or the coarsest glass-paper it would have been all right, for sometimes the companies will not go to the expense of lead. If he is not clear on the subject, and will write again, I will afford further help.—HARRY.

[60332.]—**Ferments.**—Perhaps the best all-round work on ferments and their function for "Ignoramus" to study is "Fermentation," by Schützenberger; it is a cheap work (and very well translated) of the International series. On the isolation and culture of organisms, Mr. Crookshanks' "Bacteriology," just published, contains nearly all that is known to date, with the exception of a proper and exhaustive description of the best means of conducting cover-glass culture, and I believe this will appear in the next edition of his work. If "Ignoramus" can read German or French, there are many other works in these languages treating on the subject. The choice of a microscope and its cost is a more difficult question. I believe that English powers are as good as any; but that the cost of those of the best makers keep them out of the reach of many workers. I began my microscopic work when living on the Continent, and bought my instrument at Berlin for about £6 with two objectives, ¼in. and ⅛in., and two eyepieces; magnifying power ranging up to 700 diam. with very fair definition. I have, however, since then obtained objectives by Zeiss, and find them worth all the extra money, especially for prolonged observation in bad daylight. For studying yeast, "Ignoramus" would find the Zeiss ⅛in. an invaluable power, and for Pasteur's "Maladies" the same maker's ⅛in. is a fine working glass, magnifying power being less important than good definition with the maximum light obtainable. I am sorry I cannot give experience of English objectives and their price.—CYGNET.

[60334.]—**Falling Bodies.**—Surely the eastward velocity cannot be independent of latitude. How much would "R. E. F." make it at the pole, and what direction is east at the pole? A balloon or cloud n feet above the equator doubtless describes a circle exceeding the equator itself by $2\pi n$ feet; but anywhere else its journey can only exceed that of the ground by as much less than this, as the cosine of latitude is less than l.—E. L. G.

[60334.]—**Falling Bodies.**—A stone allowed to drop freely *starts* along the vertical, though it will reach the ground to the eastward of the plumb line let down from its point of starting. The curve described by it (the stone), relatively to the plumb line, will be a tangent to said line at said point. The time of fall being t, the height of fall is proportional to t^2, and the advance eastwards is proportional to fall $\times t$, or to t^3. Therefore, when the time is indefinitely small, the advance eastwards is indefinitely less than the fall. In one second the plumb line (at equator) moves through an angle of 15″. In that time the body would fall 16ft., and the advance eastwards would be 16ft. × tan. 15″, or 1 ÷ 71in. In 1-1000 of a second the fall would be 1-1000² of the above, and the advance eastwards 1-1000³ of the above.—DUBLINIENSIS.

[60336.]—**Keeping a Pony.**—If this querist can come across a little book called the "Handy Horse Book," I think he would find it of great use. The price, I think, is 4s. 6d.; but, being from home, I cannot give the publisher. It is difficult in the space of a reply to give much useful information on such a subject. One piece of advice might not be amiss: have your animal amply strong enough—a bit stronger than you may at first think necessary.—D. G.

[60336.]—**Keeping a Pony.**—Size, 13 to 14 hands, say £14 to £20 for a warranted animal; don't buy unless it is warranted, and beware of dealers. Food: corn, peas, and Indian corn, crushed and mixed with a little—a very little, say about one-sixth part—of cut hay; give it, say, 1lb. or 1½lb. three times a day, but quantity depends on the work it is doing. Feeding will cost 7s. 6d. or 8s. per cwt. To clean, use curry-comb and dandriff brush, and finish with body brush. A little "condiment" or linseed boiled with the food occasionally will help the gloss on the skin. Harness cost £7 to £10; conveyance, dog-cart or inside car, or phaeton for a lady, cost, say, £14 to £25. Harness and machine could be got for less second hand. If you advertise your address, I could give you rough plan and probable cost of stable and coach-house, and perhaps other information.—I. LOW.

[60337.]—**Small Compound Engine.**—H.P. cylinder 2in. diameter, l.p. cylinder 4in. diameter, both 4in. stroke; 80lb. pressure, cut-off at ¾ in h.p. cylinder. Heating surface, say, 8 or 9 sq. ft., and surface condenser 6 sq. ft.—T. C., Bristol.

[60337.]—**Small Compound Engine.**—Taking the boiler pressure at 80lb. per sq. in., to develop one horse-power the h.p. cyl. should be 2⅝in. diam.; l.p., 5in. diam. by 6in. stroke. The cooling surface should be at least 6 sq. ft.; the length and number of tubes will, of course, depend on the shape of condenser. The condenser tubes should not be less than ½in. internal diameter. If you intend having the pump ½ stroke of engine, the air-pump may be 3in. diam., and circulating pump 2in. diam. For the above size of engine the circulating pump can be of the ordinary plunger type, and a good pet-valve should be fitted. Heating surface of boiler, about 10 sq. ft.—ENGINEERING, MANCHESTER.

[60341.]—**Mechanics.**—The pull on the rope would be as you say, 8 to 1 of the power, or 8 × 30 × 2 = 480lb. The pressure on the spindle is only due to the pull of the rope (as the moments of the men are equal and opposite), as above—viz., 480. This neglects the strain due to leverage of height of rope from ground line, tending to break off the spindle. Get some of the old vols. of *Engineer* for firebox stays and illustrations.—T. C., Bristol.

[60343.]—**Heating Small Conservatory.**—"Householder" will need to convey all gas fumes out of his greenhouse, as they contain sulphur, and would damage almost any plants. The fumes from a petroleum lamp, if free from soot, do no damage. The light certainly will do no harm—rather the reverse, as greenhouse plants suffer more in the winter from want of light than want of heat.—998.

[60343.]—**Heating Small Conservatory.**—Ninety-nine persons out of a hundred would tell you that in a conservatory heated by gas it is necessary to have a flue to convey the "fumes" outside, as they are inimical to plant life. To make free ventilation of that kind is to lose, say, half the heat, and I do not think there is any necessity for it, as the injurious products of the combustion of gas might all be seized by compelling them to pass through suitable materials, such as pumice or coke kept continually moist. The light certainly does not damage plants, and when the heat source is a paraffin-oil stove, there is certainly no necessity for a flue.—ORCHID.

[60346.]—**Charging Accumulators.**—The evolution of gas in charging is a waste of power, as it means that the dynamo is sending through the cells more current than they can take up in charging, and the surplus gas escapes in the form of bubbles. The battery acid should be stronger—eight parts acid to one water. You do not say what current you get from your dynamo, or what E.M.F., so it is almost impossible to judge the exact effect of your charging. Have your cells ever been properly formed? Reversal "many times" is not enough; cells require from time to time, during formation, certain intervals of rest, to allow of the carrying on in them of certain chemical reaction, which is necessary to the proper formation of the plates, and without this you might keep on reversing for a year and get no more effect than if you did so for only a week. I am inclined, from your description, to think this is the case. With ordinary dynamo machines and accumulators you could not charge only six, especially in two rows of three. It would short-circuit the machine, and either stop it or burn the armature; but from the circumstance of gas coming off, it would seem that you have sufficient current. The drop of potential when the cells are left standing, is bad. It shows they are short-circuited somewhere; either within the cells, from plate to plate, or by wet along the edge of the cells, or by the acid leaking right through the cells, and carrying the current along the table where they stand. You should lift all the plates out, and wash them and clean the cells out. The grey sediment is sulphate of lead; and if there is enough of it on the bottom of any cell to touch the positive and negative plates at once, that would short-circuit the cell internally, and they would run down just as you say they do. If they drive the dynamo as a motor for five minutes, it is not bad, considering the size of the cells and the fact that they would be running through a very low resistance, as the joint resistance of the dynamo armature and shunt (I suppose there is a shunt) would, I should think, be not more than about half an ohm. The length of time that cells will last depends on the resistance of the circuit they are run through; the greater the resistance the longer they last. You must remember that six cells or series give no greater quantity of current than a single one. Wash and clean your plates and cells as above, then set up battery again, keeping everything very dry, and the cells standing on little bits of thick china or flower-pot soaked in hot grease, and, if possible, keep the cells where there is a circulation of air; then charge, and if they do not run out of themselves as before, but are all right, leave them standing for at least a week; then discharge and reverse, and continue reversing for about a week (six or seven reversals); then leave standing for another week, and probably they will then be better. I shall be glad to hear from you how you get on with them. If you cannot quite follow my description, or want to know further, write again.—E. CONRY.

[60347.]—**Westinghouse Brake.**—To "TRIPLE VALVE."—The statement that the Westinghouse brake does not work well upon trains of more than 12 carriages is incorrect and absurd. I have myself seen it work perfectly upon 35 vehicles; and at the Burlington trials in America just recently it was highly efficient upon trains of not less than 50 cars.—CLEMENT E. STRETTON, Leicester.

[60348.]—**Testing Gold.**—A mark is made on the stone with the piece of gold you wish to test; a drop of nitric acid is then applied to the mark. In proportion to the quality of the gold the mark will be more or less effaced by the acid. I presume the studs are made of a known quality of gold, and the stone is also marked with them or one of them for comparison with the gold to be tested.—OS.

[60349.]—**Florida.**—I have by me a sort of magazine about the size of the *Graphic* or *Illustrated* on the resources of Florida, and if you like to advertise an address, I will send it to you; but you must remember it is written to attract emi-

grants, and therefore describes the country as a sort of earthly paradise; so you must discount the statements considerably.—E. CONRY.

[60351.]—**Coil.**—I would advise Mr. Peckham not to interfere with his medical coil, but to make a new spark coil at once. He will find it quite as cheap in the end, and far more satisfactory. There are dozens of coils fully explained in back numbers of the "E. M."—OS.

[60351.]—**Coil.**—TO MR. BOTTONE.—Do not alter the primary wire, but put on ¼lb. No. 39 silk-covered for secondary, carefully insulated between each layer with paraffined paper. Let the condenser be built up of 50 sheets of tinfoil, 5in. by 3in., interleaved with paraffined paper. One pint bichromate will give a ½in. spark with such a coil if well put together. This sized spark will do for most experiments.—S. BOTTONE.

[60351.]—**Coil.**—A single-wire medical coil can easily be converted into a spark coil by taking off all wire in excess of two layers. The two layers that are left on will do for the primary wire, provided the wire is not too thin. If the wire is between Nos. 16 and 24, it will do. The length of spark obtained will depend on how much secondary wire the reel will now hold. A little more than ¼lb. of No. 36 silk-covered, carefully wound and thoroughly insulated, should give ¼in. spark. For condenser, begin with 20 sheets of tinfoil, with the full battery power, and add more sheets, one at a time, as long as good results are obtained. The number of sheets is really best determined by experiment, and their size will depend on the cavity of the base-board in which they are placed. For many of the ordinary experiments, ¼in. spark will be sufficient.—BOBADIL.

[60353.]—**Testing Water with Nessler.**—Nessler's reagent is a solution of mercuric potassium iodide, containing excess of potash, and in reacting with ammonia, forms the brown insoluble body oxydimercuric ammonium iodide:—$(4\,HgI_2 + 6KHO) + 2NH_3 = 2NH_2Hg_2OI + 6KI + 4H_2O$. Hard waters, treated with Nessler's reagent, separate out a portion of their lime, magnesia, iron, and alumina, as a white flocculent precipitate, and in presence of small quantities of ammonia displays itself as a yellowish opalescence.—NORMAN McCULLOCH.

[60359.]—**Freezing Meat.**—The means employed in the Atlantic steamers for preserving meat is the following:—Cold rooms (in which the meat is hung) are constructed, having a lining of wood, outside which there is a packing of 12in. or 15in., either of dry sawdust, silicate cotton, or some other good non-conductor, this packing being inclosed by another wood casing. Into these rooms is conveyed cold air at a temperature of from 20 to 40 degrees below freezing. The cold air is obtained by compressing it in a suitable machine to a pressure of about 50lb. or 60lb. on the square inch, and afterwards allowing it to expand, the heat due to compression being removed by the circulation of cold water. Usually the air is taken from the cold rooms by a suction pipe, compressed, cooled, and returned by a delivery pipe; a constant circulation is thus maintained.—S. G.

[60362.]—**Cold Compressed Air.**—It is made in many sizes; any apartment will do, as a rule, where the dirt of a steam-engine does not matter. Steam power is usually used; but refrigerators can be made with other methods.—E. CONRY.

[60362.]—**Cold Compressed Air.**—Cold-air machines are made suitable for dairy work; they answer well both for cooling cream and milk, and hardening and preserving butter. A properly constructed cold room is required, also power for working the machine, either a steam or gas-engine. The capacity of the cold room, as well as the size and power of cold-air machine, would depend on the size and requisites of dairy. I have recently been engaged in connection with the arrangement of cold-air room and machinery for a large dairy in Berkshire, where they make about 1,200lb. of butter per day.—S. G.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

[60380.]—**L. and S.W. Locomotives.**—(1) Could any of your readers give me details of L. and S.W. goods engines built by Neilson and Co., such as 151, 395, 433? (2) Are 135, 460, 470 classes all alike in dimensions?—V. J. B.

[60381.]—**L.B. and S.C. Locos.**—(1) Are all the engines in the two following lists respectively alike? Four-coupled: 208 Richmond, 209 Devonshire, 210 Cornwall, 211 Cavendish (was formerly Beaconsfield; why changed?), 212 Hartington, 213 Norfolk, 214 Gladstone, 215 Salisbury, 216 Granville, 217 Northcote, 219 Cleveland. Single drivers: 326 Grosvenor, 327 Imberhorne, 329 Stephenson, 332 Shanklin, 333 Ventnor, 334 Petworth, 335 Connaught, 336 Edinburgh, 337 Yarmouth, 338 Bembridge, 339 London, 340 Medina, 341 Parkhurst, 342 St. Lawrence, 343 Wilmington, 344 Hurstmonceux, 345 Plumpton, 346 Alfriston, 349 Albany, 350 Southbourne. (2) Are 197 Cavendish, 451 Lancing, 452 Worthing now scrapped? (3) What are the dimensions of 301 Caen class?—V. J. B.

[60382.]—**Equal Balance.**—I use a balance, or pair of scales, having a light sling hung at one end and a heavy scale board at the other end of the beam. To poise it, I have placed a heavy ball of iron midway between centre and end of one arm of beam, and strapped tight to underside of it by means of an iron band passing round beam and screwed to ball. As this ball projects about 8in. below underside of beam, would any of "ours" please tell me what influence it will have when weighing, seeing that it moves in the same circle as the beam when it leaves the horizontal?—A. J. W.

[60383.]—**Resistance of Battery Working.**—In "Munro and Jamieson's Pocket-book," page 111, a method (similar to Muirhead's) is given for this; but what value should be given to the shunt s? Unless high, there will be free passage of currents, with much heat—in fact, will not a temperature correction be necessary in any case?—AJAX.

[60384.]—**Dead Black Lacquer.**—Recipe wanted for use on fine steel articles and to withstand washing.—GUN.

[60385.]—**Work on Carpentry and Joinery.**—Can any reader give me the name of a work on the above giving details and instructions for making panels, framing, and dovetailed and mortise work? I am fairly expert in the use of tools; but being an amateur, of course I have had no shop experience to guide me as to proper proportions in joiner's work. I am aware of the various articles that have appeared from time to time on this in the "E. M.," but want the information in a more concise form.—NEMO.

[60386.]—**Letters on Brass.**—TO MR. S. BOTTONE AND OTHERS.—I have a brass door-plate to fasten small bolts on. During process, the mixture falls out off the letters, leaving bare the brass. Will anyone kindly tell me what to get, and how to use it? I want black and red letters.—A. D.

[60387.]—**Toolholder.**—Will "J. K. P." kindly inform me what is the best kind of toolholder for a slide-rest of 6in. centre? Is the "Willis" holder a good one, or is it superseded by more modern forms? What is the proper way of fastening bolt in top of rest for toolholder to swivel round? What should be thickness of table for tool to rest on? Is the step in front of slide of any great advantage?—ANGLO CELTIC.

[60388.]—**Wimshurst Influence Machine.**—Will Mr. Wimshurst, or Mr. Gray, kindly answer the following questions? (1) If a Wimshurst influence machine has discs 24in. or 30in. in diam., how thick should the glass be? (2) How long should the bosses be, and how many inches in diam. should they be at each end? (3) How long and how broad at each end should the sectors be? (4) What size should the driving wheels be? (5) How should the glass discs be drilled and the edges rounded and smoothed? (6) What should the diam. of the steel spindle for the bosses be? (7) Are machines furnished with large discs of 30in. or more worth the extra trouble and cost in making, and are they far superior to those furnished with 17in. discs?—INFLUENCE.

[60389.]—**Apparatus for Ringing Hand-bells.**—I have a set of eight hand-bells without tongues, and am anxious to make a self-acting apparatus to play tunes on them. Can any reader of "E. M." kindly give me a few hints on the subject?—CYMRO.

[60390.]—**Carving.**—Will some kind reader give us hints on machine and hand carving? Have searched from Vol. XII., and the information is altogether meagre for "Ours."—T. WOOD.

[60391.]—**Inspector.**—TO "GLATTON," OR "T. C., BRISTOL."—I have been in charge of a pair of horizontal engines for about three years, and have passed a 2nd elementary steam exam. If I continue my studies on steam, &c., do you think that in course of a few years I shall be able to hold the situation of engine and boiler inspector for an insurance company? Would you please state what is required of one who holds such a situation?—YOUNG AND HOPEFUL.

[60392.]—**Magic or Inexhaustible Inkstand.**—Years ago I bought an inkstand, so-called. Different ones were sold for black or coloured inks. The one I bought was for black ink. I believe they were of English or American make. To obtain ink it only required to put water in it, and when it was exhausted to put some more. I used mine for about five years, writing profusely, and left it when the tin, being oxydated, it could no longer keep liquid. Could any kind reader tell me what substance was used to produce such results, which are so very handy?—ONE WHO WRITES.

[60393.]—**Straight Wires.**—How can I get perfectly straight brass or copper wire, in lengths of about 9in. long? Is there any special machine for the purpose?—A. S. J.

[60394.]—**Pocket Magneto Machine.**—TO MR. BOTTONE.—Will you kindly give me the full dimensions and details of a small pocket magneto machine?—A. S. J.

[60395.]—**Water Motor.**—I want a 6-horse water motor, or turbine. Water is unlimited, and costs me nothing. The main considerations must be simplicity and non-liability to get out of order, as I live far away from a town. Do Bailey's water motor (Haag's patent) or the Vortex turbine fulfil these conditions? They are the only two motors I know of.—F. E. A.

[60396.]—**Electric Lighting.**—I wish to light a shop with, say, 50 incandescent lamps. I have the steam power from an engineer's shop; but this would be too irregular for an ordinary dynamo. I propose, therefore, to use an accumulator. Will you be good enough to refer me to any work which would give me dimensions and details in the construction of a dynamo suited for the purpose? Also any hints as to the accumulator?—AMPERE-METER.

[60397.]—**Engine Query.**—Is Cornish boiler 12ft. by 4 sufficiently large for engine; cylinder, 10; stroke, 24; tube, 28½in.?—IRELAND.

[60398.]—**Photography.**—I am thinking of building a studio, 15ft. long, 8 wide, and 7 high. Would this be large enough for all cabinet work? I shall run it from east to west, with light on the north side. How large should window be, and which end (I don't want to make it double ended)? Should I have any glass in roof, or on south side? Any other hints would be very acceptable to—Z. Y. X.

[60399.]—**Electrical Foot Warmer.**—Did M. Tommasi (No. 1118, p. 574), by means of electricity, really improve the acetate of soda foot warmer? Perhaps so; but he surely complicated it so as to render it impracticable. Has the system a real value? I doubt it. When the invention broke out, I procured an apparatus made on the best principle, and compared it with a common stone bottle—in this manner: I put water in a tank, in which I placed both the acetate instrument and the bottle full of water, and heated it at 100° C. for a time, sufficient to be sure that both were at boiling temperature. I took them out, put a stopper to the bottle, and placed both instruments at opposite ends in a bed. After twelve hours, I found that the bottle was still warmer than the acetate instrument. Several trials gave a similar result. This suggested to me a system entirely different, in which no water nor acetate is used. Heat to any wished degree can be applied, up to 300° C., and even more. The heating is very quick and economical, and the heat keeps much longer. The system can be applied for almost any sorts of warming. Should you know an honest, enterprising man who would feel disposed to patent it, under your recommendation I will send full particulars to him.—CH. RABACHE.

[60400.]—**N.E. Locos.**—Can any reader kindly give the dimensions and weight of 6-coupled goods engine bearing the company's name (Gateshead works)? Also, if possible, the weight of No. 14, 8-wheeled, winged tank, 6-coupled, in full working order? The above are new engines, and, I believe, designed by Mr. Worsdell.—W. R. B. A.

[60401.]—**To "A., Liverpool," or "Fiddler."**—I am making a violin belly of cedar wood, and should be glad of any information as to graduation. Should it be thickest at middle, or outside edges? I have made sound holes, and roughed out to uniform thickness ⅛in. I am leaving bass bar in the solid.—FRANK.

[60402.]—**Violin D String.**—What is the cause of defective D string on violin? I have tried several strings, both thick and thin, without success. The violin is good on all strings except D.—FRANK.

[60403.]—**Revolving Cylinder.**—Will some reader please tell me how to make a cylinder, revolving upon parallel axis, revolve slowly, say once in three or four hours, the cylinder being unevenly weighted? I don't like clock-work because of the ticking, and because it occasionally comes to a stand before the weights have run down. Could it be done by strong springs and a fan like musical boxes, or by some other method? The cylinders weigh 50lb. or more.—BEE.

[60404.]—**Condensing Tube for Launch.**—I am wishing to fit my 4in. launch engine with a condensing tube, simply to condense the exhaust steam that it may be pumped into the boiler. Will anyone tell me the length and dia. of copper tube for outside condenser, and will an ordinary horizontal feed pump draw the condensed water out of the tube, or is an air pump absolutely necessary to deliver it into a hot well for the feed pump to draw from? I don't want any vacuum. The engine is 4in. by 4in.; working pressure, 80lb. to 100lb., 300 revolutions. I would like a sketch of natural draught boiler to suit, with dimensions for working from. Please say area of grate, heating surface, and size of tubes. Exhaust pipe from engine is ⅝ dia., now contracted to ⅛in. in chimney. Present boiler is vertical, with 10 sq. ft. heating surface.—ENQUIRER.

[60405.]—**Chimney Rain Guard.**—Can any of your correspondents tell me the method of marking out the shape of a sheet of metal, so that when joined together at the edges it shall form a cone, such as are placed on the top of a chimney to keep the rain out? I believe it is to be done by some method of projection; but have tried several ways without success.—NEMO.

[60406.]—**Photographic Exposures.**—Burton's table of exposures is a very handy form for reference on subjects and various lenses. Can someone, however, supplement a little by what I have recently found myself at a loss? Suppose one has, as per table, a lens of $\frac{f}{11}$, which on a sunshiny day requires for an open landscape ⅛ second exposure at noon. Here we have as constants the lens and the subject; but let the time of day or weather vary and I want a little guide—i.e., what will exposures probably be at (1) noon if sun was obscured, (2) if a dull day, (3) at, say, 6 p.m. with sun, without sun, and dull. Would anything like this do: For (1) multiply exposure by 2, for (2) multiply exposure by 3, for (3*a*) multiply exposure by 2, for (3*b*) multiply exposure by 4, for (3*c*) multiply exposure by 5?—N. Y., Plymouth.

[60407.]—**3in. Telescope.**—I should be greatly obliged if some reader would kindly give me instructions for making an astronomical telescope. I have a 3in. achro. object-glass, focal length 42in., mounted in brass cell.—ENQUIRY.

[60408.]—**Iron Workshop.**—I am about to erect an iron shed, 36ft. by 12ft. by 9ft., to be used as a workshop and showroom for pianofortes. I have chosen iron, as it is fireproof and portable. Will anyone who has had ex-

perience with iron buildings point out their defects for my purpose?—T. E. D.

[60409.]—**Boiler.**—Would any of "ours" assist me in the following? What dimensions and how many tubes will be required for a $1\frac{1}{2}$ H.P. copper boiler? Also, I should like a sketch of same and the experience of anyone having one of these or similar boilers. It is intended for practical work, and not a plaything. Also if an iron vertical will have any advantage over the above? It will not be in constant work, perhaps for two or three days in each week.—DOUBTFUL.

[60410.]—**Electro-Motor.**—Can some reader give me a drawing and description of a model electro-motor to drive screw boat 3ft. long? Please, if possible, give measurements and length of wire.—ROCHDALE.

[60411.]—**Engine.**—Wanted, drawing, with description, of model electro-magnetic engine, if possible, with measurements, quantity of wire, and cost.—ROCHDALE.

[60412.]—**Steam.**—TO "GLATTON," OR "T. C., BRISTOL."—Will you be so kind as to give me the why and the wherefore of the following questions in plain figures? I understand decimals. The engines are compound; cylinders, 16in. and 27in. dia.; stroke, 4ft. 6in. What I want to know is how to find out what the saving will be, steam cutting off at $\frac{1}{2}$-stroke at 50lb. pressure, in the boiler? We want to raise the pressure in boiler to 65lb. What will be the terminal pressure at 50lb., cutting off at $\frac{1}{2}$ stroke? Where shall we cut off at 65lb. pressure to get the same terminal pressure? We have no indicator, only when the inspector comes every three months. I hope the questions will be fully answered in plain figures. Will you please say how it is there is a greater saving with high-pressure steam when higher the steam gets and heavier it gets, so I understand?—FIREMAN.

[60413.]—**Steam Escape, or Relief Valve.**—Required, a valve (to act automatically) which will allow steam to pass from a boiler, pressed at, say, 30lb., into a pipe connected with other boilers at a lower and constantly varying pressure (10lb. to 25lb.), in order that whenever the steam should rise above the 30lb. it would escape into and assist the others. Will someone kindly say whether there is a valve to meet the case, and, if not, whether there would likely be any demand for such an article?—TYNESIDE.

[60414.]—**Overhead Wires.**—I am about to connect my house to that of a friend's by means of an overhead wire; and, the distance being about a mile, whose permission must I get to allow me to cross the several public roads and streets? A reply to this, with other particulars relating to the law on the subject, will be a boon to—BRADFORDIAN.

[60415.]—**Brazing.**—Will some reader tell me how to proceed with brazing a brass plug $\frac{3}{8}$in. long into the end of a steel tube, so as to make a strong air-tight joint?—MOORGATE.

[60416.]—**Portable Forge.**—I have a circular portable forge, which I cannot get to work satisfactorily. Will some reader be good enough to instruct me how to get a good fire?—MOORGATE.

[60417.]—**Railway Fish Plates.**—Is it not the fact that the nuts on fish plate bolts often fall off the bolts when in place, through vibration, or from being improperly screwed up? Have any means been devised at any time to prevent this occurring? I have an idea, and not, I think, too expensive, which would prevent this, provided a railway company would not object to pay some slight extra cost on their permanent way. I should be grateful if any of your practical correspondents on railway subjects would kindly tell me whether such a thing has been attempted, or, if an effective method were introduced, whether it would be commercially valuable, and to what extent? Any information on this head, and a reference to the best work treating on this subject, would be highly appreciated by—ADAM BEDE.

[60418.]—**A Novelty.**—Could any kind reader please give me any information on the following? At "The Convent" on the Stourhead Estate, Wilts, is a novelty which to many has been the subject of much discussion. It is a fly, which some say is painted on the glass window, others argue that it is a real fly imbedded there—in fact, there are so many different opinions that it is impossible to know which is correct. In whatever way it is done it shows great skill and ingenuity, and is the admiration of all who see it. Any information, therefore, bearing on the subject will, I know, be received with gratitude by all interested in it, and, amongst others, will greatly oblige—CONSTANT READER.

[60419.]—**Clark Cell.**—In report of discussion at Birmingham on Prof. Blyth's current meter, Lord Rayleigh is stated to have said, "the Clark cell would measure the current at any moment." How is this effected? Kindly explain, with diagram of connections. Prof. Forbes also said: "People were abolishing every sort of standard instrument except the Clark cell."—X. Q. Z.

[60420.]—**Steam Whistle.**—I am about to make a small steam whistle for a $\frac{1}{2}$ horse-power boiler; steam, 80lb. per sq. in. Could I not make them without the bell? I have seen them something like the common whistle, but forget how they were made. Any information, and sketch, would oblige—STEAM WHISTLE.

[60421.]—**Carriages.**—TO MR. STRETTON.—I notice in a Manchester paper that Mr. Stretton, under cross-examination in connection with the railway mystery, stated, as an expert, that a pistol would ride on a carriage step from London to Leicester. Will he kindly give the class of carriage and weight, and perhaps his reason for his opinion?—INTERESTED.

[60422.]—**International Association for Protection of Life.**—Can any reader give me the full name and address of the Protection of Life Society, and the class of work they undertake?—INQUIRER.

[60423.]—**Zither.**—Would any kind friends favour with necessary instructions as to how I should proceed in making a zither, and its dimensions and material?—MUSICAL COUNTRY LAD.

[60424.]—**Acid Stains for Wood.**—Can any correspondent give particulars of how to stain wood a cherry-red colour by the fumes of acid, what acid, and what degree of heat to be applied in a closed chamber?—CAUSTIC.

[60425.]—**Hard Soldering Aluminum.**—Can anyone give me information through the columns of your valuable newspaper as to the best process of hard soldering aluminum?—W. S. F.

[60426.]—**Nickel Polishing.**—Will any of your readers kindly inform me what are the best materials for buffing and polishing nickel silver by the lathe process? I have tried a course of the following, and in the order here given—viz.. emery-flour and oil, rottenstone and oil, and rouge; but find it unsatisfactory, as it does not leave the polish free from scratches. Also, what description of bobs or buffs are most suitable for the work?—POLISHER.

[60427.]—**Sheet Wax for Micro Objects.**—Will some correspondent give particulars of the best method of using sheet wax for mounting micro. objects?—THETA.

[60428.]—**Silvering Glass.**—I shall feel obliged if any correspondent will tell me where I can find an account of the mode of depositing silver on glass, such as is used for astronomical reflectors.—J. M.

[60429.]—**Electric Pen.**—In order to expedite the copying of specifications and other lengthy manuscripts of a similar nature, I should be pleased to have directions and sketches for making one of these useful instruments to work with about six cells of a Daniell battery (gravity form), which latter can be placed in a cellar or other convenient position, wires being led from that to the desk, and thus the power might be always at hand and constant in strength; or, for the sake of portability, I should like to work it with two chromic acid single-fluid cells. Description of paper, ink, and hints on working same would oblige—PI.

[60430.]—**Gravity Daniell Battery.**—I have trouble with mine as follows: Zincs were well amalgamated at start; but though very lightly worked, they become alarmingly corroded in a short space of time, turn black, are covered with a dark flocculent coating; and this goes on even with open circuit, being at the same time accompanied with an abundant evolution of hydrogen. Will some electrician kindly explain my probable error, and describe a reliable and efficient form of Daniell gravity cell which would answer for working an electric pen?—RHO.

[60431.]—**Lattice Work.**—I am required to fix wooden block letters, about 3ft. in height, upon a suitable lattice or net work, so that while the letters are prominently visible, the groundwork of lattice may be unobserved. Practical instructions for securing this effect will be welcomed by myself. N.B.—They will be in an exposed situation.—TAN.

[60432.]—**Architecture, &c.**—I am articled to an architect. I have plenty of out-door experience, but unfortunately, through the limited amount of time my principal has at disposal for the purpose, I am unable to obtain much assistance in the theoretical portion of the subject, and being left to myself in a great measure to grope my way through the various arts and sciences which are included under the head of architecture, my progress is much slower than I care for. Consequently, in order to give me a helping hand, will some professional reader indicate a course of study, giving the names of the text-books necessary to use under the following branches, as well as under others, which may be thought needful to pass the R.I.B.A., Surveyor's Institute, and those examinations required to qualify as a district surveyor? The branches referred to above are: Architectural History, Building Construction, Draughtsmanship, Law concerning Building Operations generally, Mensuration and Land Surveying, Quantity Surveying, Sanitation, Hygiene, and Natural Philosophy.—UPSILON.

[60433.]—**Manure.**—My sincere thanks to any fellow reader who will recommend a good work on the manufacture and trade analysis of superphosphate and other artificial manures.—LEVERAN.

[60434.]—**Crank Movement without Dead-point.**—I have made a small crank movement to work by hand with connecting rod, the power of which is equal the whole length of stroke. By placing my guide in an eccentric position, it reverses and does away with the deadpoint, at the same time enabling me to lift a weight without a flywheel. By keeping the guide in centre of gravity, a flywheel is necessary; but as soon as the crank moves $\frac{1}{8}$in. in the direction of the circle it has as much power as at the highest part of stroke. My object in making it is believing the piston of the present has to wait at each end of flywheel (mine has not), I would like to hear from some of your correspondents—their view of my theory that a vast amount of speed is lost through the piston being retarded waiting on the flywheel.—SCOTTY.

[60435.]—**B.A. Degree, Dublin University.**—Will any of your readers kindly give me information respecting examinations for above—when held, subjects required, and, if possible, where questions set at previous examinations may be obtained.—SCHOLASTIC.

[60436.]—**Telegraph Connections.**—I should be glad if Mr. Conry would inform me, by means of a sketch, how to connect a single-needle telegraph, so that by pressing a push I could ring both my bell and the bell at the far end of the line together. Also the number of large sized Leclanché cells that would be required to work a line of one mile in length.—E. M.

[60437.]—**Zinc Stencil Plates.**—Will some kind reader say what tools are required to make the above, or is there a book with instructions?—VERY ANXIOUS.

[60438.]—**Photography.**—Will some reader kindly give me a few hints on burnishing and enamelling photos.? I have tried burnishing, but get my photos. spotted in doing it. I have also tried enamelling, but lose the gloss in mounting.—AMATEUR.

[60439.]—**Petroleum Engine.**—Can any reader inform me as to the working of the above engines, such as Spiels, Eteve-Humes, &c., as to the modes of compressing the air, the proportions of oil and air, formation of vapour, the manner of injecting it into the cylinder, and the method of firing or exploding it, and also if there is any work of instruction on anything of the kind published, or drawings or illustrations obtainable?—ARCHBALD.

[60440.]—**Frogs.**—I want to keep some of these animals. What food and conditions will best suit them?—KENSINGTONIAN.

[60441.]—**Engraving Ivory Tablets.**—Will some one kindly describe the process of engraving the small ivory, bone, ebonite, and celluloid tablets which makers of instruments affix to the articles they vend? Where may the tools and ivory plates be had? The engraving in ebonite is finished white.—C. C.

[60442.]—**The Thimble Battery.**—Could "Penruddocke" (letter 26326) kindly give dimensions of his battery, sizes of zincs, carbons, porous pots, &c.? Also, could he inform me how his mercury connections are made, as I do not understand them, and whether clamp screws would do instead?—AMATEUR ELECTRICIAN.

[60443.]—**Japanning.**—I want to make a stove or other apparatus for japanning small articles. Will some of "ours" tell me the most economical, as well as efficient, method of going about it?—HARRY.

[60444.]—**Turning Vulcanite or Ebonite.**—What tools are best for turning hard rubber in the form of vulcanite or ebonite? What speed and what lubricant?—G. H. B.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Sept. 15, and unacknowledged elsewhere:—

ARCHIBALD AND PECK.—Morris Cohen.—A. Hirst.—R. Card.—G. Plant and Son.—G. L. Scurfield.—Vibrator.—A. C. and Co.—J. M. Chadwick.—G. O.—F. M. Rogers.—Carstairs.—Young Engineman.—I. Low.—S. Bottone.—W. A. Haren.—B.—W. G. Penny.—Thomas Pearson.—H. Gilbert.—V. J. B.—P. H. Marrow.—Salus.—E. T.—W. R. L. N. W.—X. Y.—Atom.—Amateur.—Chimney.—B.—Sober.—Paul Ward.—G. H. H.—C. D. R.

NIL DESPERANDUM. (The current may do good; but seek medical advice. See pp. 243, 306, Vol. XLI., and the indices of back volumes for many hints on the subject.)—MIKADO. (To prevent the hot steam coming in contact with the tube or metalwork of the gauge. It is usual to fill the siphon with water, but the steam would soon be condensed in the bent portion.)—FONS. (The small fountain referred to was illustrated and described in No. 402, p. 294; No. 405, p. 366. Your idea of the construction is correct. The glass flasks must be reversed from time to time, to keep up the action. They revolve with the joint piece.)—W. GRIFFITHS. (An improved Æolian harp was illustrated in No. 1,048, p. 163. See also No. 742, p. 344; and the indices of some of the earlier back volumes.)—J. TOWNES. (Entirely depends on whether they are to study in class with laboratory practice; but see the lists issued by Macmillan and Co. and J. and A. Churchill.)—EBLANA. (We do not know of such a book. You do not say what kind of workroom.)—E. T. H. (It is a useless receipt, as was stated so recently as p. 539, No. 1116. The only serviceable method of cold soldering is that given in No. 888, p. 81.)—HORLOGER. (Yes, electric launches have entered the sphere of practice—one has already crossed the Channel. Accumulators are most convenient, and cheapest because they are charged by a dynamo. See the indices commencing with Vol. XXXVI. As to cost, so much depends on circumstances; but the price of the accumulators can be ascertained, and where a dynamo is used for lighting purposes at night the cost of charging the cells in the day would not be much.)—JASON. (For bright plating—that is, for plating surfaces which cannot easily be scratch-brushed, it is usual to add a little bisulphide of carbon. Put an ounce of the bisulphide into a pint of strong silver solution, having cyanide in excess; shake frequently, and in a few days a drop or two may be poured into the bath.)—YOUNG BEGINNER. (You should procure an illustrated list. Briefly, a "grand" is a horizontal (as a rule) with strings of full scale; a "cottage" is an upright, and a "cabinet," stumpy upright.)—ELECTRO-BELL. (The mat should be placed on a hinged part of the flooring, which will sink down when trod upon, and so make contact.)—W. S. (Have you a dynamo, or do you want to light up by batteries. Full particulars have been given many times. See, for instance, pp. 147, 148, 268, 285, 369, 390, 543, Vol. XLII.)—GEORGE. (Explained many times. You know that it is a patent, of course. Two wires are better, as "earth" return is not satisfactory with telephones. See any recent volume, or p. 266, No. 1079; p. 198, No. 1049.)—E. D. (A good form of mechanical telephone was described in No. 1061, p. 447.)—MOULDER. (When not cut out of retort scurf, they are made by moulding a paste of carbon dust and sugar or treacle under hydraulic pressure, and carbonising in vessels from which free air is excluded.)—T. SMITH. (Why use cement at all? Developing dishes are cheap enough, and can be readily moulded up in guttapercha to any desired size. However, if you must have cement,

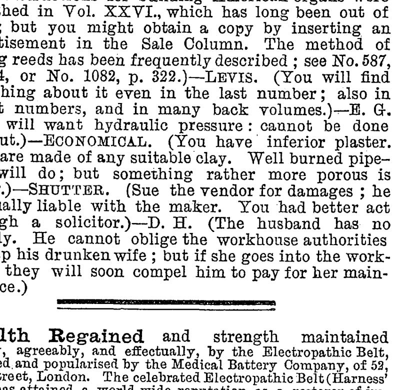
use marine glue.)—F. E. A. (There are plenty of small portable mills in the market for making meal. Probably you would find some at any large ironmongers in your town.)—E. W. (Red, green, and white. The number of sails on the foremast depends on circumstances; but say five at the outside—the foresail, or fore course, the topsail, topgallant sail, royal, and sky-scraper.)—IGNORANT. (Clean the metal thoroughly, and then coat with any good paint of the desired colour, and varnish with copal. Properly, it ought to be stoved.)—AMBULANCE. (See pp. 200, 220, last volume. Do not understand what is meant by "cannot fill it to the required height by 1 or 2 degrees"? There are no "degrees" in a barometer.)—H. WALKER. (Apply to Mr. Wray, North-hill, Highgate, for his lists, and compare with others.)—G. H. B. (If it is pure, the tools used for brass will do, keeping the work moist with water; but it is often adulterated with silicious matter, and the tools consequently require frequent grinding. Use a slow speed. As the question is of importance, we insert the query, as some reader may know of a better method.)—CHEMICAL. (The metals potassium and sodium inflame when in contact with water. Calcic phosphide will also do the same, so also will the gas obtained when potassic hydrate is allowed to act on phosphorus. You require special apparatus for the preparation of the metals.)—THOMAS ARMITAGE. (There is no remedy. Either have it regalvanised, or run solder over the parts—cleaning them thoroughly first.)—H. G. S. (Get Stainer's book from Metzler and Co., and see the lists.)—R. CARDWELL. (Full instructions for building American organs were published in Vol. XXVI., which has long been out of print; but you might obtain a copy by inserting an advertisement in the Sale Column. The method of tuning reeds has been frequently described; see No. 587, p. 384, or No. 1082, p. 322.)—LEVIS. (You will find something about it even in the last number; also in recent numbers, and in many back volumes.)—E. G. (You will want hydraulic pressure: cannot be done without.)—ECONOMICAL. (You have inferior plaster. They are made of any suitable clay. Well burned pipe-clay will do; but something rather more porous is better.)—SHUTTER. (Sue the vendor for damages; he is equally liable with the maker. You had better act through a solicitor.)—D. H. (The husband has no remedy. He cannot oblige the workhouse authorities to keep his drunken wife; but if she goes into the workhouse they will soon compel him to pay for her maintenance.)

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MIX.—BY J. PIERCE.

Black.



White. [8 + 8

White to play and mate in three moves.

SOLUTION TO 1007.

White.	*Black.*
1. Q-Q B 8.	1. P takes Q (*a*).
2. P takes Q, becoming Kt mate.	
	(*a*) 1. Anything else.
2. Q, B, or Kt mates.	

(Seven variations.)

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,007, by A. Dean (construction splendid), J. Mackenzie (very difficult for two-mover), J. A. M. (well constructed), I. M. Brown, "——," A Beginner, G. A. A. Walker, and Avon; to 1,006, by Avon, J. Thompson, and Isoa.

A BEGINNER.—You are under a misapprehension in thinking that White cannot claim a third Kt on P reaching the 8th square; a second Q may be claimed, a third B, &c. We have, however, allowed you marks for your attempt.

J. OUGH.—Your 2-er can also be solved by 1. R takes Q B P. Can you make it right?

T. H. BILLINGTON.—Thanks for 2-er.

"CHESS PROBLEM TEXT BOOK, WITH ILLUSTRATIONS."—Under this title a notable addition to the literature of the Chess Problem Art is in course of preparation, and will be issued as soon as possible. It will be the joint work of Messrs. H. J. C. Andrews, E. N. Frankenstein, B. G. Laws, and C. Planck, M.A., and, besides including a selection of 400 problems and positions by those well-known composers, will contain an illustrated essay on the art. The latter will be a novel and special feature in the book, no treatise or dissertation by any recognised authority having hitherto been published in this country. The volume will be brought out by the eminent firm of Cassell and Co., Limited, and the published price will be 6s.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and CO., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XI., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words, afterwards 9d. per line. Paragraph advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

Twenty-four words	0	3
For every succeeding Eight Words..	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Good Value Offered (cash or instruments) for all kinds of sound or repairable Scientific Appliances.—CAPLATZI, Science Depot, Chenies-street, near British Museum. Established 1862.

Commutator, 48 sections, nicely fitted, small Gramme Dynamo, 10 am., 35 Volts. Offers, electric,—NELSON, 13, Orr-street, Glasgow.

Wanted, a **Hayden Bar** in exchange for a muzzle loading Saloon Pistol, rifled and accurate; or offers.—Address, C. TOWNLEY, Ballingarry, co. Limerick.

Sliding **Resistance Box** and **Reflecting Galvanometer**, as new, by Varley Bros., cost £9. Offers in Photo. Apparatus.—A. J. S., 194a, Mare-street, Hackney, N.E.

Tricycle, 56in., Audax, good condition, roller bearings, very fast machine, offers to £5 value. Stamp for particulars.—J. R., 17, Newland-street, Kettering.

Magic Lantern **Lenses**, back and front, to show 7ft. picture, cost 6s., for electric bell or shocking coil to above value.—3, Lapstone-road, Millom, Cumberland.

Foot **Lathe**, 4in., in good condition. Will exchange for anything useful value 30s.; tools preferred.—W. S. CROKER, 51, Sutherland-road, Bow, E.

Will exchange capital 54in. Premier **Bicycle**, with ball bearings, for vertical boiler, about 2-horse, suitable for launch.—BRYAN, 37, North-street, Charlton, Kent.

Wanted, 50in. **Bicycle**, in good order, in exchange for Anglo-German Concertina, nearly new, cost £3 15s.—DUNLOP, 37, North-street, Charlton, Kent.

Will exchange last 10 Vols. "**English Mechanic**," unbound, for Photographic Camera or good half-plate Lens.—W. BALMFORTH, Scout-hill, Dewsbury, Yorkshire.

Will give 2¾in. **Slide-Rest** for Photo. Camera.—HOWES BETTS, Chatham.

Reflector, 6½ mirror and flat, perfect, Calver's, home-made equatoreal motion. Offers.—A. B., 2, Comboss-road, Hackney-wick, London.

Cylindrical **Electric Machine**, 10 by 5½, with brass stand, dischargers, &c. Exchange 6-cell Bunsen Battery or Induction Coil.—ROBINSON, 52, Bloomfield-road, Plumstead.

Sausage Machine, to fix on table, in exchange for something musical—cornet, banjo, concertina, or something mechanical.—Address, W. COX, Plumber, Beechen-grove, Watford, Herts.

"**English Mechanic**," from September 1, 1882, till present time, in exchange set of twist drills or gas stocks and dies, or pipe vice, or something mechanical.—Address as above.

10in. new powerful **Fan**, suit a smith, in exchange for gas tongs, pipe cutters, or small anvil (in order), or something mechanical.—Address as above.

What offers in **Photographic Apparatus** for 250 numbers ENGLISH MECHANIC, unbound?—J. FRAIL, Calderbank, Airdrie, Lanarkshire.

Exchange metal top, steel note **Concertina**, new, 20 keys, and Telescope, 3 draws, 6 inches, 16 inches length. Anything useful.—C. A. FOULSER, 48, Minerva-street, Hackney-road, E.

Compound **Microscope**, brass body, object table, reflector, test objects, and pair forceps, fitted in polished mahogany box. What offers?—G. GRANT, Queen's-street, Banbury.

Photographic.—Suter's No. 2 A Lens, Suter's No. 3 C Lens, both quite new. What offers?—A. B. C., 74, Tollington Park, London, N.

Four large Granule **Batteries**, 10 by 6 by 10 inches deep; 12 Leclanché Cells in box.

Lot of **Electric Light Fittings**, Permanent Magnets and Sundries.

The above will be exchanged for **Dynamo.**—KING, 15, St. John's-square, Clerkenwell, London, E.C.

Fan, 12½in. blades, Lloyd's, for six fires; also 6in. Fan, with hand wheel. Exchange for small drilling machine, or other useful tools.—PATRICK.

E.P.S. **Accumulators** (modern) wanted. Exchange dynamo, arc or Swan lamps, or any electrical goods.—PATRICK and SON, 529, King's-road, Chelsea, S.W.

Organ Materials.—90 Metal Pipes, 58 Wood Pipes, 1½ Octave Pedals, and other Materials. Will exchange for good English Lever Silver Watch or Gold Albert.—Address, 9, Brown Lion-street, Bloomfield, Tipton.

Pleasure Boat, cutter rig, 19ft., copper fastened, nearly new. Exchange for ½-horse Launch Engine and Boiler. Offers.—W., 39, Durham-street, Hartlepool.

44in. **Bicycle**, by Davies and Co., in good running order. Offers.—W. SAUNDERS, Dickleburgh, Scole.

Coventry roadster **Bicycle**, 54in., good condition, value £3. Exchange Lathe and Fretsaw. Approval.—ANSLEY, 32, St. John's-road, Faversham.

Wanted, cheap modern **Books** on Pattern Making, also on Practical Receipts; or I have two 16-wick Lamps; would exchange; quite new.—W., 78, Viaduct-street, London, E.

Lantern Slides, 30, in exchange for anything useful. Views, Hymns, &c.—R. BARCLAY, Gariochsford, Forgue, Huntly, N.B.

Tricycle, Coventry, two-track double-steering, perfect order, newly painted; suit any height of rider. Offers.—FORD, 76, St. Paul's-road, Camden, N.W.

Bichromate Battery, ten-cell, double carbons, 7 by 3½, rest on frame and wind out of solution. Exchange for Lathe. Also Powerful Electro-Magnet. Offers.—146, Campbell-road, Bow, London.

Loco. Wheels, new, set, brass, two 3in. drivers, and 4 Bogie, 2¼in., cheap.—What offers to G., 204, Devonshire-street, London, E.

Shafting, 1½in. pulleys and brackets; 28in. single Lathe Wheel, 90lb., 3ft. crank; Chemist Carboys, 1½ gallon each. Offers.—W. SMITH, Bilston-road, Wolverhampton.

Youth's **Tricycle Frames and Fittings**, three ready for wheels, 50 yards Wire Netting, Perambulator Wheels, Axles. Rubbers, Plated Caps, 2½in. Steam Gauge. Exchange.—W. SMITH.

Steam Engine, about 2 H.P., fair condition, in exchange for good 50in. Bicycle, or anything useful.—R. SMITH, Fazackerley-street, Chorley.

Horizontal Tubular Boiler, about 6 H.P., excellent condition. Exchange for good Tandem, or anything useful.—R. SMITH, Fazackerley, Chorley.

Sympiesometer (Adie), Surveyor's 3in. Aneroid, scale 8,000. Rothwell Dividing Micrometer, cost £15 15s. Double Refracting Goneonometer, Protractor, Book of Tables.—S., 211, Ball's-pond-road.

Wanted, a pair of new or second-hand **Back-geared** LATHE HEADS, about 5in. centre; must be well fitted; exchange.—12, Mill-street, Nantwich.

Exchange **Magic Lantern** and good half-plate View Lens. Wanted, Symmetrical half-plate Lens.—J. FRASER, Cottown, Glencarse, by Perth.

Good exchange for **Ginger Beer Plant.**—H. SANDERS, 19, Percy-street, Hull.

For 3¼in. **Object Glass** (Dollond preferred) will exchange Silver English Lever Stop Watch; good condition; cost £6 6s.—H. NAYLOR, 9, Carberry-terrace, Burley, Leeds.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

New Illustrated Price List of **Screws, Bolts, and** NUTS for Model Work, drawn to actual size, sent on receipt of stamp.—MORRIS COHEN, 132, Kirkgate, Leeds.

Fretwork.—Catalogue of every requisite, with 600 illustrations, free for 6 stamps.—HARGER BROS., Settle, Yorks.

Perspective, do you understand? "Knight's Practical Guide," 1s.—SIMPKIN and MARSHALL, or of J. P. KNIGHT, Art Master, Cheltenham.

Mica or Talc.—RICHARD BAKER and CO., 9, Mincing-lane, London.

Hardy's Patent **Safety Benzoline Lamp**, self-lighting, self-extinguishing, and unspillable post free, 1s. 3d.—THISTLETON, Oakham.

—**Wheel-Cutting** to 12 inches diameter in brass only.—CLEGG, 18, Belinda-street, Hunslet, Leeds.

Planing to 12in. by 12in. by 8in. Boring, Turning, Screw-cutting, Slide-rests, &c.—CLEGG, as above.

Tracings heliographically reproduced at from 3s. Mechanics' drawings prepared.—Patent Office, Ashcroft-buildings, Victoria-street, Liverpool.

Patents.—Provisional Protection from £2. Complete from £5.—MANAGER, Patent Office, Ashcroft-buildings, Victoria-street, Liverpool.

Lathes, 3in. to 7in. centre, chucks, tools. Illustrated List, 3d.—MILLS, Tintern-street, Sunderland.

Castings, Lathe Heads, Beds, Standards, Wheels, Slide Rests, Chucks, rough or machined. Illustrated List, 3d.—MILLS, Sunderland.

Launch Boilers and Engines up to 6½in. bore. Locomotive Boilers, Engines, Castings supplied. State requirements.—MILLS.

Model Engines, Parts, Tubing, Screws, Castings, rough or bored, turned, fitted, finished. List, 3d.—MILLS, Sunderland.

Lathe Castings, &c.—See T. Taylor's advertisement in ENGLISH MECHANIC every other week. Established 1847.

Turning, Boring, Planing. Low rates. First-class machinery, best attention. Quantities estimated for.—PARFREY, Engineer, Hounslow.

Gas Engines, new patent, double acting, simplest and best in the market, ½ to 100 horse-power.—Particulars of H. CREWE, 16, Montpelier Vale, Blackheath, S.E.

Electric Light Installations. Complete sets from £8, with and without machinery.—H. CREWE, as above.

Photographic Dark Slides, warranted light, tight; ½-plates, double, 2s. 6d. each.—31, Yates-street, Aston, Birmingham.

Elastic Stockings, Abdominal Belts.—SMITH, 37, Breck-road, Liverpool. Only wholesale and retail makers in England.

Bentley's Electrical Stores, 7, Newton-street, Manchester. The cheapest house for bells, batteries, wires, and all fittings.

Lathe Castings, heavy geared heads; 3½in., 5s. 6d.; 4in., 6s. 6d. Standards, Gap and Plain Beds, Chucks.—Below.

Taps, Dies, and Screws cut to order. Reply, stamp.—JARRATT, 15, Short-street, Queen-street, Leicester.

Organ Pipes.—Metal Dulciana Tenor C, Wood Flute, Pedals, &c.—Mr. REID, Addington-villa, Wendover, Bucks.

Wimshurst Influence Machine.—Sole manufacturers of new and improved pattern. 12in. from 30s.—KING MENDHAM, and Co., Bristol.

Deposition of Smoke—Complete Apparatus to perform this never failing experiment, with static electricity, 5s. 6d. and 10s. 6d.—As above.

Standard Ohm, in boxwood cylinder, guaranteed correct to ten thousandth of ohm, 18s. 6d., with copper poles, 21s.—As above.

Galvanometer Cards for tangent and ordinary combined, vertical, astatic, reflecting, and unmounted compass cards.—As above.

Variable Resistance Incandescent Lamp STAND, invaluable for battery power, vide ENGLISH MECHANIC, Oct. 16, 1885, price 3s. 6d.—As above.

Write for **King, Mendham, and Co.'s** large new and reduced Price List, post free, 4 stamps.

"Beginner's Guide to Photography," one shilling. Wholesale of the publishers, LEJEUNE and PERKEN, Hatton-garden, London.

"Beginner's Guide to Photography," one shilling. Free from abstruse technicalities. Retail of Opticians and Booksellers.

Boilers, Vertical, Portable, and Cornish, one horse-power upwards. — GRANTHAM CRANK and IRON COMPANY (Limited), Grantham.

Perambulator Wheels, rubber tyres, with axles complete. Set of four, 10s. 6d.—CYCLE SUPPLY, Blackheath, London.

Tricycle Frames (front-steering central gear), all parts brazed, 50s. Photo, 3d.—CYCLE SUPPLY, Blackheath, London.

Sociable Tricycle, Starley and Sutton's Coventry, grand machine for hiring; perfect condition: £8.—CYCLE, Blackheath, London.

5in **Shaping Machine**, hand or steam power, very strong; nearly new; a bargain.—F. BRITTAIN, 50, Upper George-street, Edgware-road, London.

Rotary Pump, cheap, hand or power, pump any kind of liquid.—J. STOREY, 37, Farringdon-street, London.

Organ Metal Pipes voiced and unvoiced. Lowest prices.—SHIELD, 127, Little Green-lane, Small Heath, Birmingham.

Leclanche **Batteries**, 14s., 16s., 24s per doz. Sample, 1s. 9d., free.—SEDDON, 5, Queen's-road, Chadderton, Oldham.

Dynamo, F.M., planed and bored, very cheap, 4 cwt. copper wire, No. 10 cotton-covered, lengths from 250 yards, all clean, 6d. lb.—NELSON, 13, Orr-street, Glasgow.

Trouser Lengths, 5s. Cheap cloth for ladies' jackets, ulsters, dresses. Patterns free.—HEWITT, Winfield Mount, Leeds.

Indigestion.—Remarkable cure for flatulency, &c. Send postal order 1s.—WATSON, care of 11, Gildredge-road, Eastbourne.

The Art of Staining, Graining, French POLISHING, &c., seven stamps.—HARVEY, 45, Halton-road, London, N.

Electric Depot, 10, Deansgate, Manchester. Handiest shop in the trade. Largest stock. Greatest variety. Lowest prices.

1s. **Rules for Learning to Write**, with exercises and instructions.—R. H. KAY, Ramsbottom-lane, Ramsbottom.

Britannia Co., London Showroom, first floor, 99, Fenchurch-street. All letters to Britannia Works, Colchester.

We are **Bona Fide Makers** of upwards of 250 varieties of Lathes and Engineers' Tools.—BRITANNIA.

Thousands of **Castings** for Lathes, rough or milled, drilled or turned. Give exact details.—BRITANNIA CO.

Surplus Stock.—New **Files**, 6in., 4d.; 8in., 6d.; 10in., 8d.; 12in., 10½d. Sent per post 1d. to 2d. extra.—BRITANNIA CO., Colchester.

Patent Treadle **Saw**, easily cuts 4in. square. — BRITANNIA CO., Makers, Colchester.

Patent **Saw** and Samples of Work on view.—BRITANNIA CO., 99, Fenchurch-street, London.

3½in. **Electric Bells**, plated under domes, 4s. 3d., free. Ebonised or boxwood Pushes, 8d. free.—PENNING.

Chromic Acid, 1s. per lb. Salammoniac, crushed, 8d. Ebonite Cells, 7 by 5½ by 3½, 1s. 6d.—PENNING.

Wire, cotton and silk covered, per lb., No. 16, 1s. 7d. and 2s. 6d.; No. 26, 2s. 6d. and 4s.; No. 36, 6s. and 10s.—PENNING.

Ilford ½ Dry **Plate**, 1s.; ditto, 5 by 4, 1s. 9d.—PENNING, Southsea Laboratory, Southsea.

The **Safety Governor**. — MATTHEW TAYLOR BROWN, 33, Hope-street, Glasgow.

Brass **Door Plates**. 9 by 4, any style, sent free, 4s. 6d.—DEACON and SON, Ramsgate.

Brass Plates made and engraved at lowest prices Estimates given.—DEACON and SON, Engravers, Ramsgate, Kent.

Zinc **Stencil Plates** for marking sacks, boxes, &c. Estimates free on application.—DEACON and SON, Ramsgate.

Hot Air Engines.—Models that will work constantly, 12s. Particulars, stamp.—J. SEAL, Chapel-street, Hammersmith.

J. Seal's **Hot Air Engines** give satisfaction wherever supplied, and are pronounced well worth the money.

120 Fretwork Patterns for 1s 6d. Full-size black designs, brackets, glove, jewel, and work boxes, trays, stands, easels, photo frames, clock cases, panels, alphabets, &c., post free, 1s. 6d.—COLLINS, 1, Westgate-buildings, Bath.

What offers for **"Dr. Ure's Dictionary of Arts,** MANUFACTURES, &c.," 4 Volumes, seventh edition, bound in half Russia leather, in good condition?—C. W. HARDING, Lynn.

Lathes, Files, Saws, Steel, cheap and good, cash or hire. Satisfaction guaranteed.—ROBINSON, Catherine-street, Sheffield.

Mesmerism.—"The book is a very good one, and anyone can learn the art from it."—*Weekly Budget.* 2s. 6d.—W. THOMAS, 22, Clarendon-road, Anfield, Liverpool.

Gas Engines, 1-man to 10 horse-power, reliable and cheap, numerous references.—ELLIS BUTTERWORTH, Rochdale.

Dancer's Jubilee **Opera and Field Glasses**, 12 lenses, new series—Catalogues, 11, Greenhill-street, Greenheys, Manchester.

Collapsible Boats and Fishing Punts, as exhibited at Liverpool, measuring 9ft. 6in. by 30in. by 13in. when open, 30in. by 30in. by 5½in. closed. Weight about 30lb. Two sents, very portable, price £7.—Patentee, G. BARRETT, 253, Essex-road, Islington.

Metallic Violin Strings, acknowledged best Six post free 1s.—JOHN ELARCO, 24, Fern-grove, Liverpool, S.

An 8in. Silvered Glass **Reflecting Telescope**, also a 4in. Achromatic Reflecting Telescope. Will sell at one-fourth usual prices.—Address, 16, Victory-street, Holbech, Leeds.

Brass Castings of Model Engines of all classes, in sets or otherwise. These castings are the best in the trade, and have obtained the highest testimonials from amateurs and others in all parts of the United Kingdom for cleanness of moulding, ease in finishing, and correctness of detail and design; being models of engines of modern construction. Boilers supplied of every type to suit the above from stock or to order. Fittings of all kinds, feed pumps, governors, safety valves, steam gauges, water gauges, &c. Comprehensive price list, post free, two stamps.—LUCAS and DAVIES, 21, Charles-street, Hatton-garden, London.

4½in. **Screw-Cutting Treadle Lathe**, 4ft. gap bed; 8in. four-jaw chuck, drill-chucks, tools, &c., all new, £23 the lot.—E. B., 64, Park, Eccles.

Terminals, Terminals.—One shilling per dozen. Sample Terminal, free, two stamps.—CROOK, 77, Vernon-street, Bolton.

Organ Materials, new and second-hand, cheap.—R. F, 184, Kennington-road, London, S.E.

Violinists will hear of something to their advantage by sending address to W. RITCHIE, Grove Market, Hammersmith.

½in. **Spark Coil and Motor** combined, took first prize at Shildon Exhibition, 1886, will take £2, or part wire and cash.—J. BATE, Bowden Close, Crook, via Darlington.

Bust.—Fowler's Phrenological China Bust, cost 10s. 6d., will take 7s. 6d. Without blemish.—J. BATE.

Electro - Plating and Gilding successfully Taught. Every requisite supplied.—Address, HENRIC, 234, Great Colmore-street, Birmingham.

Nickel - Plating. — Batteries, Nickel Salts, and Anodes. Every requisite.—Address, HENRIC, 234, Great Colmore-street, Birmingham.

Lacquers.—Green, Gold, and Silver (light or dark), any shade, complete with brush, post free, 1s. 6d.—Address, HENRIC.

Parallel **Vice**, quite new, 10in. jaw, intake 13in., very strong, very cheap, 20s., on rail.—TAYLOR.

Files, seconds practically firsts. Sorts to suit. Best maker's brand. Above 12in., 8½d. per lb.—TAYLOR.

Lot 4½in. half-round frame **Saw Files**. Excellent, perfect, new. Dozen, 2s. 3d., free. Worth 4s. 6d.—TAYLOR.

Two **Force Pumps**, 1½in. ram, worth 50s. Exchange printing press and type.—TAYLOR, Wakefield-street, Warrington.

Wood Engraving.—Blocks for Advertisements, Patents, Trademarks, Machinery, engraved by W. FORBES, 3, Cable-street, Liverpool.

Quantity of **Music and Instruments** for sale, ridiculously cheap. Approval. List free.—W. RITCHIE, Grove Market, Hammersmith.

Safe, 30in. high, 2 drawers, very secure, powder and fireproof, £4.—32, Cleveland-street, Wolverhampton.

Glass Discs for Specula.—6½in., 2s. 6d.; 7½in., 3s.; 8½in., 4s. Pamphlet, "Polarised Light," 2 stamps.—HOLMES, Essex-road.

100ft. Glass, cut sizes, packed, 13s.; 21oz., 18s.; Opal Glass, cheap.—HOLMES, Essex-road.

Violin, magnificent solo tone, rare antique looking, labelled "Stradvarius, 1691," good lock-up case and bow, only 21s. Approval.—Mrs. T., 86, Avenue-road, Acton.

First-class **Lathe**, equal to new, compound geometric, eccentric, and spherical chucks.—GEO. PLANT, Alsager, Cheshire.

Lathe Castings for 3in. Bench Lathe, 25s. per set. A few sets with slight imperfections, 21s. These are smooth castings of best design. Other sizes in proportion.—BRITANNIA CO., Colchester.

Gas Engine, two-man Bisschop, equal new, replaced by larger, £21. Shown working.—BARKER, Scholefield-street, Birmingham.

Pair Gillett's **Telephones**, never been used, cost 16s. Will sell for 12s.—15, Canal, Salisbury.

Complete Amateur **Engineer's Outfit** for sale. Ornamental Lathe, by Milnes, Engine, Tools, &c., perfect and nearly new. Offers.—ERNEST SKURRAY, Moulsford House, Moulsford, Berks.

40 Pounds No. 26 **Copper Wire**, cotton-covered, 9d. per pound. Small quantities 1s. per pound.—KING, 15, St. John's-square, Clerkenwell, London.

12 Layer Compound Permanent **Magnet**, 6¾in. by 4in., 12s.—KING, 15, St. John's-square, Clerkenwell, London.

Dynamos.—Machines for Incandescent Electric Lighting, capacity from 300 to 30,000 watts.—STAFFORD and EAVES.

These **Machines** contain all the latest improvements. We guarantee them thoroughly efficient and reliable.—STAFFORD and EAVES.

The **Magnet Limbs** are made from solid Forgings of the finest brand of wrought iron.—STAFFORD and EAVES.

Compact, Neat, Reliable, Cheap.—Catalogues, two stamps.—STAFFORD and EAVES, Dynamo Engineers, Volt Works, Coventry.

Deblooming Rosin Oil.—For its special manufacture write to J. M., 6, Hamlet-street, Bootle, Liverpool.

Set of **Patterns** for 3in. Screw-cutting Lathe. No reasonable offer refused.—BULLOUGH, 6, Meads-row, Lambeth.

Architect's **Staff**, Tripod, and 12 Sight Rods, £3, nearly new, a bargain.—JOSEPH WOOD, Barrow-in-Furness.

"Encyclopædia" 13 Vols. Mackenzie's, or 14 do. Blackie's, complete, nearly new, bargain.—JOSEPH WOOD, Barrow-in-Furness.

Microscopic Objects.—Good collection for sale. Sample 2 doz., in rack box, 10s. 6d.—Particulars, W. WHITE.

Microscopic Objects.—12 beautifully prepared objects ready for mounting, 1s. 1d.—W. WHITE, 17, York-street, Nottingham.

Smythe's Celestial Cycle for sale, or exchange for good 3in. Telescope, Wray preferred.—W. FREEMAN, 98, Plumstead Common-road, Woolwich.

Launch Engines, Boilers, Lathes, Propellers, and all kinds of Machinery at reduced prices.—S. SMITH, 11, West-street, Soho, W.C.

Lathe, 4in. Screw-cutting, 4ft gap bed, chucks, and change wheels, complete, £20; 5in. single, £9 10s.—S. SMITH.

Block Letters for Engineers' Patterns, from ⅛in., in "Wide," "Medium Condensed," "Extra."—LEANEY, Langton-road, Brixton.

Type Writer for 21s.—FEETUM, 3, Belmont Drive, Liverpool. P.O.O. payable at Tuebrook.

Electric Indicator Dials written gold or any style. Lowest prices.—69, Stonebridge-road, South Tottenham, N.

Classes for Amateurs in Carving, Turning, and Carpentry will reopen 27th inst.—SYER, 1, Finsbury-street, E.C.

Fretwork.—New Catalogue of Wood Machines, Saws, and Designs, nearly 300 illustrations, post free, 4d.

Fretwork.—Complete outfit, 12in. frame, 48 Saws, Awl, File, 4 designs, and sufficient Fretwood, 3s. 6d., free.

Fretwork.—12ft planed Fretwood, 3s. 6d. Fretwood, 3d. square foot.—J. H. SKINNER and Co., East Dereham, Norfolk.

Brass **Model Engine Castings**, rough and finished, best quality. List, stamp.—WOOD, Dalley-street, Broughton, Manchester.

Recipes for making Cements, over 60, post free six stamps.—C. TARR, 5, Providence-place, Ayliffe-street, New Kent-road, London.

Camera and Stand, Merveilleux landscape lens and portrait combination, developing dishes, ruby lamp, all nearly new, 30s., part exchange, mitring machine. Offers.—J. LEVH, Grove, Stanmore.

Shippey Brothers, 13 and 14, King-street Cheapside, London, are prepared to give estimates for Electric Lighting of any magnitude. N.B.—Domestic Lighting a speciality.

The Wonderful Lamps under discussion, as used by Mr. Bottone, are supplied by us in 2½, 5, and 10 candle-power. Sample by post, 3s., 33s. doz.

Shippey Brothers' New Glow Lamp in opaline globes, 45s. dozen, specially adapted for reading lamps. Price 4s.

Shippey's Portable **Electric Battery** and Reading Lamp, in polished case, complete, 30s., 42s., and 63s.

Shippey Brothers keep the largest stock of Electrical Fittings in the trade. Electric Lamp Brackets from 1s. 6d.

Arc Lamps, Holders, Switches, Cable Leads, Carbons, Dynamos, Batteries, Bells, Indicators, at lowest prices. Inquiries solicited.

Shippey Brothers, British Agents for the Daussin Domestic Motors and Steam Engines, ½ to 6-man power.

Shippey Brothers require District Agents in all parts for the sale and hire of Electrical Plant.

Steel Name Stamps, 3d. per letter. Figures, set, 2s. 4d. Letters, 6s. 4d. — E. F. BALDWIN, Robinswood-hill, Gloucester.

Amateurs' Water Motors, half-horse, registered, Brass Sets, 12s. Full-size Working Drawings, 1s.—WHEELER, Preston.

Water Motors.—32s., 42s.: horse-power, £9; Half, £6; Quarter, £4; Eighth, £3.—THOMAS WHEELER, Preston.

Fan Castings.—Improved Registered Designs; set, 5in., 3s.; 6in., 4s.; 8in., 5s. Drawings, 4d.—WHEELER, Engineer.

Drawings, Tracings of every description. Working, Plain, and Coloured Drawings, &c., on shortest notice. Moderate charges.

Sawing, Milling, Pumping, Electrical, and other Machinery designed, and models made at moderate charges. Estimates free.

To Inventors who file their own Specifications.—Drawings for British patent at moderate charges.

Thorough Knowledge of the requirements for both British and Foreign Patent Drawings. All at moderate charges.

Rough Sketches only needed for any of the above.—Address, A. MELHUISH, 138, Hemingford-road, Barnsbury.

"The Dynamo." How made and how used. S. BOTTONE'S new book. Price, post free, s. 6d.

Dynamos of the highest efficiency, from 30s. Plating dynamos, from £5. Numerous testimonials.

Am-meters, 5s. Voltmeters, 5s. Galvanometers, 5s. Tangents, 10s. Standard Ohms, 2s. 6d. Bridges, 5s. Lists, 1½d.—S. BOTTONE, Stanley-road, Carshalton.

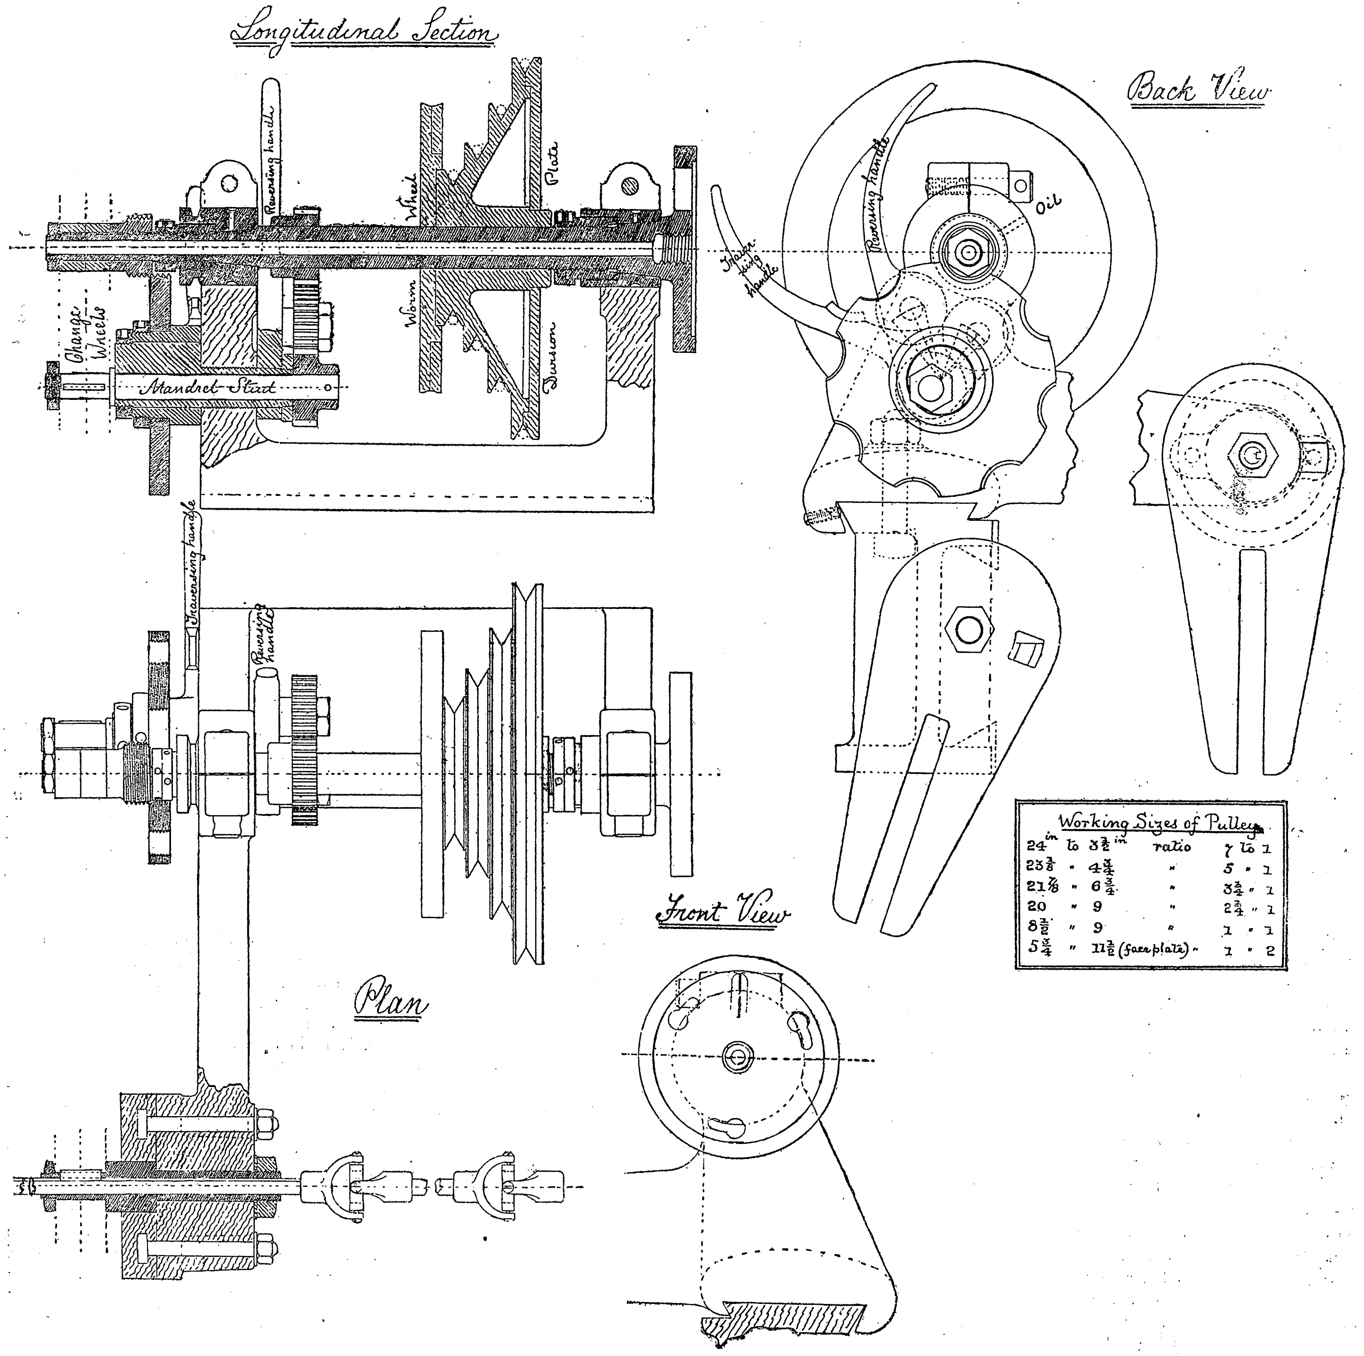
Bicycle, 50in., roller bearings, Timberlake head, crank handles, pouch, bell, lamp, £3.—A. BOTTONE, Carshalton, Surrey.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, SEPTEMBER 24, 1886.

A NEW FORM OF HEADSTOCK.

THE accompanying drawings show a headstock in which there are many departures from the orthodox form. Each of these appears to have some advantages, and perhaps some of them may be considered to be improvements. Some of these devices originated with correspondents in the columns of the ENGLISH MECHANIC, and have been partly discussed already, and they are here embodied in the design. The drawings include also plans of the lathe-bed with saddle, having the front and vertical slide so many times discussed, and now put into practical shape, and these can be sent if desired.

The first feature in the new headstock which requires explanation is the traversing mandrel. This has conical necks, and could not traverse at all if the collars were fixed in the usual way. These collars are, however, so fitted into the split bearings of the headstock that, when the grip screws are released, the mandrel, collars and all, can traverse forth and back. They fit, however, rather tighter than the running part, as, since this movement is very small, friction is here of no account. When the grip-screws are tightened, the collars are grasped all the way round, and held as firmly as when shrunk in, so that, when using the lathe for ordinary work, the traversing movement not being required, it would act with exactly the same steadiness. The fit of the collars to the conical necks can be adjusted with the same nicety as with a lathe having a non-traversing mandrel. Moreover, were this mandrel fitted to traverse in the usual way, and were it then frequently used for small metalwork, milling, &c., it is only reasonable to suppose that, however hard the mandrel might have been made, there would be a danger that at last it should become necked, and so run too loosely, which looseness would be naturally fatal to good work, and could by no means be taken up. This form of mandrel with traversing bushes is intended to give the power to take up all looseness caused by wear, and it appears therefore well suited to a lathe intended for small metal work, as well as for ornamental turning. One of the nuts for setting up each collar is very long: this is to insure a good and true bearing on the end, and it enters within the collar in order to shorten the surface exposed to friction. The average diameters of the two bearings are 1¼in. the larger, and ⅞in. the smaller, both being 1in. long. This is as large a surface as could well be driven by the foot at a speed ratio of 7 to 1, which speed is required by those who do small work in hard wood. It would, of course, be much better for the metal-work, and especially for milling, to have the necks a great deal larger in diameter; but then all thought of small work in wood requiring speed would have to be abandoned, whereas this headstock is intended for small ornamental turning as well as for metal-work, such, for instance, as making the chucks and appliances required in eccentric turning. Another matter in connection with the collars is the method of oiling. These collars, as well as sliding endways, are free to turn; it has not been sought to prevent this, because it may tend to equalise the wear and insure continued centrality. A shallow groove has therefore been cut round the collars, and two



or more holes are bored through the collar at the bottom of the groove for the passage of the oil. A hole must be drilled through the casting to introduce oil into the groove: this hole may be seen dotted in the back view. The mandrel is shown with a female thread, and a large flange, which is not a necessary part of the design. The small chucks would screw into the mandrel in the usual way, also the lathe centres, except that they would have rather large shoulders. The ornamental chucks and faceplate chucks would have no central screw, but only a plain fitting and three small screws, similar to those used in mounting the American universal chucks, except that, instead of removing these screws to fix and unfix, their heads would be passed through the holes seen in the front view, the chuck would be turned slightly round, and the three screws would then be fixed one after the other by half a turn of a small spanner. No doubt this would take a little longer than the usual plan, and it would apparently be impossible to pass the ring of the oval chuck over the flange; but the interchangeability by this method should be more perfect than by any other, owing to the size of the flange fitting. We come now to the traversing mechanism. The star-guide is mounted upon the strap of an eccentric, and from this strap proceeds an arm forming the reversing handle. When this handle is depressed, as shown in three views, the star-guide is raised into contact with the screw-ferrule, and the mandrel will traverse; by raising the handle the star is disengaged. This should be done when the mandrel has taken up its proper position; the tongue or wedge seen on the reversing handle will then fall into the deep groove in the hinder collar and hold the collar and mandrel from further endlong movement. Thus the movement of the reversing handle is all that is required to fix or set free the mandrel for traversing; moreover, the retaining wedge does not take effect upon the revolving mandrel, but upon the sliding collar, so that it would not add to the friction nor tend to wear itself away.

The reversing arrangement is another new feature. In order that it should not interfere with the traversing mechanism, the eccentric on which the star-guide is mounted is bored, and the mandrel stud passes through it. A fair-sized wheel can now be placed upon the stud without interfering with the mandrel. If, however, a larger wheel still were required, as, for instance, when cutting a quick-pitch spiral, it would be better to avoid the looseness caused by the small reversing wheels, and in this case the pin securing the small-gear wheel on the mandrel stud would be removed, and then the stud would be pulled out to the left, leaving the mandrel end free to receive wheels of any size.

In the plan, an arm is seen carrying a boss with wheel-plate, and a sliding shaft with long key-way and Hooke joints, to carry the motion to the screw of the ornamental slide-rest or to the traversing screw of the saddle for surfacing metalwork, or for giving the feed in milling with the slide at any height. A lead-screw and second wheel-plate may be added, as seen in the back view, if long work is to be done, and in that case the wheel-plates could be used together, if necessary.

There are 4 grooves on the speed-pulley running into 4 on the flywheel, and giving speed ratios of 7 to 1, 5 to 1, $3\frac{1}{4}$ to 1, $2\frac{1}{4}$ to 1; besides these four speeds there are two others by a shorter band running from the largest groove on mandrel to a ring the same size on the wheel, giving a ratio of 1 to 1; and a still slower speed may be obtained by a groove cut round the large 12in. face-plate, and working into a small 6in. pulley beneath, on the crank shaft, giving a ratio of $\frac{1}{2}$ to 1. This last speed ratio should be slow enough to allow of iron of 4in. or 5in. diameter being turned—as much as the mandrel is fit for; it would, therefore, be of no use to add back-gear.

To assist in determining the scale, it may be added that the extreme length of the mandrel is 16in., and the largest diameter of the pulley $9\frac{1}{4}$in., whilst the height of centres is 6in.

F. A. M.

IMPROVEMENTS IN VOLTAIC BATTERIES.

AMONGST recent improvements in voltaic batteries which deserve more than a passing note, we find several that have features which will recommend them for certain purposes, and some which may be specially suited for electric lighting, though it is as well to observe that the advantages and disadvantages of any given battery are never fully recognised until it has been tried for a considerable period in critical work. Schanschieff's new sulphate of mercury cell, which we described in No. 1094, p. 26, has for its principal improvement a new liquid, though the general arrangements make it a handy and useful cell, giving little trouble in recharging, while the zincs can be worked until they are practically worn out without amalgamating them. The Schanschieff cell consists of elements of carbon and zinc, and the exciting liquid is prepared by mixing basic sulphate of mercury with three times its weight of water. To this is gradually added drop by drop strong sulphuric acid, which dissolves the sulphate until at last a drop of the acid produces a precipitate. This preparation is then cooled and filtered, and the resulting liquid forms the exciting fluid for the battery. In working the mercury is recovered, being found in a metallic form at the bottom of the cells.

In the battery devised by M. Desruelles, of Paris, and patented in this country by Mr. J. H. Johnson, two liquids are employed—one being an exciting liquid for dissolving the soluble electrode, the other a depolarising liquid whose function is to absorb the hydrogen set free during the electrolysis. The exciting liquid is composed of water and sulphuric acid which has macerated for about seven or eight days with peroxide of manganese, bisulphate or sulphate of peroxide of mercury, oil, and glycerine in the proportion of, say, about one thousand parts weight of water to three hundred of the prepared sulphuric acid (at about 66° sp. gr.), eight parts of the sulphate, one part of colza oil, for example, and two of glycerine. The depolarising liquid is composed of water, with the addition of an alkaline bichromate, such as bichromate of soda or potash, in proportion varying from, say, about one hundred to one thousand parts by weight of the bichromate to one thousand parts of water, and an equal quantity of sulphuric acid at about 66° sp. gr. This sulphuric acid is soaked or macerated with peroxide of manganese for about one month before it is used. To this mixture is added about one quarter of its weight of nitric acid at about 40° sp. gr. The zinc employed as the soluble electrode is carefully covered before being introduced into the existing liquid with a fatty or greasy coating composed of, say, about one hundred parts by weight of tallow, twenty-five parts by weight of paraffin, and three hundred of mercury, ground or pounded together. The electrical resistance of this coating is not sufficient to interfere with the working of the battery, but it protects the metal from the corroding action of the acid when the circuit is open. The positive electrode of the battery is formed of plates of carbon prepared by soaking in water containing sugar, after which the plates are dried and exposed to a smoky flame, so that the sugar melts and is converted into caramel or burned sugar. The specific gravities above given are probably degrees of Baumé, but it is not stated.

A German device of Messrs. Pollak and Wehr, of Berlin, patented here by Mr. H. J. Haddan, is a battery cell in which the depolarising substances are stated to be always regenerated. The patentee uses zinc and "metal" elements, the "metal"—copper, say—being in conducting connection with carbon, which dips only partly into the exciting liquid. The liquid will vary with the nature of the element. The patentee claims (1) in an element with two metallic electrodes the combination of porous carbon in electric connection with the positive electrode, for changing by local action the positive electrode partly into depolarising salts when the circuit of the element is not closed, from out of which salts, when the circuit is closed, the metal of the positive electrode utilised for their generation is again precipitated upon the positive electrode. (2) The porous carbon for use in the element made from small pieces of carbon and carbon dust by pressing and baking in the shape of plates or blocks, forming compact and good conductors of electricity, which plates may or may not be provided with perforations.

The Howard battery is an American device, patented in this country by Mr. Loeb. Like most American inventions of the kind, the claims are numerous, but the cell appears to be one of those using bichromate of soda with dilute sulphuric acid. There are two patents dated this year, Nos. 2647, 2648, but as the second seems to include the first it will be sufficient to indicate the nature of the chief claims, which are:—In a galvanic battery an outer jar of some infrangible material, as wood, with an inner cell, preferably of paraffin, or similar material. A porous cell with a grooved bottom, constructed to hold free mercury and the zinc element, which is a cylinder having its inner surface coated with paraffin. The liquids are bichromate of soda and salt, with (preferably) sulphuric acid in an aqueous solution. The salt is added with the object of producing free chlorine.

A "compound" battery has been patented by Mr. S. H. Emmens (10011, 1885), in which he employs one or more peroxidised lead plates in each cell, so mounted as to be readily removed and replaced when they are exhausted of their available oxygen. One or more plates of zinc, with dilute sulphuric acid or any suitable saline solution, complete the battery, which, however, requires a charging bath. This latter is composed of sulphate of copper, and the lead plates are charged with oxygen by being used as anodes.

SPEED-CHANGING MECHANISM FOR LATHES.

IMPROVEMENTS in speed-changing gear for lathes, which are also applicable to cycles and other machines, have been recently patented by Mr. A. G. Meeze, of Redhill, and the principal features are shown in the annexed engravings. One of the leading objects of the invention is to improve the construction of turning lathes—especially such lathes as are designed for the use of amateurs—by providing a cheap, compact, and efficient means of regulating and controlling the motion of the headstock mandrel and of adapting the angular velocity of the latter to the work in hand. To this end the ordinary back-gear is dispensed with and the headstock is constructed as described.

In Fig. 1, *a* is the frame of the headstock shown partly in section, and *b* is the mandrel, all of ordinary construction. To adapt the invention, at a suitable point near the middle of the mandrel, *b*, which may if desired be made of the traversing pattern, there is keyed or otherwise securely fastened a small cogwheel, *f*, and on opposite sides of this cogwheel is arranged a pair of step or cone pulleys, *d* and *e*, so as to turn freely and independently about the mandrel, *b*, as an axis. The face of one of these pulleys—preferably the pulley, *e*, on the righthand side of the said cogwheel *f*—carries one or more, by preference two projecting arms *h*, *h*, which serve as axles for secondary cogwheels or pinions *g*, *g*, turning freely thereon and at the same time running in gear with the cogwheel, *f*, upon the mandrel. The adjacent face of the second step-pulley, *d*, carries a cog-wheel, *i*, which is larger than either of the others and furnished with internal or hypocycloidal teeth cut and allocated to gear with the secondary cogwheels or pinions, *g*, *g*, described as mounted on the arms of axles *h*, *h*, which project from the face of the first pulley, *e*. The whole is thus arranged in gear to form an epicyclic train. In Fig. 2 is shown a sectional elevation (on the line 1, 2) of the essential elements of the epicyclic device; the similar parts of which are lettered to correspond with Fig. 1. From the arrangement of the elements of this combination it is obvious

FIG. 1.

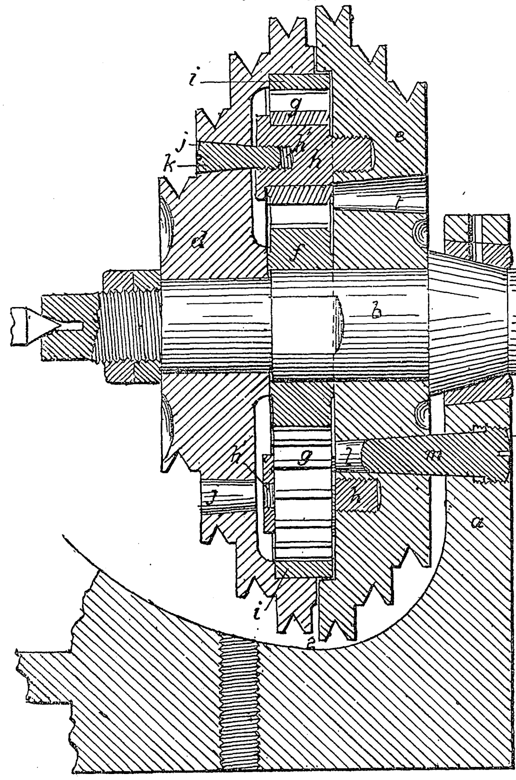


FIG. 2.

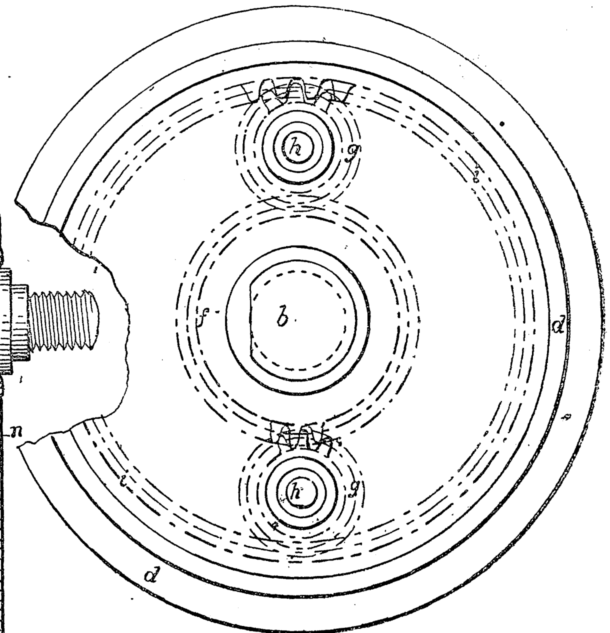

that if the first described pulley, *e*, be driven, while the second, *d*, is kept fixed, the headstock mandrel, *b*, will be caused to rotate in the same direction, though not with the same velocity, as the moving pulley, *e*; and it is also evident that if the first pulley, *e*, be fixed and the second, *d*, driven, the motion of the mandrel, *b*, will be retrograde. If, therefore, both pulleys, *e* and *d*, be driven in the same direction with a certain determinate difference of velocity, depending upon the relative diameters of the cogwheels, *f*, *g*, *i*, forming the epicyclic train, the mandrel will remain at rest. Any departure from this fixed ratio, as, for example, an increase in the relative velocity of the pulley, *e*, will result in a differential motion of the mandrel, which motion may be quick or slow as desired.

The way in which the patentee provides for the suitable and convenient motion of the step-pulleys of the headstock is by attaching to the driving or treadle shaft of the lathe a step-driving wheel or wheels, from which motion is transmitted by means of a pair of driving belts to the pulleys *d*, *e*, of the headstock. By this device each of these pulleys has an independent motion, and, by adjusting their driving belts to the proper steps or grooves of the driving-wheel, a convenient difference of velocity is created between them, suitable to the required velocity of the mandrel. Normally, the patentee uses only one driving belt and provides a suitable bolt or fastening for locking the two loose pulleys firmly together at will, by which means they are constrained to move as one with the headstock mandrel. In Fig. 1 is shown a device for this purpose consisting of a taper pin, *k*, contrived to fit a hole of corresponding shape bored through the pully *d*. One end of this pin screws into a hole, h^1, in the stud axle, *h*, and thus firmly bolts the two pulleys *d* and *e* so as to move as one with the mandrel. Also he provides means of locking or fixing, at will, one of the pulleys—for example the pulley *e*—so that it shall not revolve, while the other is left free to be driven by a belt from the driving-wheel; and, in this manner, a very much greater range of velocity is obtained in the headstock mandrel than has been hitherto possible. A simple device for fixing the pulley *e* is a taper pin, *m*, inserted as shown in Fig. 1 through a partially threaded hole, *n*, in the headstock frame into a conical aperture, *l*, in the pulley. In some cases a bolt is used (not shown in the drawing) attached rigidly to the frame of the headstock and contrived to be shot into the opening, *j*, in the pulley *d*. By this means pulley *d* may be prevented from rotating while the pulley *e* may be driven, and thus an additional set of velocities secured. Altogether the range of velocity possible to the mandrel of a headstock, proportioned as in the drawings, varies from the slowest conceivable creep up to three times that obtained in the normal way when the driving belt runs from the largest step of the main wheel to the smallest step of the headstock pulleys.

ENAMELLING COLOURED PHOTOGRAPHS.*

THE main objection to tinted or partially-coloured photographs lies in their unfinished and smudgy appearance, the albumen surface being in some parts covered and in others left untouched. To obviate this means either to fully work up the picture or to provide it with a new surface altogether. Enamelling, at first sight, seemed to offer an easy remedy, but was soon announced to be impracticable, at least by the same method used for the enamelling of plain or uncoloured photographs. The colours were found to run into each other, and over parts of the picture where they were not required, and where their presence in no way enhanced the pictorial or realistic *tout ensemble*. Such being the case, photographers naturally gave up the idea, and enamellers do not seem to have continued their research. Personally, I at one time gave a great amount of thought to the matter, and was somewhat agreeably surprised to meet, while in Malta, an artist who also seemed to think considerably on the subject. With his aid, I conducted a series of experiments, and after meeting with many rebuffs and failures of all descriptions, we were at last gladdened by the production of a genuine coloured enamel photograph. . . . In the first place, the picture which is to be subjected to the double process of colouring and enamelling should be printed a shade lighter than one meant to be treated in the ordinary way and turned out plain. Care should be taken not to over-tone it, a sepia grey being the tint calculated to produce the best results; and it should be untrimmed, a margin of at least ½in. all round being left. After fixing and washing it should be pinned, while still damp, on to a drawing-board, and when dry it is ready for the artist's hands. Ordinary moist or cake water-colours may be used; but to minimise the chances of failure we found the so-called albumen colours the best to use. The colours I refer to were introduced by M. Lambert some years since for colouring chromotype photographs, and were sold on cards by the Autotype Company, from whom I believe they are still obtainable. Care should be taken not to put the tints on too high, as enamelling serves to intensify them, and carmine should be used very sparingly, not only because the colour is fleeting, but because it has a tendency to run into spots, and give a rough appearance to the finished picture. The print being coloured and ready for enamelling, a sheet of glass (preferably plate glass) is prepared in the usual manner—that is, either with a solution of yellow wax in benzole, or with powdered talc. I personally prefer the first-mentioned, as the print usually comes off cleaner and more easily. A few drops of the solution are poured on the glass, which should be perfectly clean and free from scratches or flaws, and gently rubbed over the entire surface with a piece of clean flannel until it begins to set. It is then polished off with another piece of the same material until it appears clean, and polished again. To test if enough wax remains, the tip of the finger should be pushed along the surface near the edge, when, if properly prepared, it will meet with a considerable resistance, and produce a grating noise. It is then coated with enamel collodion in the same manner as a plate used to be coated for the wet process, or as a negative is varnished, and care taken that the collodion be not allowed to run into crapey lines. Immediately the collodion sets (not dries) it is immersed in a dish of cold water until all greasiness disappears. The coloured print should then be carefully collodionised in the same manner as the plate, and when the film is thoroughly set it should be passed through a solution of gelatine in hot water, then laid upon the plate and carefully squeezed until all air-bubbles disappear, which may easily be seen from the back of the glass. It is then put aside under pressure for an hour, when it is ready for mounting—or, rather, for a sheet of thin cardboard to be attached to the back by the aid of thin Russian glue, gelatine having a tendency to reduce the gloss of the finished result. It is then again placed under pressure for about an hour, and then set up to dry in a cool place. When thoroughly dry, the blade of a knife may be placed under the edges, and the picture will come off perfectly flat, and with a high enamel surface; and if the operations have been carefully performed the colouring will be found as clear and perfect as when first done. It now only requires trimming and affixing to the final mount, which is best done by the aid of coaguline, applied to the edges only. This may appear at first sight a very tedious and difficult process, but after one or two pictures have been enamelled it will become quite easy to manage.

A COMPENSATING PENDULUM WITH SOME SUGGESTED IMPROVEMENTS.*

By Richard Inwards, F.R.A.S.

THE best pendulums are already so delicately true in their timekeeping powers, that if any improvement be still possible, it seems likely to be in the direction of minute correctness in the compensation adjustment. Hitherto, in lengthening

* From the *Horological Journal*.

or shortening the pendulum for regulating purposes, the whole alteration has been necessarily made in the length of the steel centre rod of the pendulum. Now a minute error here occurs because the pendulum being built up of tubes of zinc and steel in the lineal proportion of, say, 7 of the former to 17 of the latter metal, it is evident that this proportion is disturbed if you shorten or lengthen one of the metals without doing so to the other in a proper degree.

The suggestion illustrated by the lower part of Fig. 1 shows the way in which I propose to remedy this defect, by the introduction of a peculiar form of nut A which is provided with two different interior threads, one in the lower part, of 20 to the inch, working on the end of the central steel tube B of the pendulum, and the other, of 50 to the inch, working on the lower outside end of the zinc tube C. The effect of this arrangement is that when the nut A is turned ever so little it shortens or lengthens the two tubes in the proportion of 20 and and some mechanical contrivance for easing the movement of the adjustment will be an advantage. Of course, the system of tubes must be prevented from turning on each other, and this may be done by the insertion at two or three points of screws and distance pieces as shown at E in the upper part of Fig. 1, the various tubes, except the middle one, being perforated with slits which allow of a slight up and down movement. It will be seen that the tangent screw operating on the nut A is prevented from turning round with it by a screw F traversing a depression G in the solid part of the centre rod of the pendulum. The arrangement of the worm wheel and tangent screw is shown in Fig. 3, in which it will be seen that the screw is carried by two pieces of metal (aluminium by preference), fastened together round the central screw; and it is also furnished with a lock nut I to fix the whole when adjusted. The upper part of the nut A is split, and when in its place is firmly pressed against the zinc tube by a ring J, so

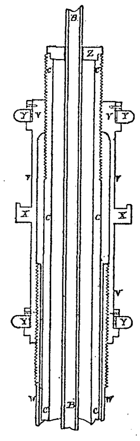

FIG. 2.

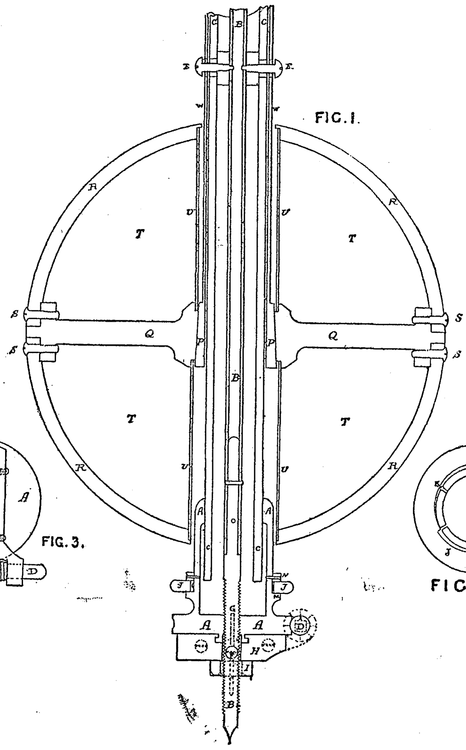

FIG. 1.

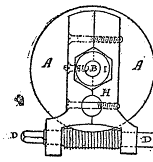

FIG. 3.

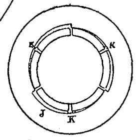

FIG. 4.

50, instead of affecting only one of them as in the arrangement now generally adopted. (I have put the screws as of 20 and 50 threads advisedly. The proportion given in books is generally 21 to 51 or 7 to 17. But I am informed that in practice the zinc almost alway comes out too long, and that two samples of zinc tube will give different results. Of course there is no difficulty in making the threads 21 and 51 to the inch if preferred; 14 and 34 would leave the central screw too coarse.) It is proposed to turn the nut by means of a tangent screw D, which will give almost any desired delicacy of adjustment. In round numbers, if the tangent screw have 20 threads to the inch and the worm wheel on the rim of the nut A have 125 notches, then $\frac{1}{8}$th of a turn of the the screw will raise or lower the nut by about the $\frac{1}{20000}$th of an inch, and as, of course, the screw may be turned much less than $\frac{1}{8}$th at a time, any required degree of fineness may be secured. It is besides to be remembered that this pendulum bob will weigh between 50 and 60lb., arranged (see Fig. 4) as when turned to press with great force on the small studs K, and so close the nut firmly on the tube. J is kept in place on the lower side by a flange M turned on the nut, and on the upper side by a ring N secured by fine screws (there is no great strain on them). This has been thought better than the more obvious plan of a screwed ring working on a taper, as the present plan secures against any minute difference which might be caused by using more or less force in screwing up the ring, and so leaving it in a different place. Naturally the precaution must be taken to loosen both I and J before turning the head of the tangent screw D. The balancing of the pieces H may be secured by slightly varying the form as found necessary, or by drilling small holes in the side opposite to the screw, and filling them with lead to the requisite extent.

With respect to the other features of this design, some of which are by no means novel, it will be seen that the central rod is made tubular except at the ends, where plugs of steel are inserted, secured by soldering and riveting as at L, and, of course, at the upper end of the pendulum not shown in the sketch.

It will be seen that the pendulum bob is supported at its centre, as Mr. Buckney has shown that it should be, so as to throw the expansion and contraction of the bob itself out of the question. In this pendulum I propose to fit it into the foundation plate Q bob by a cone fitting such as that of a lathe mandril. P is the turned and coned end of the *outside* steel tube of the pendulum which ends here, and Q is a turned disc of gun-metal on which the bob is built up; R R being hemispheres of gun-metal turned inside and out, screwed at S to the central disc Q, and the space T filled with lead, which may be conveniently done after fitting the parts together, by means of holes in R, which can be afterwards plugged. U U are brass tubes to confine the lead at the central aperture. The bob is preferentially spherical, on account of exposing the least surface in proportion to its mass.

As to the upper part of the pendulum (see Fig. 2), another refinement has to be considered. In finally adjusting the compensation, it is desirable to do this without repeatedly cutting the zinc tube, which is very liable to be cut off too short, and when once fixed cannot be altered without great trouble. Now the proportion of zinc to steel may be, by the means shown, minutely altered (and it is with minute quantities we are dealing) by raising or lowering the tubular casing nut V which embraces the outside steel tube W of the pendulum. At its upper end it similarly embraces the end of the zinc tube C. It is threaded at each end by inside screws of the same pitch, so that its only effect when turned by means of the milled projection X is to grip the zinc tube at a higher or lower point, and to raise or lower itself on the steel tube W. This latter action has no effect on the compensation, as both tubes are of steel, but its altered position on the zinc tube gives to that metal a slightly different proportion of length to that of the steel. For instance, if the total lengths of zinc and steel were in the proportion of 20 to 50, and the tubular nut V were raised half an inch, the proportion would then be $20\frac{1}{2}$ to $50\frac{1}{2}$, so that a very minute change in the relation of the two metals may be secured. It is, of course, taken for granted that an approximation has been made as nearly as possible (always leaving the zinc a little in excess) before the tubes are fitted with their screws. When in place the tubular nut V is firmly fixed by turning the rings Y which act on the split ends of the tube in the same way as already described (see Fig. 4). Z is a cap to close the upper end of the zinc tube.

The plan I have just described differs from that of Mr. Buckney (whose invention I had not heard of when this idea first occurred to me) by having the outside threads on the pendulum tubes proper, and not having to cut an inside thread on the large steel tube of the pendulum.

His contrivance for locking the screw between the two tubes is ingenious and beautiful, but I thought it better thus to give this plan to the light as showing another way of attaining the object, and without creating a large space between the zinc and outer steel tube. I prefer this space inside the zinc tube, as it allows of the said tube (which is the weaker member of the system, and has to act as a prop to the whole weight of the bob) being kept of larger diameter, and consequently stiffer as a pillar. As this pendulum would be an unusual weight, these considerations become of more importance. There is one other adjustment which might be made, and that is to compensate for what is called the barometric error. This could be done by a Bourdon tube, fitted outside the pendulum case, causing a properly-shaped disc or pair of discs of thin metal to project in a greater or less degree near the path of the pendulum according to the varying pressure of the atmosphere. When there was much pressure, and consequent tendency to retard the pendulum, the disc would be withdrawn and so offer less opposition, not to the pendulum itself, but to the air which must accompany it in its swing.

I am indebted to Mr. Thos. Buckney, F.R.A.S., for some important suggestions on this pendulum, which instrument might be found suitable for gravity experiments concerning the figure of the earth.

MOULDING SCREW PROPELLERS IN LOAM.*

THE foundation plate A, as shown in Fig. 1, should be levelled up true in the pit, and should be about $2\frac{1}{2}$in. thick, and made the shape of the screw, with allowances for joints and lugs at proper intervals. It may be perforated with holes, made with cores or pieces of brick, to allow the free escape of gases, and for better drying.

* By CHAS. A. DEVLIN, in the *American Machinist.*

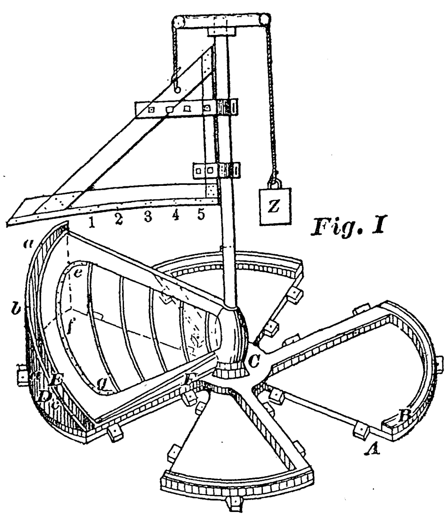

Fig. I

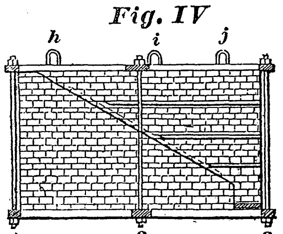
Fig. IV



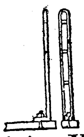


Fig. V

The bearing B and C are then swept up on one course of brick by a sweep that will also form the base of the hub high enough to allow the blades to be built. On this sweep notches are cut to indicate on bearing B the proper place for the guide board D and the joint board E. The bearing is thus divided into four right angles, with centre at the hub, which will show the true centre on bearing B to which the centre marked on the guide-board at *a* is placed. The false hub is then swept up by a sweep made for it.

The guide-board should be bevelled on the top edge, and a strip of hoop iron screwed on to insure easy and accurate travel for the sweep, which works with a counter balance weight Z, and when drawn down the guide-board describes the face of the blade. Notches are filled in the guide-board at *a*, *b*, *c*, and by scribing along the sweep from the notches to the hub gives the top, bottom, and centre of the blade. The joint-board E serves as a protection to the guide-board, and also makes a neat joint, as does the joint-board F on bearing B.

When the guide-board D and the joint-boards E and F are properly secured the bricking commences. Good, soft brick should be used, and kept the proper distance from the face of the mould to prevent scabbing. The pier should be built open with plenty of cinders champed in between the joints of the brickwork to allow vent; in the back of the pier brick should be left out occasionally for vents also. The brickwork finished, the pier should be loamed up and finished off.

The notches filed in the sweep 1, 2, 3, 4, 5 will describe on the pier the proper place for the thickness strips, which are cut out by the pattern-maker, and are cross sections of the blade at different intervals. They are generally about ½in. thick and pliable, so as to bend readily to the proper curve, marked on the pier. They are fastened on with nails or brads at their proper places.

A good idea is to make the form for the outer edge of the blade of a strip of lead properly shaped, as *e*, *f*, *g*; it makes a much neater job, and the outside will be uniform in thickness, especially in composition wheels, which are generally much thinner than iron ones.

When the thickness strips are fastened on, strong green sand is to be used to fill in with. It should be packed hard and struck off with small strips properly curved for the top of the blade. The strips may then be drawn and their places filled in with sand, when you have the proper shape of the blade. Clean the pier and spread oil over the face and joints, and shake on parting sand, then you are ready for the cope.

This style of a cope is interesting, shown in Fig. 2. The lifting and binding plates—1, 2, 3, 4—are cast in opening sand, as are the binding irons (Fig. 5).

Fig. II

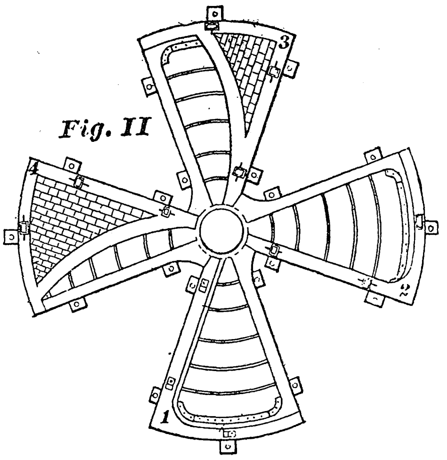

Fig. III

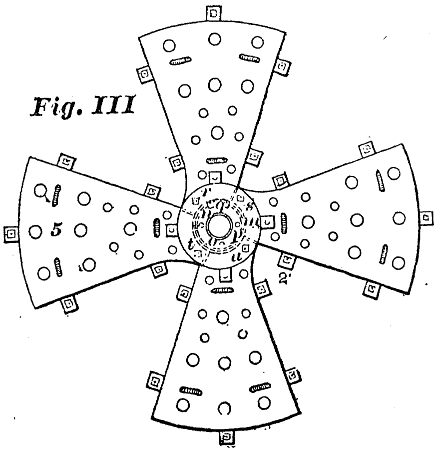

The lifting plate 1 is about two inches thick, with lugs at proper intervals. Three bolts are cast in this plate for securing the binding irons. The binding irons are made long enough to secure the top binding plates. After the cope is bricked up, a top plate 5, Fig. 3, about 2in. thick, with prickers about 1in. long, is then bedded on, after being loamed up. Binding bolts are then put through the lugs and screwed taut, when you have the cope safe and sound.

In the top plates staples are cast, as *h*, *i*, *j*, Fig. 4, to lift the copes by, after you have made proper marks and guides. After all the copes are built, the next thing is to make over the top of the hub. The best way is to sweep up a seat for the hub-plate *m*, which is cast with a hole for the core print and gates, *n*, *o*, *p*, and seeding head *g*. This plate is cast with prickers the proper length to extend down to the top of the hub; it also has four bolt holes cast in the lugs to correspond with small bolts cast in the top plates to secure it by, as *r*, *s*, *t*, *u*.

After the mould is all bricked up, it is taken apart, the thickness sand taken off and the false hub dug out, when it is ready to be dressed. If the screw is too large to be put in the oven, the piers may be dried by building fires between them, and placing a curbing around and plates over the top of it. The copes can be put on a carriage and dried in the oven. When dry, set the core and put the mould together, and bolt up by the binding bolts 1, 2, 3, Fig. 4, from the lugs on the foundation plate, through the lugs on the cope plates. Risers may be taken off from the highest point of the blade if the blades be thin. For greater safety in securing the mould, the cross and slings may be used, but it is hardly necessary.

GENERAL PRINCIPLES GOVERNING THE ACTION OF CARRIAGE WHEELS.*

A WHEEL is a contrivance to utilise some of the principles of motion of a ball or sphere. A ball or sphere moves upon a level surface easier than any other form of solid matter. This is because its centre of gravity is not changed in its progress. If a ball moves upon a level surface, its centre of gravity describes a line parallel to the surface. A ball is balanced in every direction when it is at rest. The power required to set it in motion is just enough to unbalance it. Like a pair of scales balanced with a ton weight on each end of the beam, a few ounces added to either end will move them.

A carriage wheel, in principle, is a slice from the centre of a ball. So long as such a wheel moves uprightly upon its rim, it has the facility of a ball to move in two directions only. To keep it in this position an axle is put through its centre. This adds friction to it, and also shortens the leverage by which it is propelled, from its rim to its centre.

A carriage wheel has to do duty generally upon a common road, the best kind of which is the macadamised. A wheel sinks somewhat into the loose material upon the surface, which it has to surmount in its progress. This is called traction or rolling friction.

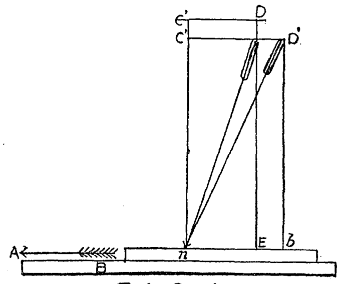

FIG. 1.

The rubbing of two substances together causes friction. It is the resistance to the motion of one substance bearing upon another. It increases with the weight or pressure of objects at their frictional contact, but not with the extension of the frictional surfaces.

If four blocks of wood or other material, of one kind and of similar weight, be placed one on the top of the other, and dragged upon a board or other smooth surface, and the weight or force be noted that is required to pull them; and then, if the same four blocks be spread side by side, and dragged upon the same surface, it will be found that the same weight or force will pull them. This shows that, if the surfaces in frictional contact be extended, but the pressure upon them be not increased, the resistance called friction is not increased. This law applies to axles.

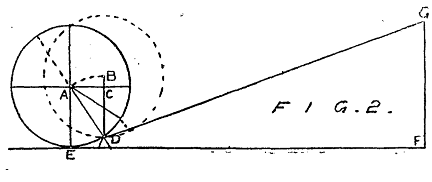

FIG. 2.

Friction does not increase with the size of an axle; but a wheel loses power or leverage with the increase of the size of its axle, and also by increased weight.

To find the amount of resistance there is to two smooth plates of metal—such as an axle and its box, with a layer of oil between them—sliding upon each other, we proceed as follows:—

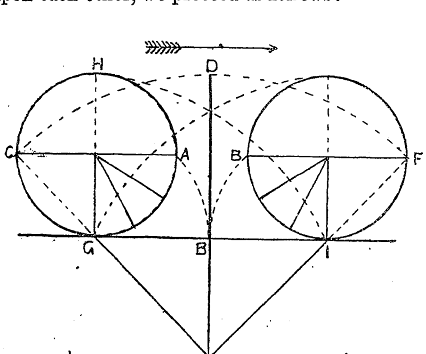

FIG. 3.

Let A B in Fig. 1 be the plates, and A C a perpendicular to their two surfaces. Draw E D parallel to A C, and C D parallel to the plates, thus resolving the force D A into two forces, one D E pressing A upon B, and the other D C tending to make A slide towards F. It will clearly depend on the strength of the friction between A and B how far the force D A may be made to decline from the perpendicular without actually causing A to slide upon B.

Suppose the pushing force be brought into the position of D′ A, and as A is just ready to slip on B; then, since D′ E′ and C′ A are the forces pressing

* By J. G. Cameron in *The Hub.*

together A and B, and D′ C′ and E′ A the forces tending to produce motion, D′ C′ will be $\frac{2}{25}$ of C′ A. D′ A C′ is called the limiting angle of resistance of the surfaces A and B. If 500lb. be the pressure, made to decline until it reaches the limiting angle of resistance, $\frac{2}{25}$ of 500lb. = 40lb., or 0·08, would be required to pull the plate A on B on a dead level. The figure 0·08 is called the coefficient of resistance of these substances, and may be used to compute the friction of oiled metals.

The actual friction going on within an axle-box is more than 0·08, because we have not taken into consideration the rubbing of the washers on the axle end and collar, and the gather of the axle; but these are so little in good-running waggons that they may be neglected.

Traction, or the resistance to the progress of a wheel upon a macadamised road, has been practically proved to be about $\frac{1}{30}$ of the load. The power required to move 500lb. would be 17lb. Upon a good, hard road, therefore, a horse will require to pull at the rate of 40 + 17 = 57lb. to draw 500lb. on free-running wheels.

The Power of a Wheel.

If an obstacle, say 4in. high, be in the way of a 4ft. wheel, the centre of gravity will have to be raised 4in. to overcome it. The lever to do this with is just half the height of the wheel—viz., 2ft. This lever is of the third order of levers—that of having the power come between the load, which is lifted, not pried, and the fulcrum. Neglecting any momentum the waggon may have, and calling it a dead lift, by the law of virtual velocities "the power multiplied by the distance it moves vertically, or in a right line, equals the load or weight multiplied by the distance it moves vertically or in a right line." See Fig. 2.

In Fig. 2, let the power be at A, the axle; the load 500lb.; and D be the height of 4in., to which it has to be raised. A will move through the curve A B, while the centre of gravity is raised upon D; then A, the power, will be plumb over it. The power A will have moved forward the length of from A to C, and up from C to B upon the resultant curve A B. It is clear that the length from A to C is just one-fourth the diameter of the wheel, equal to 12in. Now, according to the law of virtual velocities, it is with a right line from A to B, upon which the force was truly effective, that we have to do; and this is found by taking the square root of the base line A C times the square root of the upright line C B, which is $\sqrt{12^2 + 4^2} = 12{\cdot}65$. Now the load, 500lb., times the height, 4in., which it is to be raised, equals 2,000, which should be equal to the product of 12·65 times the power. If we divide 2,000 by 12·65 we have 158lb., which is the force required to put 500lb. upon the obstacle in front of the wheel.

This can be proved by the inclined plane E G. Let a base line from the point E be drawn, equal to the length of the circumference of the wheel, which is its diameter, 4ft., multiplied by 3·14169 = 12·566. Now, as the incline rises 4in. to the foot, as is shown by the object in front of the wheel 4in. high, and 12in. from point of gravity upon the ground at E, therefore, an upright drawn upon the extremity of the base line at F, to be of the same proportions, will require to be four times $\frac{12{\cdot}566}{12}$ in height, which is 1·0472 × 4 = 4·1888ft. high. The length of the incline to this base and upright equals the square root of the base line times the square root of the upright:

$$\sqrt{12:566^2 + 4:1888^2} = 13{\cdot}20\text{ft.}$$

The power of an inclined plane is as its length is to its height; therefore the load multiplied by the height of the upright, and divided by the length of the inclined plane, which is 500 × 4·1888 ÷ 13·20 = 158lb., the power required to sustain 500lb. upon it.

Now, by adding the friction of the axles, and traction, already found to be 57lb., to 158, we have 215lb., which is the force a horse will require to exert to haul 500lb. up such a slope of a macadamised road. This 500lb. means all that bears upon the axle-boxes—that is, the total weight of waggon and load, minus the weight of the wheels.

The Motion of a Wheel.

That the part of a carriage wheel above the axle moves faster and through more space than the part below it, is because this kind of wheel is a lever of the third order. Such a lever has the power applied between the weight, which is to be pushed, pulled, or lifted, and the fulcrum; the same as in raising a ladder. Imagine two spokes in a line to be a ladder; the lower end is on the ground, the force or hand being exerted at the hub; the point on the ground, which is the fulcrum, remains stationary, while the upper end moves through a space which will be double the distance that the middle or hub goes. The rim, being endless, each point as it touches the ground becomes a new fulcrum. A carriage wheel is thus called a perpetual lever of the third order.

In Fig. 3 the reader will observe that, while the point of spoke A moves to the ground at B, the opposite end C of the spoke in a line with A goes up to D, and the line of spokes A C there coincides with the line B D. The wheel has now made a one-fourth revolution upon its rim, from G to A, upon the ground G B. When it makes its next quarter-revolution, B goes up to E, and D goes to F. Thus it is clear that the point A, on the dividing line between the upper and lower halves of the wheel, goes down to B, and up to E, while the point C on the same line sweeps through the great curve C D F. The wheel has now made one-half of a revolution, and the line of spokes A C now coincides with the line E F. The upper part of the wheel has now become the lower, and, with the onward movement of the wheel, the same thing is continuously repeated.

To show the ratios in decimal notation of the curves which the points opposite in the lower and upper half of the rim of a wheel describe, or of their motions, would require the use of a calculus, which would be of no practical value here, as these curves are graduates—that is, having no centre.

USEFUL AND SCIENTIFIC NOTES.

Cheap Battery.—Each of the zinc plates is 2in. square and covered with fustian or other fabric, outside which thick copper wire is wound to form the other plate; the exciting liquid is weak chloride of zinc. Pairs of plates thus made can be arranged in series to form a battery to give out weak currents for a great length of time.

Amalgamating Zincs.—The simplest and quickest method of amalgamation of battery zincs consists in immersing the zinc in a liquid composed of nitrate of mercury and hydrochloric acid. A few moments are sufficient for the complete amalgamation of the zinc, however soiled its surface may be. With a quart of this liquid, which costs less than 50 cents, 150 zincs can be amalgamated. The liquid should be prepared in this manner: Dissolve in warm water 200 grains of mercury in 1,000 grains of aqua regia (nitric acid 1 part, hydrochloric acid 3 parts). When the mercury is dissolved add 1,000 grains of hydrochloric acid.

Warping of Wood.—Straight-grained woods are not subject to any considerable change in the lengthwise of the grain, but a distortion called warping is very prevalent in the soft, as well as in the hard varieties, in the cross directions. Thin boards are sometimes curved like a bow in their cross sections. The first method to be tried to restore these to their original condition is to range them round the shop with the convex sides to the fire, or place them in the sun, when the evaporation of the moisture causes the wood to contract, and so bring it to its proper shape, but the wood must not be too long exposed, as the board will become convex on the side next to the heat. This may be avoided by frequently changing the sides. If the wood is too much distorted to yield to this treatment it is to be bent as straight as possible by the hands, and if still retaining a warped form must be placed between two stout planks drawn closely together by hand screws. Any after prominences must be removed by the plane. The finely figured woods, which chiefly owe their beauty to the great irregularity of the grain, would be very liable to twist if employed of the same thickness as the straight-grained descriptions; it is their being cut into thin slices that saves them.

New Submarine Torpedo Boat.—A new submarine torpedo boat, the invention of Prof. J. H. L. Tuck, of New York, and constructed at the yard of Messrs. C. H. Delamater and Co., has just been tried on the Hudson River. The vessel, which has been named the *Peacemaker*, is of iron, 30ft. long, with a breadth of beam of 8½ft. and a depth of 7½ft. The bow and stern taper off from amidships, the forward end being surmounted by a small dome 12in. high, set with glass, and just large enough for a man's head, while at the stern is a circular scuttle, which may be hermetically closed from inside. The interior is half-filled with machinery and apparatus, including a 14-horse power Westinghouse engine, supplied with steam from a caustic potash boiler, and driving an ordinary screw propeller. Compressed air is stored in 6in. pipes running round the interior. The boat is steered by a rudder of the usual pattern, but she has also two horizontal rudders, by means of which she may be deflected up or down. A gauge registers the depth of the vessel beneath the surface. The hold is lighted by a glow lamp. The *Peacemaker* is to carry two torpedoes, held together by a chain and fastened to corked magnets, which will attach themselves to the iron or steel sheathing of the vessel to be attacked, and are fired by electricity after the boat has reached a safe distance. The torpedoes were not tried during the experimental run, but in other respects the boat is said to have behaved well, reaching a depth of 40ft. and attaining a fair rate of speed.

SCIENTIFIC NEWS.

THE death of Rowland Mason Ordish removes from our midst one of the most skilful of constructive engineers, though he was little known to the world outside the profession. He was born at Derby, where his father practised as a land-agent and surveyor, and coming to London in 1847, he speedily found employment, and in 1851 was an assistant draughtsman to Sir Charles—then Mr.—Fox, a large part of the more important work in connection with the Exhibition of 1851 falling to his share. Before the Exhibition opened Mr. Ordish was engaged in making the working drawings for the New-street Station, Birmingham, and subsequently assisted in working out the constructional details of the Crystal Palace. By this time his abilities were well known, and he became a real consulting engineer, designing amongst other important works the roofs at St. Pancras station, and at Enoch-square station, Glasgow. The roof of the Chapter House, Westminster Abbey, is now in reality suspended from a hidden polygonal iron roof designed by Mr. Ordish. He also designed the Farringdon-street bridge of the Holborn Viaduct, and with the help of his chief assistant, Mr. Max am Ende, the roof over the Albert Hall. Outside professional circles Mr. Ordish was little known, but the most distinguished architects and engineers were accustomed to consult him, and place the designing of difficult works in his hands. Many engineers throughout the world will hear with regret of his death—he was only in his sixty-second year—for he was pre-eminently one of "those who know," and he was never chary of imparting information to his pupils.

Mr. Sampson Gamgee, the famous Birmingham surgeon, died suddenly last Saturday at the age of fifty-nine, it would seem from the effects of an accident he met with in Devonshire while on a holiday trip. The Saturday Hospital Collection is due to his initiative. He was a brilliant operator, a fluent speaker, and a member of several learned societies.

Winnecke's comet was observed at Algiers on the 23rd ult. by M. Trépied, and on the 28th by Prof. Zona at Palermo Observatory. Their observations confirm the conclusion that the comet must have passed its perihelion twelve days earlier than was assumed as the probable date in Dr. Lamp's ephemeris.

A "Handy Map of the Moon," drawn by Mr. T. K. Mellor, F.R.A.S., has been published by Messrs. Horne, Thornthwaite, and Wood, of the Strand and Cheapside. It is 11¼in. in diameter, and has been photographed from the drawing and mounted on cardboard (about 14in. by 13in.) so that it can be conveniently held in the hand while the eye is at the telescope. About 300 formations have been delineated and clearly named, and on the back of the map is a description of the principal features. It will be found very useful by lunar observers who are not yet familiar with the principal markings on the moon.

Mr. H. C. Russell, the Government Astronomer for New South Wales, has published his paper on "Local Variations and Vibrations of the Earth's Surface," which he read before the Royal Society of N.S.W. last year. The paper is supplemented by a number of tables and curve diagrams, including automatic records of the height of the water in Lake George, Murray Co., which reveal the effects of terrestrial motions. Sydney and Greenwich level curves are also supplied for comparison.

Mr. M. Auty, of Front-street, Tynemouth, sends us two prints of lightning flashes taken by him on the night of August 9, 1884, the only successful attempts in six exposures. They do not represent so remarkable a flash as that illustrated in No. 1118, but they both show the ramifications of "flashes" of lightning.

At the meeting of the Royal Scottish Society of Arts last week, the report of a committee on Mr. W. M. Hardie's fluid prisms was read, in which it was stated that Mr. Hardie obtained widely separated spectra of various kinds of light, and enjoyed views of the composition of some groups of lines therein, which were beyond the optical power of not a few modern spectroscopes of the orthodox and expensive kind for measuring. There might be ultimate doubts as

to whether the prisms could ever be made so large and so perfect as to bear being looked through by the powerful telescopes now beginning to be employed in spectroscopy. Another paper read was that by Mr. George R. Primrose on a new electric scale-reader. The instrument is one designed to measure the height of a varying column of mercury at any distance from an observer to which it is possible to convey one wire. It is intended to be used principally to register atmospheric changes in high altitudes, or deep and dangerous places. The scale may be divided into almost any degree of fineness. The principle of action is applied to a siphon barometer. A small wire rod in the electric circuit is passed perpendicularly into the exposed end of the mercurial column. When the contact is broken by the rod moving out of the mercury, the height of the mercury is indicated at the distant station. The necessary motion is conveyed by an electro-magnet acting upon a toothed wheel, which, by a succession of beats, turns a second diminishing wheel, gradually raising the rod. The rod, on arriving at its highest point, falls again, and the operation is repeated. This movement is got by a section of the wheel having no teeth. The instrument is also intended to be applied in recording the flow and ebb of tides, and the amount of water in a distant river or reservoir.

According to American papers, the sea-serpent has been seen in the river Hudson, near Albany, N.Y., and two members of the United States Fish Commission have expressed an opinion on the probability of such animals existing. Prof. Gill says: "The true serpent is an air-breathing animal, and could not exist indefinitely beneath the surface of the sea. Such monsters were common in the cretaceous age of the world, and their remains are common enough in the deposits of those times, but nothing remotely resembling them is found in the deposits of later geological ages." On the other side, Prof. Goode does not wholly discredit the statement that a monster as yet unknown to science, of reptilian shape, and having the power and habit of lifting its head far above the surface of the sea, may still be in existence. From time to time captured creatures which are reported to be sea-serpents fall into the hands of naturalists, but when submitted to the tests of science, they uniformly prove to be abnormal specimens of familiar forms, such as the basking shark and the oar fish.

The Secretary of State has directed the Inspectors of Mines to call attention to that portion of the report on Accidents in Mines which says that "The source of light within the lamp should be unable, under any circumstances at all likely to occur in working coal, to cause the ignition of any inflammable mixture of fire-damp and air, even when this is passing at a high velocity." Neither the Secretary of State nor the Inspectors of Mines point out which lamp will comply with those conditions, though they imply that there is one.

A writer in the *Revue Scientifique* affirms that, from a comparison of animal and steam power, the former is the cheaper power in France, whatever may be the case in other countries. In the conversion of chemical to mechanical energy, 90 per cent. is lost in the machine, against 68 in the animal. M. Sanson, the writer above referred to, finds that the steam horse-power, contrary to what is generally believed, is often materially exceeded by the horse. The cost of traction on the Mont Parnasse-Bastille line of railway he found to be for each car, daily, 57f., while the same work done by the horse cost only 47f.; and he believes that for moderate powers the conversion of chemical into mechanical energy is more economically effected through animals than through steam-engines. Similar calculations have been made in this country without, however, affecting the position of steam-engines.

The waterfall of Teverone is now used to supply power for driving two dynamos for the illumination of the city of Tivoli. The motive-power is equal to that of several thousand horses. The illumination of Rome by electricity is contemplated.

Another school is about to be added to the numerous practical and technical schools established by the City of Paris. Next month an *école de meublement* will be opened, the object of which is to rear able and skilful workmen who will maintain the artistic traditions of the furniture industry in France. Instruction will be given by professors in cabinet-making, sculpture, in wood-turning, joinery, and tapestry. There will also be classes for geometry, the history of art, technology, industrial design, modelling, &c. The period of apprenticeship will be for four years. Sixty pupils will be admitted every year, and they will be selected by competitive examination in French composition and ornamental design, and must be between 13 and 16 years of age.

At the meeting of the San Francisco Microscopical Society on August 25, a number of specimens of *Teredo navalis* and *Limnoria terebrans* were exhibited by Mr. Manson, who called attention to some interesting questions regarding the food of *Teredo*—it being asserted on the one hand that the albuminous sap of the wood bored by that mollusc was assimilated as food by the animal, while others contend that its food consists of organisms found in the sea-water, and that not only the woody fibre, but the albuminoids of the sap as well, pass through the alimentary canal of *Teredo* unchanged. Dr. Ferrer gave an exposition of the nature of various microscopic moulds, which, he said, were formerly regarded as nothing more serious than annoying invaders of the jams and jellies of thrifty housekeepers; but it is now recognised that they frequently exert a baneful influence upon some living plants and also living animals. The destruction caused in the vine by *Oïdium Tuckeri*, in the potato by *Peronospora infestans*, and in the silkworm by *Botrytis bassiana*, were cited as instances. The active part played by many moulds in some diseases of the skin and mucous membranes in the human subject was also alluded to.

Messrs. Whittaker will publish shortly, in their "Specialist's Series," a work by W. Anderson, M.I.C.E., on the "Conversion of Heat into Work;" and another, by W. H. Preece, F.R.S., and J. Maier, Ph.D., on "The Telephone and its Practical Applications." Amongst the works announced by the same firm, we note "A Bibliography of Electricity and Magnetism," by G. May and O. Salle, Ph.D.

The annual congress of the Amalgamated Society of Railway Servants is to take place at Brighton during the first week of October. We understand the Brighton Railway Company will on one day place a train and engine at the disposal of the Society, so that the delegates can carefully examine the design, construction, and practical working of the Westinghouse brake used on that railway.

A party sent out by the United States Geological Survey, under the command of Captain Clarence E. Dutton, has succeeded in making a complete survey of Crater Lake, in Oregon, a body of water whose shores, with the possible exception of one point on the south, have never before been touched by the feet of white men. The party's boats were hauled 100 miles by mule teams, dragged by a detail of soldiers up the snow-clad sides of the ridge which surrounds the lake, and lowered by ropes from the crest to the water, 900ft. below. One hundred and sixty soundings were made, the result of which gave the general character of the lake bottom. Two large submerged cinder cones were found, respectively 800ft. and 1,200ft. high, the rest of the bottom being flat. Captain Dutton believes this to be the deepest body of fresh water on the Continent. The greatest depth attained by the sounding line was 2,005ft. He writes to Director Powell: "As regards the origin of the basin, I now have a decided opinion. It has, I think, been formed in much the same way as the great *calderas* of the Hawaiian Islands, by the melting of the foundations of the original mountains, the blowing out of the molten material in the form of light pumice and fine tufa. It cannot have been formed by an explosion, like Krakatoa and Tomboro, for there is no trace of the fragments anywhere in the country round about. But the pumice and tufa which surely emanated from this crater are seen in vast quantities anywhere within a radius of 20 to 60 miles, and in quantities ample to fill the whole vast crater twice over. The age of the crater is wholly post-glacial. I have found at the extreme crest of the wall on the western side splendid examples of glacial striation while the old moraines are half a mile to a mile below. That the age of the *caldera* cannot be great is evident from the fact that though the walls are crumbling at a very rapid rate, the talus has not only not reached the water surface anywhere, but the sounding discloses little of it at the bottom."

A statement made by Sir William Dawson at the British Association meeting, in the course of a discussion on his paper, "Arctic Geology compared with that of Canada," will surprise many. It was to the effect that "the colonists in Greenland kept fuchsias and roses and geraniums in their houses during the winter, and were extremely successful in cultivating them."

USEFUL AND SCIENTIFIC NOTES.

King's College, London, Evening Classes.—The evening classes at this college form an important branch of the teaching work carried on, and we note that the Workshop classes commence on the 28th inst. Prof. Huntington will deliver a course of lectures on "The Properties of Metals and Alloys, and their Uses in the Arts," commencing on Oct. 4th, and Mr. W. G. McMillan will deliver a course on "Fuels, their Uses and Economy." There is also a class of Practical Metallurgy held on Friday evenings in the metallurgical laboratories.

University College, London, Engineering Department.—The examination for the Gilchrist (entrance) Engineering Scholarship of £35 per annum is to be held on the 28th and 29th inst. Candidates must be under nineteen, and the subjects of examination are:—I. Mathematics; II., any two or more of the following: (*a*) mechanics; (*b*) mechanical drawing; (*c*) examination on some subject connected with engineering; (*d*) French or German; (*e*) the use of tools. The examination is intended to be of such a standard as can be passed by lads from school who have begun to acquire some knowledge of mechanical pursuits. The appliances of the engineering laboratory—under Prof. Alex. B. W. Kennedy—have been very much extended during the past year, mainly through a grant from the Gilchrist trustees, and are now very complete in the direction both of experiments in elasticity and the strength of materials, and in the economic work of engines and boilers. Laboratory work is so arranged that students go through a systematic course of experiments in these and other connected subjects during the session.

IN the spring of 1887 an exhibition of records and objects illustrating the history of the Jews in England will be held in the Royal Albert Hall, South Kensington. A large number of valuable and interesting objects have already been promised by public bodies and private individuals. An influential and representative committee of an undenominational character has been formed.

PRINCE PUTIATIN has presented to the Russian Archæological Society a stone slab which was recently found in the course of some excavations at the Boulogne Station on the St. Petersburg and Moscow Railway, along with some stone weapons and utensils. A representation of the constellation of the Great Bear was, although rudely, carefully drawn on the slab. It may be remembered that some years ago a similar slab was found near Weimar.

Aluminium.—Senet has devised a new process for obtaining aluminium, as well as copper, silver, &c., by electrolysis. He exposes a saturated solution of sulphate of alumina, separated from a solution of chloride of sodium by a porous vessel, to a current of six or seven volts and four ampères. The double chloride of aluminium and sodium is decomposed, and the aluminium is deposited upon the negative electrode.

Gold Bronze.—Gold bronze may be prepared in the following manner: Melt two parts of pure tin in a crucible and add to it, under constant stirring, one part of metallic mercury, previously heated in an iron spoon until it begins to emit fumes. When cold the alloy is rubbed to powder, mixed with part each of chloride of ammonium and sublimed sulphur, and the whole inclosed in a flask or retort which is embedded in a sand bath. Heat is now applied until the sand has become red hot, and this is maintained until it is certain that vapours are no longer evolved. The vessel is then removed from the hot sand and allowed to cool. The lower part of the vessel contains the gold bronze as a shining, gold-coloured mass. In the upper part of the flask or retort chloride of ammonium and cinnabar will be found.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

THE MAPS OF THE ORDNANCE SURVEY—COMITES TO VEGA—THE PSYCHOLOGY OF DREAMS—EYEPIECES FOR A 3¼in. TELESCOPE—δ CYGNI, &c.—FROGS.

[26279.]—ON a previous occasion I have commented in these columns on the shortcomings of the maps of the Ordnance Survey. Within the last seven days I have added to my previous unpleasant experience in this matter. I wanted the map of Weymouth and Portland, and wrote for sheet 342, which appears in the index map of the new 1in. survey. The answer came that it was "not yet published." Hence I had no option but to order Section 17 of the old survey, which has just reached me. As a single example of the shameful way in which the duty of keeping these maps up to date is neglected, it may suffice to say that *the Convict Prison at Portland, built in 1849, is not even marked upon it at all.* I say quite unhesitatingly that this is a simple disgrace to this country. I wonder what a German staff-officer would say were he supplied with so worthless a map of any country he had to operate in? The fact is that the Ordnance Survey is one of those Departments which is managed on the most parsimonious principles; and while any Brompton quack has no difficulty in getting State aid to advertise himself, this most important national work is starved to keep down the estimates. But, granting this, the authorities at Southampton are most culpable in issuing in September, 1886, a map in which a huge pile of Government buildings erected 37 years ago, is not indicated in any way whatever. I could point to half a dozen similar gross omissions in the map before me.

In the penultimate line of letter 26218 (p. 36), "⅝in. objectives" should be 1⅝in. objectives.

Writing these lines more than 110 miles as the crow flies from my own observatory, I am quite unable at present to accede to the request preferred by Mr. Sadler (letter 26219, p. 36), that I should examine the field near Vega. Upon my return home, however, I will take the earliest opportunity of doing so.

"Crumby" (letter 26231, p. 38) must not imagine that I advanced my own experience of dreaming that I was dreaming—and satisfying myself (quite erroneously) by a legitimate train of reasoning that I was *not*—as "curious," in the sense of being unique or peculiar to myself. I suggested this odd experience as throwing more or less doubt upon the operations of the mind in ratiocination of any description.

"A. R. B." (query 60360, p. 46) had better get a power of 25 to 30 for comets, nebulæ, and clusters. One of 150 for lunar and planetary detail, and two others of 200 and 250 respectively for stellar observation. These should all be of the Huyghenian form. Nothing is equal to it for all-round astronomical work.

Far away from books, I cannot at this present writing give any reply worth reading to query 60369 (p. 46); but 0·8" is certainly a ridiculous distance to be ascribed to the components of δ Cygni. Is this a misprint for 1·8"? May I once more reiterate that δ Cygni is emphatically a star to be observed in twilight; the brighter the better. On my return to more civilised regions I will endeavour to supply Mr. Atkinson with definite answers to as many of his questions as I can.

"Kensington" (query 60440, p. 74) should keep his frogs in a glazed vivarium, with a pan of water and some moss in it. They are fed on live flies and worms. I have kept them thus for years.

A Fellow of the Royal Astronomical Society.

LIVERPOOL ASTRONOMICAL SOCIETY—CIRCULAR No. 9.

[26280.]—GORE'S Nova (1885) Orionis was observed here last night (Sept. 14th), and found to have a magnitude of 9·2. The star is very red. The small *comes f.* was estimated as of 9·7 magnitude.

T. E. Espin.
Observer to the Society.

Wolsingham, Darlington, Sept. 15.

ON FLATS FOR REFLECTORS.

[26281.]—IN all the correspondence in "E. M." upon flats, &c., I do not remember anything being said of any means of using a flat otherwise too small in a way to obtain the light from the whole of large mirror. In the ordinary way a 9in. mirror requires a flat 1⅝in. for sun and moon, and not less than 1⅛in. for stars; but by using a Barlow lens in draw tube the flat may be moved another 4in. away from mirror, and then a flat ⅞in. minor axis is large enough for a star, and 1¼in. is abundant for sun and moon. This hint may be useful to some whose flats are small; and in another way, where a flat is provided only large enough for stars, by the use of a Barlow it can be made to be large enough for sun, &c. I do not recommend this, because the gain in light will be much less than will be lost at the surfaces of the Barlow lens; but a reduction in the brilliancy of diffraction rings would follow. Of course, it would be best to use a special Barlow of such focus as to allow the flat to be moved to an extreme distance from large mirror, and thus reduce it to the very smallest size possible.

Edwin Holmes.

THE ADVANTAGE OF STEAM DOMES.

[26282.]—I THINK that "J. T. M." is mistaken when he asserts that the use of a dome upon a boiler is to increase the area for containing steam. Surely the object of using a dome is to prevent priming by raising the mouth of the steam-pipe to a greater distance from the surface of the water, and thus, aided by the large diameter of the dome, as compared to that of the pipe, the sucking action, so to speak, is done away with.

A., Liverpool.

CONCERNING CHAMBER ORGANS, HARMONIUM PLAYING, AND HOME STUDIES.

[26283.]—MAY I express the great pleasure with which, in company with I am sure all musical readers of the ENGLISH MECHANIC, I have perused Mr. Audsley's "Notes on the Chamber Organ"? They are of the deepest interest to me. I thank him also for his kindly reply (p. 530) to my queries upon the subject of "Home Music." With reference to that letter, the juvenile portion of my family varies from about ten years to some ten days. I am now only anxious to be prepared for each child taking up some instrument in addition to the piano as early as may be. Of course I intend that the piano and Mustel shall accompany the other instruments.

I read with much interest, too, Mr. Audsley's programme of one of his musical evenings. It is upon an ambitious scale indeed. The only observation occurring to me upon it is that one rather regrets to see in it so much of the "music of the future," and which is to me simply drifting back to chaos. If Wagner's music and the music of others whose names appear in that programme is to be the music of the future, all I can say is I am sorry for the future.

I venture to subjoin a programme of a musical evening at my own house, and which I hope may not be unacceptable as showing what may be done by very unambitious amateurs simply with piano, harmonium, and flute.

"Brave musicians for the night,
Watch that time and tune go right."

1. Andante from Symphony in C minor. Beethoven.
Trio for Piano, Mustel Organ, and Flute.
2. ... ... Sonata No. 7. ... ... Haydn.
Piano Solo.
3. ... ... Marche Hongroise ... Schubert.
Duet—Piano and Mustel Organ.
4. Sonata No. 1 (Scherzo, Trio, Rondo). Schubert.
Piano Solo.
5. ... Sonata in F (first movement). Beethoven.
Piano Solo.
6. ... "Miserere and Ah che la Morte" ... Verdi.
(From "Il Trovatore.")
Duet—Piano and Mustel Organ.
7. ... "Auf Flugeln des Gesanges." Mendelssohn.
Song.
8. ... Adagio from Scotch Symphony. Mendelssohn.
Trio—Piano, Mustel Organ, and Flute.

Though a very insignificant-looking programme in comparison with that of our friend, I fancy it would be found to have been quite as satisfactory in the hearing, so far as the list of pieces is concerned, as that given by our friend. We make it a point to head our programmes with a musical poetical quotation, generally from Shakespeare. This serves the useful purpose of testing the Shakespearian and other poetical lore of the company. It is simply marvellous the number of passages admirably suited for the purpose which are to be found scattered throughout Shakespeare.

And now with regard to Mr. Audsley's comparison of the Chamber Pipe Organ with the Mustel. He must have struck sorrow, I think, into the hearts of those of your readers who, either like myself, are possessed of a purse of limited capacity or are bent on possessing a Pipe Organ of their own manufacture. Personally I agree with what is implied by Mr. Audsley, that to have a decent Chamber Organ of any kind it must be made by an artist and one thoroughly skilled and at home in every point of his workmanship; and that in ninety-nine cases out of a hundred amateur-built instruments are fit for one purpose only—firewood. But Mr. Audsley has satisfied me more than ever that for strictly *home* purposes the Mustel Organ is, after all, the instrument.

The catalogue price of it is easily ascertained, and, as everybody, whether in or out of the music trade, knows, cash will buy them for less. And whilst an instrument of the kind Mr. Audsley properly enough advises in a Chamber Organ must cost at the least from £500 to £600 for the instrument alone, Mustel's one manual instrument with the double touch and metaphone can be had for literally a fraction of the money. Moreover, when the price of Mustel's instrument is paid it is done with; but the Chamber Organ, which our friend considers alone worth having, must have a room to itself, and which in very many houses would have to be built expressly for it, thus putting the total cost at a sum which would have to be represented by four figures. If I am incorrect in this, I should be very glad to be set right, for with most of us in these bad times price is a matter of terribly serious moment indeed. I trust that in his future papers Mr. Audsley will deal fully with the probable price, the space actually taken up by, and the size, shape, and kind of room best adapted for such an organ as alone he is prepared to recommend. In even a moderate sized drawing-room a Pipe Organ seems entirely out of place. I even make bold to say that the organ proper is fit only for a cathedral or other building where the 32ft. pedal notes have room to speak.

Mustel's instrument is as perfect in a small drawing-room as in a large concert room. Only last week a friend of considerable musical knowledge and skill, hearing Mustel's instrument for the first time in a small drawing-room, exclaimed, "Why there is as much music in it as in our church organ," alluding to a very complete instrument of three manuals, pedal organ, and some fifty speaking stops. I quite agreed with my friend. After all is said and done, even Mr. Audsley must be constrained to admit that even his pet organ is a soulless instrument devoid of all expression—and, pray, what is music without expression?

In answer to your correspondent, "A Lady Reader," I am sorry to say I do not know Elliott's "Tutor." No doubt, however, it is an elementary one. If, as she says, she has worked well through this, and if she has thoroughly carried out the suggestions I made in my first letter on harmonium playing, she could not do better than work through King Hall's "Harmonium Primer," and the scales and exercises in the "Pianoforte Primer" of Novello's series. She might also practise well playing hymn tunes, say those from "Hymns Ancient and Modern," taking care to play them as smoothly with regard both to fingering and blowing as possible, practising also playing the treble with one hand and the remaining parts with the other. She might also work through Elliott's "Harmonium Treasury," taking, of course, the easier pieces first. The fault, however, of this "Harmonium Treasury," as of almost all other cheap collections of harmonium music, is that they are made to sell, and so are supposed to be arranged indiscriminately for harmoniums without stops and for large instruments. Unfortunately, music so arranged is almost worthless to the true artist. Instead of it he will go to the original and make his own arrangements; but to do this he must possess a knowledge of thorough bass, and without that, I say again, good harmonium playing is impossible.

Matters musical have occupied a good deal of your space latterly, and many of us rejoice that it should be so; but there is one consideration that should be borne carefully in mind, and especially by those who may contemplate making music their special leisure study. The bane of music is that to become a proficient in it hour after hour *must* be spent simply in finger practice, exercise neither for brain nor body. The mind meanwhile is unoccupied and no food supplied for further use or reflection, a twofold loss indeed. What happens to an idle mind may be judged from the fate universally accorded to idle hands, save that the result will probably be worse tenfold. An hour spent intelligently with the telescope, or in the careful consideration of the most elementary facts of astronomical science, or, again, with the microscope, upon a gathering from almost any pond, ditch, canal, or rock pool, or upon a slice of the commonest diatoms,

or of Enoch's insect preparations, will yield more lasting advantage, will infinitely more enlarge the mind, than ten times the amount of labour spent in music. For after much consideration I say deliberately, and after much reflection, that I think music must be looked upon simply and solely as a recreation, and is in its proper place only when made use of as such and nothing more.

Country Solicitor.

ORIGINAL ELECTRIC EXPERIMENTS, No. 8.—ERRATA—TO "SIGMA."

[26284.]—ON page 61, in the tenth line, for "Bunsens" read "brushes"; also 21 lines from the end the term "minus" has been left out.

No. 9. Upon repeating the experiments described in No. 8, I find that the theory propounded there cannot be upheld, because on applying a knuckle to a charged jar there is evidently a comparatively small quantity of electricity which comes "off" to same. But I am certain that, in the arrangement described, no electricity is given from either disc to any of the four brushes. It may be of some use to state that I do not, so far, coat any part of the glass with shellac varnish, applying it solely to the bosses and the framing, having discovered that it gives good results if the air be damp, to rub all the glasswork with the ordinary paraffin oil of the lamp shops, applied moderately by means of a rag sprinkled therewith. I have also discovered "that by inserting a plain sheet of glass between the discs, and, say 2in. larger in diameter than said discs, the machine will be greatly improved"; also, having found some difficulty in getting a Wimshurst machine to start, possibly on account of not using shellac varnish upon the discs, I find it advantageous to cut a strip of cloth or drugget rather larger than one of the sectors, cover the same with lining paper, and paste it upon one of the discs. When dry, apply paste to a suitable piece of tinfoil (don't put the paste direct upon the paper, or it will probably render it baggy by reason of a second wetting), and this small rubber won't seriously increase the friction of turning the machine, but will cause it to go ahead in almost any state of the atmosphere without any apparent injury to the action of the machine. It may be as well to warn anyone from putting a knuckle near a charged jar whilst the other hand is holding the driving handle, as a circuit is formed through the bands, and a dangerous shock will result if a large charge be in the jar, as I painfully experienced.

In "Sigma's" work upon "Electricity" I find it laid down that "static electricity is understood to mean that produced by frictional means." Also, that static electricity is only to be found upon the external surfaces of bodies. Will he kindly explain how these statements are to be reconciled with the following experiments? If we take a sheet of ordinary window-glass, and fix it so as to overhang a table by means of a weight, then placing upon this, say, an ordinary thin glass drinking-goblet, suspend so as to dip into this goblet a small strip of tissue-paper attached to a silk thread;—now, if we rub underneath with a rubber composed of a piece of wood, a piece of cloth or drugget, a piece of paper to secure same to the wood, and tinfoil over the face of said paper, the slip of tissue will fly out of the glass, in order to communicate its charge to the nearest conductor. What is this, if not electricity, upon the inside? Again, if we coat the goblet inside and outside as a Leyden jar, we can obtain sparks just as well from both sides, and if we give a rub then, whilst maintaining contact with the glass and rubber, we put a finger to either inside or outside, and then remove it, upon breaking connection between the rubber and the glass we get an increased spark, similar to an electrophorus, and, still more curious, we cannot apparently charge this glass similar to a Leyden jar, as the electricity seems to be the same inside and outside. Also I may mention that I find that if any part of a piece of glass be rubbed, the whole of it is electrified simultaneously. It also appears that the electricity produced by a metallic rubber is of the same nature upon both sides of the glass, and that wherever we move the rubber to, that already produced wants more especially to place itself opposite to said rubber, as may be noticed by placing pieces of foil near each other upon said glass. I omitted to mention that if a long glass tube be excited by the aforesaid rubber, or a dry hand, it can be proved that electricity is produced upon all parts of its inside.

A., Liverpool.

NEW TRANSMITTING TELEPHONE.

[26285.]—IN a recent issue of "Ours" (No. 1115) there is a short description of Turnbull's telephone transmitter. This instrument puts me in mind of another transmitter which has not been described in any of the scientific journals, but which, nevertheless, is a very remarkable instrument, and as it possesses some really novel features, and is of home manufacture, a short sketch of its principal

FIG. 1.

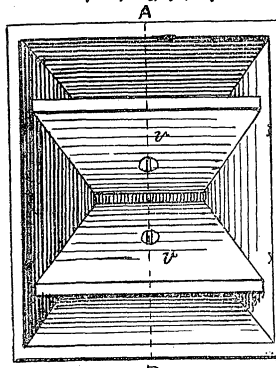

FIG. 3.

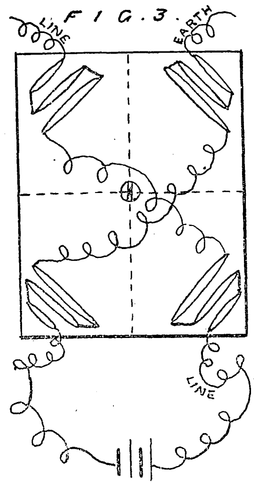

FIG. 2.

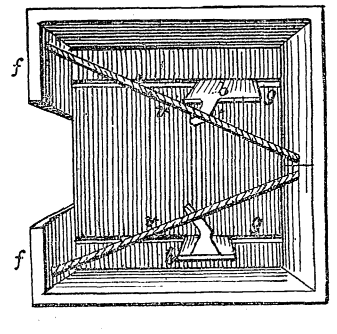

parts will no doubt be of interest to telephonists. Usually carbon transmitters have but one vibrator or diaphragm to which the carbon electrodes are attached. In one form of the instrument I am now about to describe there are two vibrators. These are placed at an angle or inclination to each other in such manner that the sound-waves pass along between them towards the vortex of the angle. By this means the sound-waves produce a maximum effect on the vibrators; each wave is compressed as it travels along between the diaphragms. Looking at Fig. 1 through a tube, or with one eye closed, the method of fixing the vibrators *v v* in the oblong box A B is at once seen.

Another important point is that these vibrators are fixed or suspended at their centres only. Consequently there is greater freedom of vibration. A reference to Tyndall's work on "Sound," where he exhibits the vibration of plates, will at once make this manifest. The centre may be said to be the natural position for fixing a plate; it can the more readily adapt its vibrations to those of the sound which produces them. The result is a remarkable clearness and distinctness in the words transmitted. Fig. 2 is a section of Fig. 1 through the line A B; *g g* are grooves in the side of the box in which slide the bridges *b b* carrying the supports for the vibrators *v v*. The shutters *f f* are not shown in Fig. 1. This figure is also best viewed through a paper tube.

Again, each vibrator has two sets of separate and distinct carbon electrodes; one set can be connected up to the line wire, and the other to earth. Or if there be two lines, each line can have its own carbon electrode. Fig. 3 shows a vibrator with its carbon electrodes attached at the more strongly vibrating portions of the plate.

Another remarkable feature in the construction of this instrument is that the contacts are automatic. The bridges, carrying the vibrator supports, slide in and out in grooves, so that the vibrator and its electrode may be taken out and examined, and put back without interrupting the circuit, or without any screwing or unscrewing, or a new plate may be put in the place of the old one, all in less than a minute.

The instrument, when in use, may be placed on a desk or table, or hung up on the wall. When speaking, the head is erect.

With the Editor's permission I shall, in another letter, give some more particulars respecting this rather novel transmitter.

Vibrator.

EGYPTOLOGY.

[26286.]—MR. SMITH must decide what value he attaches to Biblical dates and generations before coming to definite conclusions. I only look on them as rough approximations or poetical statements made in an uncritical age and long after the facts occurred.

In estimating the probable number of years spent by the Israelites in Egypt, it is necessary to consider the number of Israelites alive at that time, as the more they were the longer they must have been in Egypt. The period during which they were in Egypt cannot be found by simply adding up the generations as given in the Bible, for the following reasons:—

1. The number of generations, including Abraham, from him to David, and inclusive, is 14 (Matthew i.); but as the time was about 1,000 years, the average age of each generation before the birth of the first born of each would be 71 years—an absurdly improbable supposition. If 30 years—that usually allowed—be right, 33 instead of 14 generations must be considered. Some will confidently assert that the difficulty is got over by saying that the average duration of life is to be taken; but this is clearly not so, as the average duration of life has nothing to do with the number of generations which existed. The natural inference is that the numbers are wrong, and that no sure calculations can be based on them.

2. There were four generations before the going into Egypt, four while in Egypt, and six from the leaving of Egypt till the time of David; but according to Kings vi., the time from the Exodus to the fourth year of Solomon's reign occupied 480 years, so each generation occupied a long time. Those who insist on relying on Biblical numbers are obliged to alter the words, and insist that no generation can be considered to begin till every one of the previous generation was 70—an evidently false assumption.

3. Other things show forth the imperfections of the statements respecting the generations. The case of Canaan will show what I mean. The name of Canaan occurs as the son of Arphaxad in Luke iii. and in the Septuagint; but in the Hebrew Old Testament the name is not given as related to Arphaxad, whose son and heir is stated to have been Sala (Genesis). In Luke it will be noticed that the name Canaan occurs twice—once as fourth from Adam, and again as fourth from Noah; the second Canaan is unknown to the Old Testament—that is, the Hebrew Bible.

4. As Exodus distinctly states that "Israel dwelt in Egypt 430 years," we cannot at the same time attach absolute importance to Exodus and yet prefer Josephus' statement that they were in it but 215 years. Josephus saw the difficulty, but what historical authority had he to change it?

5. As the Israelites were said to have 600,000 men when leaving Egypt, we must suppose the total number to have been 3,000,000, which number, to arise in four generations, or 215 years, is absurd when we remember that but 70 persons went into Egypt, also when we remember that the powerful oppressor killed as many male children of Moses' generation as he could; so the males must have been well under their proper average. The case is rendered still odder by the statement that the large Israelitish population had only two midwives.

6. The difficulty as regards Egyptian history is very great, as no records whatever appear to exist to show that the Israelites were ever there, and yet the driving out or departure of 3,000,000 out of a population of 10 or 12,000,000, must have been a very serious matter. Still more strange is it that a short time before the same number of fighting men, &c. (the Shepherd kings), were driven out after serious work—of which plenty of records remain. Later records speak of the revolt of slaves, &c.; but not a word has yet been found about Moses, his mighty works, the troubles he caused, or the departure of the Israelites.

My impression is that the Israelites were a small body left behind by the Shepherds, and that they finally rejoined their kinsmen in Palestine, and that their numbers and importance were so small that the incident has escaped being recorded. The Jewish traditions referred to the main body, who were not peaceful descendants of a patriarch, but a hord of warlike Nomads.

7. One more difficulty remains to be considered—that is, of language and religion. If a few people went into Egypt and their descendants remained there for 200 or 400 years, we cannot doubt but that they would adopt the language, and probably the religion, of the country; yet we can find scarce any connections in language, and the Hebrews march out as a separate nation, and Moses writes in pure Hebrew, similar to that in use about the time of David—a most extraordinary occurrence, especially as the Israelites appear to have worshipped the Bull (Phah) in the desert, which (as the Golden Calf) shows they must have done so in Egypt.

Also, Moses was reared up as an Egyptian, in all its learning, which he apparently forgot in large part. All the Egyptians believed in the immor-

tality of the soul, and we do not find that the Israelites did so till after the Babylonish captivity. These things throw great doubt on the narrative, and I fear Mr. Smith will not be able to make it square with historical fact.

Memnon.

A PSYCHOLOGICAL PROBLEM—WAR DEPARTMENT TELESCOPES—HILL OF TARA.

[26287.]—I THINK the difference of opinion between "H. W." (letter 26270, page 67) and myself is little more than a question of the meaning attached to words. I find frequently, in argument, that the arguers are in agreement really as to facts, but do not see that they are so, on account of each holding a different view of the meaning of some word of ordinary usuage. In answer to the question he puts, my definition of "reasoning faculty" is put into words for me far better than I could do it by Browning. In fact, my whole theory may be contained in one quotation which, perhaps, "H. W." may not know, and if he do not, I need no apology for giving him the pleasure of reading it:

"Divers persons witness in each man,
Three souls which make up one soul: first, to wit,
A soul of each and all the bodily parts,
Seated therein, which works, and is what Does,
And has the use of earth, and ends the man
Downward: but tending upward for advice,
Grows into, and again is grown into
By the next soul, which, seated in the brain,
Useth the first with its collected use,
And feeleth, thinketh, willeth—is what Knows:
Which, duly tending upward in its turn,
Grows into, and again is grown into
By the last soul, *that uses both the first*
Subsisting whether they assist or no,
And constituting man's self, is what Is—
And leans upon the former, makes it play,
As that played off the first: and, tending up,
Holds, is upheld by God, and ends the man
Upward in that dread point of intercourse,
Nor needs a place, for it returns to Him."

The italics are mine. I call the second of these souls the "reasoning faculty," and the third the "will." I hope I have now made my case clear. But I own that I do not flatter myself on my power of metaphysical argument, and am not at all sure that it is not out of place in the practical pages of the "E. M.," so that I do not propose to trespass further on the patience of the Editor in this direction at present.

I cannot explain the phenomena of dreaming, nor do I believe that anyone else can. I tried to study it a little in one case where I was mesmerising a lady daily for neuralgia, and I directed her, when in the mesmeric sleep or trance, to dream of certain subjects in her natural sleep the same night. She always did so, without the least idea that the dream had been suggested in any way. But the amplification of the given subject, in the dream, was very remarkable, and often very beautiful. I have no doubt that in this way it would be possible to arrive at the true explanation of dreams, but I shall probably never pursue the subject further myself, for various reasons; not the least of which is, that I have long ago come to the conclusion that frequent mesmerism has a strong effect in altering the character of the patient, and, to quote Browning again,

"It's a dangerous thing to play with souls."

I cannot promise "H. W." to continue this discussion any further. I have not time to spare at present for metaphysics.

In answer to "Prismatique" (letter 26266, p. 66), I cannot say whether the *lenses* of the W. D. telescopes are English, but the mounting is undoubtedly of home manufacture.

I am much obliged to Mr. J. E. Gore for his trouble in ascertaining the facts about the excavations in the Hill of Tara (answers to query 59995).

Garrison Gunner.

FREE-WILL (?)—LOCOMOTIVES.

[26288.]—THE arguments by which, in letter 26230, page 38, "Garrison Gunner" seeks to establish the superiority of the will over the imagination and the reason are decidedly faulty, especially considering that reason and imagination have to do with the will only in so far as they are concerned in supplying motives of action, to the strongest of which the will submits. In the case cited by "Garrison Gunner," he has entirely omitted a very important factor—namely, that were he working a battery he would be subject to the orders of his officers; and that disobedience, more especially when caused by cowardice in action, would result in very disagreeable consequences to himself. Further, the idea of being considered a coward is in itself exceedingly unpleasant to the majority of Englishmen. Under the circumstances mentioned, there would be the danger of being hit by a bullet, or torn to pieces by a shell, producing most unquestionably a motive to run away; but, on the other side, there would be the dislike of being thought cowardly, and the knowledge that a display of cowardice before an enemy would be punished severely. In ninety-nine men out of every hundred, either of the last two considerations would produce a much stronger motive than the first; and hence they would stay at the guns. The hundredth man, being so constituted that the fear of being hit was the strongest motive, would of course run away; and probably be shot by one of his own officers for doing so. In reasoning like this I have, of course, taken it as axiomatic that a man always acts in obedience to his strongest motive, and I am quite prepared to find that some of our readers, perhaps "Garrison Gunner" himself, will question this statement. It is easy enough to quote cases in which, at first glance, persons seem to have acted in opposition to the strongest motive; but if these cases are critically and calmly analysed, it will be seen that in truth the strongest motive has been obeyed. Of course one man will often be very differently acted on from another by precisely the same set of conditions. A motive which under given conditions would be strongest for one man may possibly not exist in another. Initial constitution and life training come into play here. The action of a man at any instant is really a function of three things—two constant, and one variable. First, his initial constitution, by which I mean all the tendencies, tastes, and passions involved in the mechanism of the nerve centres in his brain; second, the training he has had, using the term to mean everything which has occurred to him up to date; third, his environment at the instant. Thus we may write $A = \psi$ (C. T. E.) Free-will is a term we use to express the fact that we cannot in any one case completely solve this question.

I am very glad that "M. R." (letter 26242, page 40) has come to my help in endeavouring to obtain practical data concerning express runs; and I hope in future our railway correspondents will give the requisite details. If an account of a run does not include coal burnt, and water evaporated, it loses much of its value, and unless the leading dimensions of the engine and the weight of the train are given it is of no value at all. To make a start I will ask for particulars of the run of the 10 a.m. express from London to Grantham.

Wm. John Grey, F.C.S.,
Analytical Chemist, Newcastle-on-Tyne.

LOCOMOTIVES, &c.

[26289.]—I AM glad to see that "P." points out some additional instances of misleading advertisements issued by our railway companies. I would have given those he mentions myself had I known of them, and consider it a lack of common honesty on the part of our companies to state deliberately what they know is not true. I agree with "P." in thinking that "Q." must have made a mistake in timing the marvellous run which he mentions, and should very much like to see full details. The G.W.R. engine No. 10 has cyl. 18in. by 26in. and 150lb. of steam, and is engaged on the South Wales trains.

"M. R." grumbles about not having the figures we want, and asks for tractive force, coal and water consumption, load, gradients, and average speed. Surely it is not necessary to fill the "E. M." with any such a catalogue.

The dimensions of our leading express engines are given *ad nauseam* in the inquiry columns, the coal consumption of each type is known pretty accurately by all who take the trouble to read the different engineering papers, the load is nearly always given when a run is mentioned, the gradients of our main lines are widely known, and Foxwell will give more information on the subject in five minutes than the MECHANIC can in as many weeks, and the average speed can be found by a glance at "Bradshaw." Add to which that probably 90 per cent. of those interested in the subject are already in full possession of required details, and I think "M. R." will agree with me that further repetition would be waste of space.

Mr. Scourfield asks if there are any inclines on the Brighton line as long or as stiff as that between Low Gill and Oxenholme. The fish train under discussion would have to *descend* this, so I cannot say I see much gained by reference to it. Owing, I suppose, to good arrangements, express trains are very seldom blocked at Oxenholme, Carnforth, or Lancaster, and never slacken speed appreciably in passing these places. "Kappa" adds this week that the fish train referred to reaches London in 7 hours 9 minutes after leaving Carlisle. Now, the N.W. Scotch expresses take 7 hours and 22 minutes between London and Carlisle; hence, I conclude, "it is better to be a dead mackerel on the N.W. than it is to be a first-class passenger by one of that company's most important trains." However, I agree with "Kappa"—the Brighton trains look slow on paper, even if the actual running is good.

What is to be done with the Midland 1669 set? The locomotive people seem almost in despair about them. There is some talk of lining up the cylinders; others say they are to be converted into single engines, whilst the only thing certain seems to be that they are no good as they are.

South-country readers may be interested to know that the G.S.W. have turned out four new express engines—leading bogie, $18\frac{1}{4}$ by 26 cylinders, 150lb. of steam, 6ft. 9in. four-coupled wheels. These, I am surprised to see, are fitted with the ball-valve vacuum brake for the train, and steam brake for engine and tender, the Westinghouse being discarded. It is curious to see the G.S.W. portion of the Midland Scotch express worked throughout with the vacuum whenever the Midland Company are content to use the Westinghouse on it. Are the N.B.R. to follow this example? On Friday the up Midland Scotch express left Carlisle 22 minutes late, owing to our old friend the N.B. train arriving at 1.24 instead of 1.3. Will "P." tell us what time it lost or gained before reaching St. Pancras? The N.W. up Scotch was more than an hour late at Rugby on Thursday evening (September 9th), but I cannot say where the time was lost.

"P." tells us of Harpy taking 21 coaches away from Euston. Can he say whether she ever arrived at Rugby on that occasion? This is pre-eminently *the* Compound for delightful surprises. I know no other in the southern division so erratic in her performances, so varied in her failures. Perhaps by now her injectors are beginning to put off the playfulness of youth, and to allow the engine to occasionally keep time.

The London Compound drivers seem particularly to dislike the 1.30 p.m. from Euston, and very rarely bring it into Rugby to time—that is, to the minute. What would they say to the 12 o'clock or the 4 o'clock down? And yet the 2.45 p.m., a very similar train to the 1.30, does not seem to trouble them much. How is it? **W. D. Thompson.**

[26290.]—I QUITE agree with "M. R." (letter 26242, p. 40) in his remarks. It may be interesting to know something concerning the speed of different trains, and it appears to me to be the principal thing under discussion, with occasionally a few dimensions of the locomotive. The compound system has been introduced, but only touched upon. To make this subject thoroughly interesting we want to know something about the coal consumption, &c. Because a train does not keep good time, I fail to see why the cause should always be put down to engine, which has to overcome such variable resistances. The compound type does not appear to be favoured by a number of correspondents, but I have not seen any argument conclusive why they are not as good as the ordinary type.

I have seen several times a compound running one of the Manchester and London fast trains. Now, as a practical question, can anyone give the amount of coal consumption of the compound against the consumption of an ordinary locomotive? Take the Manchester and London service, number of runs, and average weight of coaches.

Engineering, Manchester.

[26291.]—IT does not appear to be generally known that a four-cylinder tandem compound is working on the North British. I believe it takes expresses between Glasgow and Edinburgh. Its number is 224, and it is the engine which was in the Tay Bridge disaster. I should be glad to be furnished with the dimensions of this engine, and to learn some particulars of its working. I understand it burns as much coal as the non-compound engines.

In reply to "J. T. M.," I do not deny that it may be possible for a light engine to attain 90 miles an hour; but I attach very little importance to statements about railway speed which are merely vouched for by daily newspapers. As "J. T. M." thinks 90 miles an hour is so feasible that there cannot be any "beings conversant with railway work who would doubt it," I am surprised at his asking a question which compels me to think he cannot be conversant with railway work—*i.e.*, "can any of your readers supply authentic records of a train having been taken 60 miles in one hour." I should say that this is done on the G. N. R. every day; of course, I do not mean from start to stop, but that 60 consecutive miles are cleared at full speed in 60 minutes. I will publish shortly some particulars of a run I made on Tuesday from Manchester to King's-cross, in which G. N. R. "773" cleared 60 miles in $60\frac{3}{4}$ minutes, including the usual slack to 10 miles past Peterboro'. Mr. Rous Marten quotes three instances of 62 miles in an hour in the "E. M." of 25th Sept., 1885, p. 81. The up "Dutchman" has frequently done the 77 miles from Swindon to Paddington in as many minutes, one such instance at least having occurred within the last three or four months.

As regards steam domes, I fear that if the

"world" does not care about "the speeds of rival trains, or the performance of rival brakes," the "world" will evince scarcely greater interest in the steam dome question "J. T. M." wishes to start. I find on the G. N. the drivers would nearly all prefer domes, on the ground of the greater purity of the steam supplied to the cylinders, and the extra room for water in the boiler. I should think the absence of domes must be an advantage where the signals are placed on the wrong side, as giving the driver a much clearer view of the line.

May I give a hint to those correspondents who now and then send details of express runs? Let every train be timed from the absolute start to the absolutely dead stop. At King's-cross, for instance, the trains enter the platform at a very low speed, and continue to glide along it for half a minute or more before absolutely stopping. Passengers can, and often do, jump out; but, nevertheless, I say the time should be taken at the moment of dead stop, rather than at the time when it is practicable to jump out safely. The same observations apply to starting, and it is impossible to fairly compare trains except in this way.

I made the following capital run on Sept. 1, No. 503 (7ft. 6in. single) and five coaches:—

M.	Ch.		h.	m.	s.	Speed.
		Manchester	3	0	0	—
4	0	mile post	3	5	40	—
19	0	"	0	20	34	60·04
30	0	"	3	32	18	56·25
33	57	Liverpool	3	38	18	—

To Liverpool *viâ* Warrington is 28 chains more, and Warrington is 15 miles 55 chains from Manchester—not 16, as given in Mr. Foxwell's book. The 16 mile post stands on the bridge just west of Warrington Station, but the miles are not numbered from Central Station, Manchester, but from one of the other Manchester stations, I am not sure which. ? London-road. **Kappa.**

MIDLAND LOCOMOTIVES.

[26292.]—VERY much has been said about what these engines can and cannot do; but I have seen no mention of *one* engine lately with the 12 midnight express leaving St. Pancras with 25 coaches, then picking up three more at Kentish Town and going on to Bedford with 28, then took a pilot and went on again, and the few minutes lost was made up and the train ran into Liverpool to time. There was no pilot engine at St. Pancras or Kentish Town, so the one engine had to come and do its best. The result is pilots are to be kept at these places, and every train on the Midland with over 20 vehicles is to be divided and worked as two trains. **Anti-Vac.**

COMPOUND LOCOMOTIVES.

[26293.]—I AM much obliged to Sir Owen Scourfield in letter 26243 for giving the M.R. mileage viâ the Stoke Works loop. The run was undoubtedly a very fine specimen of Midland loco. work.

In replying to "P.," I can assure him that I was in "sober earnest" when I made the statement *re* the L. and N.W. Dreadnoughts that he refers to; and I do not think that this statement will appear so unreasonable as "P." seems to think it, if I may be allowed to offer some explanation.

With regard to "P.'s" remarks *re* bank engines, I may say that I have seen compounds leave Euston hundreds of times, and never to my recollection have I seen one leave without being "banked," unless a pilot was taken. Hence, the instance he mentions must, I think, be taken as an exception and not the rule. I would also remind him that this bank is the chief rise between Euston and Tring. After Willesden, the road is quite easy, rising gradually 1 in 400 all the way, except for a slight fall at Watford. On the other hand, the Midland road to Seagrave undulates considerably, and, to my mind, is incomparably harder than the N.W. The heavy express traffic of the North-Western Railway is now by Precedents and Dreadnoughts almost entirely. The only main-line trains worked by the compounds are the Irish Mails, work which is by no means exacting. It has, I think, been proved beyond all doubt that these engines were quite unable to perform the heavy work of the Precedents. It was quite certain that with a heavy fast train they *could not* keep time. They are now, I understand, working the Crewe local traffic with loads of 12-14 on an average consumption of 30lb. per mile, work which Mr. Stroudley's D class of bank engine would do on 20-24lb. per mile. I consider the compounds an admirable example of the fallacy of Mr. Webb's system. I contend that if the "system" was correct, the compounds ought to keep time easily with any train that the Precedent can, seeing that the compound has a tractive force of 104 (nearly) against the Precedent's 88, and at the same time have 10lb. of steam extra. But to return to the Dreadnoughts. They are doing very similar work to the Precedents. The former take heavier loads no doubt, but I consider that this is nearly counterbalanced by the higher speed at which the Precedents work. Now let us compare the dimensions of the two engines; I tabulate them for convenience:—

	Precedent.	Dreadnought.
Cylinders	17 × 24	$22\frac{1}{8}$ × 24
Heating surface.	1,083 sq. ft.	1,400 sq. ft.
Grate area.........	17 "	$20\frac{1}{2}$ "
Weight in tons...	33	$42\frac{1}{2}$
Tractive force ...	88	154
Boiler pressure	140	175

REMARKS.—As I have pointed out before, the Dreadnoughts have cylinder area equal to two $22\frac{1}{8}$in. ordinary cylinders.

A glance at this table is quite sufficient to show that the Dreadnoughts are (or perhaps I may be safer in saying should be) the most powerful express engines in Great Britain, while the Precedents are correspondingly just as small. Now, I argue that if a Precedent can keep time with nineteen coaches on some of the fastest N.W. trains, such as the 8.30 p.m. up—and they *can* do this, for I have seen them do it—such a load is but a trifle for engines of quite double the power. But the force of my argument is, I think, still more clearly shown when we turn to the all-important question of economy. I have been informed that a Precedent costs about £1,800 to build, a Dreadnought £3,000. Whether this is correct or not I am not in a position to say, but if any competent judge takes the trouble to compare the two engines, he cannot help being struck by the greatly increased cost of construction that exists in the case of the Dreadnought. The Precedents, however, are wonderfully simple engines. I feel quite certain that the difference in cost must be somewhere about the ratio mentioned above. Now let us consider the working expenses. The Precedents burn about 34lb. per mile between London and Crewe, the Dreadnoughts 36—40lb.; but lately I have heard terrible stories from the North. Several Dreadnoughts are reported to have burnt 50lb. per mile, and one, 504 Thunderer, has managed to consume 64lb., an achievement that only a Dreadnought can boast of. Surely this must convince "P." that my statement is not so very unreasonable after all, and I hope may act on him as a piece of digestive candy. The consumption of oil and grease, too, is equally amazing. As regards repairs, the Dreadnoughts are very bad, the enormous pressure being very trying to the packing-piston rings, valve faces, &c. While referring to the working expenses, I may mention that for some time a Dreadnought (Argus) and a Precedent (Courier) worked in turn the 8.50 p.m. from Euston in order to test the economy of the two engines. The trial, I believe, ended slightly in favour of the compound; but we may be quite sure that the economy must have been very small, as Mr. Webb has no objection to blowing his own trumpet. Compare the Dreadnoughts with Mr. Sterling's magnificent engines, that do on the road everything they undertake to do on paper. The G.N. 5.30 and 5.45 p.m. down and the 5.45 p.m. up are trains much harder than any N.W. to work, and yet they are worked to time and economically too by the 8fts.; but I feel certain I have said quite enough to substantiate my argument, which is this: It is far from being good work when engines of such dimensions and boiler power as the Dreadnoughts burn 36—40lb. per mile on such a good road as the southern section of the N.W., with loads which an engine of half the power and 9 tons lighter, costing far less to build and maintain, takes, with greater economy in fuel and oil, and keeps equally as good, if not better, time. I consider the Precedents very good engines for their size, but think they are too small and light to work the heavy leads imposed upon them with economy. "Kappa's" suggestion as to the disposal of the compounds to the "Celestials" is good enough; but I am inclined to think there is a still warmer climate than China which would be even more suitable. **G. D. Seaton.**

MIDLAND ENGINES.

[26294.]—I BELIEVE that the Midland Loco. Superintendent temporarily converted two of his coupled engines into singles by removing the side rods. These are 1313 and 1309. The former ran between Leeds and Leicester, and the latter between Skipton and Carlisle. I believe they did, or are doing, well, though possibly the side rods may have been replaced for the heavy summer traffic. Of course, a coupled engine without side rods would not be as efficient as a regular single, so probably one of the old 30 class mentioned by "M. R." with a large boiler and 18in. by 26in. cylinders would do far better than 1309 and 1313.

I wonder why, instead of trying two engines of the same type, Mr. Johnson did not try one of the 1309 and one of the 800 types. I was told as far back as 1883, at Derby, that they thought they should eventually return to the outside frames, and at Swindon they have done so, the last new goods engines (2361—2380) and the compound No. 7 having outside bearings, and a batch of 7ft. coupled express engines for the South Wales line are, I believe, to be on that principle.

I expect that much of the Midland unpunctuality is caused by the badness of many of the principal stations, which are much too small. The worst I know are Leicester and Nottingham. As for Gloucester, I do not call it a station at all, but a shed in a corner. Then they will send off long and important trains from St. Pancras within ten, and even five, minutes of each other from the same platform. This is bad enough in long stations like King's Cross, but St. Pancras is, I believe, nearly 200ft. shorter, and much room under the roof is wasted besides. I think that station might be very greatly improved if the booking-office were at the end of the platform instead of at the side. The short line along the wall might be carried to the end of the covered space, and then two long trains might load at the same time. The restaurant, &c., might be removed to the present booking-office, which is unnecessarily large, and might be made into a two-storied building.

Even in 1876 the arrival platforms at St. Pancras were too short for a very heavy train, for I came up from Glasgow at the end of September in that year by the night Pullman train, and several carriages were outside the covered portion, and trains are now much longer in proportion to their carrying powers than ten years ago.

The best-arranged station for the despatch of heavy trains at short intervals is Euston, because if two trains have to be loaded at the same time they are a good way from each other, and there is less chance of luggage getting mixed and confusion and delay ensuing; but then Euston is so very much larger than St. Pancras that a comparison of platforms is scarcely fair to the latter. Still, St. Pancras should either be rearranged or the trains started at longer intervals.

O. H. P. Scourfield.

LOSS OF LIFE AMONGST RAILWAY SHUNTERS.

[26295.]—SINCE my letter, p. 579 of last Vol. was written a further return has been issued.

The following comparative statement shows the number of railway servants killed or injured during shunting operations alone in each of the following years:—

	Killed.	Injured.
1877	167	1,175
1878	124	1,051
1879	99	1,047
1880	127	1,141
1881	125	1,339
1882	121	1,556
1883	130	1,449
1884	91	1,320
1885	138	1,236
	1,122	11,314

It will be observed that the number of men killed during the past year was the largest since 1878. That there should be 1,122 deaths and 11,314 persons injured in shunting only during nine years is a subject that cannot escape public attention.

Clement E. Stretton,
Consulting Engineer Amalgamated Society of Railway Servants.

Leicester, Sept. 17.

L. AND N.W. AND MIDLAND ENGINES.

[26296.]—I AM afraid there can be no hope of seeing Mr. Scourfield's (26243) suggestion as to building enlarged Precedents carried out just yet. In fact, we must wait till Mr. Webb finds out that his Compounds are a failure, and one wonders how soon this will be. There is no doubt in my mind as to the general excellence of the L. and N.W.; but it is really lamentable to see the way in which the company is throwing away money on these expensive and extravagant engines. That they have some good points is, however, proved, in that they can keep time with such fast trains as the 3.30 p.m. into Euston. As to punctuality, I am sure that in this respect the L. and N.W. stands far ahead of the Midland, and I can myself bear witness to the admirable punctuality of the service between London and Liverpool, as I often travel over this line.

I notice that the 11.5 a.m. express for London leaves Liverpool with a small Compound. Perhaps one of your correspondents can tell me whether this engine is taken off at Crewe or not; for south of Crewe the train is heavy and is timed fast.

I should like to see the particulars of the 80 minutes' run from Rugby to Willesden which "P." says the Precedent Avon made. **C. B.**

CONTINUOUS BRAKES.

[26297.]—I COMPLIMENT "Railwayman," page 40, 26241, upon putting this matter in such good form by his able questions. I take his questions just as he puts them, and add my answers. I don't wish to go into theory, but just give replies to what is asked, as below. **L. and Y.**

QUESTIONS.	REPLIES. So far as they relate to— The Westinghouse Automatic Air Brake.	The Vacuum Automatic Brake.
1.—Can the engine and tender (or both engines, when two are employed) and every vehicle in the train be fitted with the complete apparatus for each system?	Yes.	The engines are not provided with a reservoir; it is placed under the tender. Carriages and vans, Yes.
2.—In case of accident, or if the engine, tender, and every vehicle were uncoupled, would the brake act automatically?	Yes.	No, the engine having no store of power, the brake would not act automatically, and the breaking of the pipe leading to reservoir on tender would render the tender brake also useless. If the engines and tenders are fitted with so-called automatic steam brakes, the breaking of the pipe between the engine and tender renders the steam brakes useless. So far as relates to carriages and vans, Yes.
3.—If the brake on one carriage is out of order, can it be shut off without affecting the apparatus on the rest of the train?	Yes.	No, the pipe must be uncoupled in front of the defective vehicle, and the brakes on all those in the rear are then useless.
4.—Can vehicles be uncoupled for shunting purposes without trouble or delay?	Yes.	No, as soon as the pipes are uncoupled the brakes go on, and a man must walk down the train and open the release valves on every vehicle.
5.—In case of shunting vehicles when uncoupled from the engine, is the brake available either from the vans or automatically?	Yes.	No, there is no store of power available when detached from the engine.
6.—Is the brake instantaneous in action?	Yes, practically.	Quick, but not so quick as the Westinghouse.
7.—Can the brake be put on and taken off without trouble, especially upon long trains?	Yes.	There is often trouble and delay in getting the brake off, particularly upon long trains.
8.—Does the brake cause trouble by using steam from the boiler, and does it cause extra consumption of coal?	No.	The ejectors use very much steam; the extra coal used is quite two pounds a mile.
9.—Can trains be controlled when running down long inclines?	Yes.	Yes.
10.—Are there any parts in the brake which give trouble or require improvements?	Yes, the hose-pipes between the vehicles should be covered with some material to resist the action of the weather.	Yes, the engine should have its own store of power ready for automatic action, and the other defects above pointed out should be remedied or overcome.

MIXED TRAINS.

[26298.]—I HAVE read the letter of "Anti-Vac" (26237, p. 39) upon this subject with interest, and I think there can be no difference of opinion as to the necessity for mixed trains being discontinued.

With regard to the proper position for the passenger carriages to be placed in a train, very important points can be brought forward on either side; but I most certainly agree with the views of the Board of Trade and the Amalgamated Society of Railway Servants, that the balance of advantage shows in favour of placing the carriages next to the engine and in front of the waggons.

The carriages can then be fitted with continuous automatic brakes, and with a communication cord. The driver can without trouble stop the carriages at the platforms, which is a difficult matter when they are at the rear of a long coal train. Much greater fear is to be apprehended from the breakage of waggon axles, tires, and couplings, or from waggons leaving the line than from collisions.

It must also be remembered that the risk of collisions will be very greatly reduced by the use of the continuous brakes, and further, we must not lose sight of the fact that when the carriages are at the rear they are quite as liable to be run into by a following train. Quite recently a London and South Western mixed train became uncoupled near Crewkerne, and the two portions came into collision. The passenger carriage was at the rear, and six passengers and the guard were injured. That is one instance out of many in which, had the passengers been next the engine, they would have escaped all risk. **Clement E. Stretton.**

Consulting Engineer, Amalgamated Society of Railway Servants.

ENGLISH v. FOREIGN OPTICAL WORK.

[26299.]—THE recent letters on the making and selling of microscopes, as practised in England and on the Continent, have been most interesting, not only to those who have made a speciality of the microscope, but to many others having some general knowledge of optical matters. It might be profitable to extend the discussion to other optical apparatus, such as telescopes, opera-glasses, &c. Merely speaking as a buyer and user of such things, and not being in any way interested, save in procuring good instruments at reasonable prices, I cannot help expressing the opinion that "Prismatique" has shown prejudice in his unqualified admiration of English and depreciation of foreign workmanship.

Unlike our friend, I *have* seen poor work turned out by our countrymen—work decidedly inferior to some which I have seen produced by mere amateurs. Moreover, I *know* that lenses turned out by even eminent makers are not always uniform in quality, though, out of consideration to the parties concerned, I refrain from mentioning names.

In my own experience I have found it necessary to subject every fresh glass to a rigorous testing before accepting it as perfect, no matter whose reputation was involved. Seeing that no maker's name is an infallible guarantee of perfection, is it surprising that when any chance glass comes in the way, and turns out good, it should be duly appreciated—whether made by native Briton, Yankee, or even the "industrious foreigner"? By the way, I don't quite know whether Americans come under the category of "foreigners" (though I *do* know they regard us as such); but, if so, they can hold their own easily enough.

I am not at all surprised that the first living observer and discoverer of double stars should unhesitatingly prefer the instruments made by a certain American firm to those obtainable elsewhere; and I venture to think there are *some* first-class makers to be found on the Continent, too, even in such disreputable places as Munich and Paris! As to the cheaper class of terrestrial telescopes and opera-glasses, what sort of a price should we pay for them if entirely dependent upon home production? Some of these foreign objectives are of fair quality, and will bear favourable comparison with English ones costing a much higher price; indeed, between a first-class expensive English lens and a picked foreign cheap one, the difference is often so very slight that most practised observers would consider it out of all proportion to their respective cost. I have seen much more difference between two first-class objectives from the same eminent maker, and this has taught me to distrust every new piece of optical work until it passes the ordeal of a careful testing. **W. S. Franks.**

EYEPIECES.

[26300.]—RECENTLY experimenting upon the aperture necessary to see the *comes* of Polaris, I had occasion to try a variety of eyepieces. The night was not a good one, the Milky Way being barely perceptible. With 2½in. aperture the *comes* was easy, with Steinheil solid, and with 100 also. With 2in. I could just see it with the solid 275. I happen to have a very poor single lens about 550 ±, and on substituting this found the *comes* so much plainer I reduced aperture to 1½in. The *comes* was now more easily seen than with solid and 2in. But I could not with any eyepiece see it at all. There is much light lost at the surfaces of eyepieces, and plainly in looking for faint objects single lenses are of most service. If every surface loses 5 per cent., then four surfaces approach nearly to 20 per cent. of the light. The solid e.p. does not lose much at the interior surfaces; but as they are nearly ½in. in length, all solid glass, much light is absorbed in their substance. Is there no possibility of producing a single lens eyepiece to give good definition on a larger field than usual, as, of course, ordinary bi-convexes give good definition only in the middle? I have seen a single lens eyepiece by Browning which gave good results, but edges were bad and field narrow. Cannot something in the form of a meniscus be managed, or, if not, with a single lens? Could not a cemented achromatic on the pattern of the French button micro. lenses be made? These are thin, and would practically only have the two outer surfaces, and avoid the excessive thickness of the Stenheil solids. Of course, even if cemented, a considerable loss must take place when light passes from one kind of glass to another. I am sure this subject is worth attention. **E. Holmes.**

LAUNCH ENGINES.

[26301.]—I OBSERVE there is a correspondence going on about launch engines—high-pressure, or, rather, non-condensing, v. compound. I have had a considerable amount of experience with them—in former times in the Navy, and of late years in small steam yachts and launches. In my opinion the non-condensing are an unmitigated nuisance. If the blast is any good, smuts are thrown about the decks, and I well know the pleasure, with a party of ladies on board, of seeing, on first starting the engines, a shower of dirty water thrown over everything. Again, if the boats are used in salt water, it is almost a necessity to carry fresh for the boiler feed, which, of course, limits the duration of the trip.

I do not know much about the small compound engine, but it at all events would obviate the above evils, and if it be economical in fuel so much the better. Some of your correspondents seem to think economy in a small engine does not matter. It should not be forgotten that the man with a small engine generally has only a small income; and if he steams about much it may amount to something considerable, especially if he happens to live, as I did a short time ago, where coal was 25s. per ton.

Can any correspondent tell me the name of a German technical paper on the lines of the ENGLISH MECHANIC dealing principally with mechanical work.

Stuttgart, Sept. 13th. **R. N.**

[26302.]—IN reference to "Ingeniero" (letter 26254, p. 63), I admit that there is more friction in the compound non-condensing engine than in the single high-press. type. If we take the small cylinder of the compound to have the same amount

of friction as the high-press. engine, can we not use some of the exhaust to overcome the friction in the large cylinder and the rest to do useful work? Take as an example a single cylinder high-pressure engine: diameter of cylinder, 5in. by 6in. stroke; steam pressure, 80lb.; revolutions, 200 per min.; cut-off, $\frac{1}{2}$ stroke; we shall have a mean pressure of 67·7lb. Now taking the resistance of atmosphere at 15lb., and that arising from the various parts of engine at 1lb. per square inch, and again $\frac{1}{7}$ of the effective pressure to overcome the friction of engine when loaded, we shall have a useful pressure in round numbers of $\frac{(68 - 16) \times 7}{8} = 44$lb. The engine will thus give out about 6 effective H.P.

Now taking the compound and so dividing the work that each cylinder shall do about the same amount of work, which will be 3 H.P. to be equal in power to the high-press. engine; to do this we shall require cylinders 4in. by $7\frac{1}{2}$in. diam.

The useful pressure in small cylinder will be the same as in the high-press. engine, as will also be the terminal pressure—viz., 40lb.; this amount is really lost in the high-press. engine. As the ratio of the cylinders is $3\frac{1}{2}$ to 1, the average pressure in the large cylinder will have to be about 20lb. to do the same amount of work and to overcome the resistances as the small cylinder. It is needless for me to remark that a double cylinder engine is much more handy than a single engine; but this is not all, as the high-press. engine uses $\cdot125 \times \cdot25 \times 2 \times 200 \times 60 = 762$ cubic feet of steam per hour; whereas the compound uses only $\cdot07 \times \cdot25 \times 2 \times 200 \times 60 = 420$ cubic feet per hour. It may be argued that the compound is much heavier than the single high-press. engine; it certainly will be a little, but not much, as the flywheel is not required. I do not agree with "Ingeniero" that there is no advantage derived from tandem compound engines. I am rather pressed for time just now to state my reasons, but will do so in a future letter.

Engineering, Manchester.

CANTERBURY CATHEDRAL ORGAN.

[26303.]—I DO not doubt but that many readers of the "E. M." will be glad to see an account of the organ erected as above, which has recently been opened—maker, Henry Willis. The organist will occupy a raised position in the second arch of the south aisle. The instrument is in the triforium just above, and there is electric communication between the claviers and the sound boards; the wind is supplied from bellows blown by four men in the old singing school. There are four prismatic combination pistons to each manual, and four composition pedals to pedal organ. In the following list of stops, those marked * are from the old instrument, whilst those in italics are as yet only prepared for.

John T. Lawrence, B.A.

THE CASE HEAT CELL.

[26304.]—IF any readers of this paper have made experiments with this cell, I should like to know if their results agree with mine.

I recently made up a cell with carbon plates at the top and bottom, carbon rods being inserted into each to form the poles. The granular tin and chromic chloride were not tested for impurities. For comparison of E.M.F. I made up a Daniell cell, the E.M.F. of which I took to be 1·1 volt.

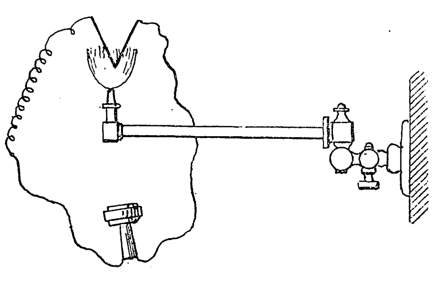
The following are the chief results worth mentioning I obtained from the heat cell. Average E.M.F. through 1,000 ohms resistance at a temperature a little below boiling point, 0·41 volt; average E.M.F. cold (60°), 0·12 volt; the internal resistance (hot) of my cell was about five ohms. On short circuit the current falls off rapidly, as if the cell became polarised, but I do not know the true cause. Impurities in the tin is the only explanation I can give for the E.M.F. being so high when cold.

Although this cell is undoubtedly a new departure as a practical means of converting heat into electricity by means of chemical action, I think other methods must be known. Water, for instance, may be decomposed by heat into oxygen and hydrogen, and the two made to furnish a current in a Grove gas battery, with the re-formation of water. **L. Miller.**

SENSITIVE FLAMES AND AIR WAVES.

[26305.]—I HAVE read with must interest in the ENGLISH MECHANIC of September 3rd your article upon "Sympathic Vibration of Jets of Air Impinging upon Gas Flames." If you deem the following of interest to your readers, you are at liberty to publish it.

Some two years ago I noticed, when conducting some experiments in my laboratory, the singular sensitiveness of a broad sheet of flame to very small air waves. I put together roughly some strips of brass and iron, so as to form a species of thermopile, thus:



This arrangement I suspended so that the broad flame from an ordinary fish-tail burner was in close proximity to it. A telephone was next inserted in the circuit, and I found that upon breathing upon the frame, or by interrupting it in any way, a very distinct sound was produced in the telephone. Speech was tried, whistling, and a variety of other effects depending upon or inducing vibration. In several instances the result was little inferior to that produced by an ordinary transmitter connected up in the usual manner. I did not follow up the experiment by making a thermopile consisting of a large number of couples; but I have little doubt that with properly-constructed apparatus a transmitter producing its own current could be made. So far as I was able to see, it was only needful to keep either the Bunsen or ordinary gas-jet at the predetermined distance from the ends of the thermopile which was found to give the loudest sound. This being done, the slightest vibration imparted to the flame was recorded distinctly.

Some of your readers may think this worth while experimenting upon. Lack of time prevented my doing so, and beyond mentioning the fact to one or two scientific friends, it has stood over.

F. M. Rogers.

HAS ENGLAND GONE UP HILL OR DOWN, &c.

[26306.]—BY an of error either myself or the compositor, in letter 26257, the amount of coal raised in 1850 and 1870 is stated as pound value instead of tons weight. **B. R.**

THE Northern Railroad of France has found by experiment that nickel can be rolled upon soft steel plates in such a manner as to produce a material for lamp reflectors of equal brilliancy with those made of silvered copper. These reflectors are reported also not to rust, and owing to the greater strength of the material, to be less easily knocked out of shape. The cost is only 55 per cent. of the cost of silvered copper reflectors.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[59842.]—**Space Filled with Spheres.**—For laying the floor of a box, evidently some mechanical guide is used. If square, a close row has to fit across each diagonal. If oblong, a thin diagonal lattice, whose laths are at least two-fifths as wide as their intervals, might be the best thing. There is an obvious reason for the square piling being mostly confined, as I said, to cannon balls, and for orange-sellers keeping the triangular base. The former needs a curb round the foot, but the latter none.—E. L. G.

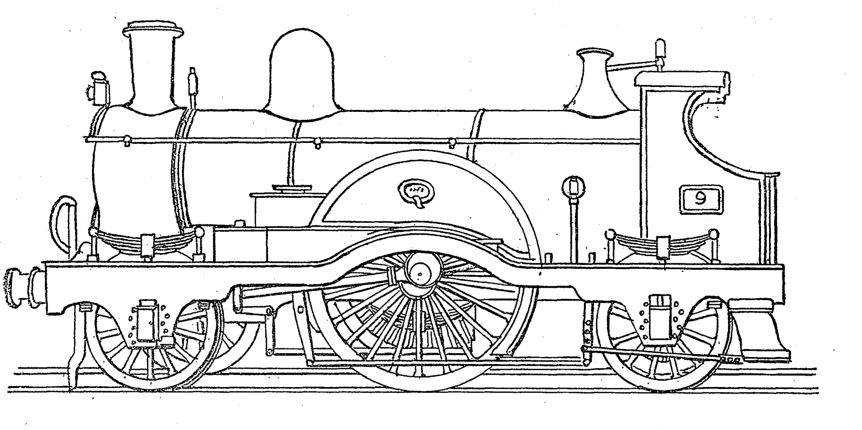
[59854.]—**Space Filled with Spheres.**—What "J. K. P." meant was plainly that the two kinds of pile he found to differ interiorly only in position as to the horizon. Tilting either of them through 54° 44′ makes its parts all correspond to those of the other. If he would see this very plainly, let him build half of a tetrahedron thus:—For the base, three rows of 5, 4, and 3; for a second layer, two of 4 and 3; and then a single ridge line of 3. This will make a solid of five plane faces, two half hexagons (on one of which it rests), two equilateral triangles, and a square. The last, he will see, is a chequer plane, though bisecting what would be a tetrahedron of five balls in each edge, and the same tetrahedron could have been bisected just the same in two other directions; so that it would contain three square chequer layers of nine, all intersecting in its sole inside ball. It has but one inclosed, though 34 superficial.—E. L. G.

[59854.]—**Space Filled with Spheres.**—"Does 'J. K. P.' really know what he wants?" Thus commences "G.'s" rather positive and slightly supercilious reply on p. 69, numbered 60050. Thanks, very much. "J. K. P." really does know what he did want, and is now quite satisfied. What he did want was to find out whether "G." was aware of the "fact" that the internal arrangement of a mass of spheres is the same, whether the building of the mass is commenced as in the base of a triangular pyramid, or as in a square one (see p. 42), and that this is the reason for the air spaces being of like capacity. "G." says it is not a fact at all, and tells me to buy some marbles. Hence I may conclude that he is not aware of the "fact" being a fact, which, however, it is. I have bought some marbles, and wonderful things they are, being nearly $1\frac{1}{4}$in. diameter, at $1\frac{1}{2}$d. per dozen; also I turned ten wooden ones of like size, and glued and nailed them up as a triangular, or "orange sellers'," pyramid, and have built them up in the inside of a square pyramid of the said marbles. Also I have taken a triangular pile, and by holding it in the right position, and removing some of the upper balls, have revealed the exact arrangement of the successive tiers of a square pile. As I said before, I do not concern myself with boxing them in. I had no sinister intention in calling "G." "Another G.," as I really believed he so signed himself, and am sorry for the oversight. The "original question" was 59854, and had nothing to do with the shot paradox, 60050.—J. K. P.

[59961.]—**Frosted Letters on Glass.**—TO W. MAIN.—I have tried the method described on page 42, "E.M.," Sept. 10th—viz., adding carbonate of ammonia to fluoric acid piece by piece, testing each time, till no more would dissolve, and the only effect it seems to have is to weaken the fluoric acid. If I allowed it to dry on the glass it would leave a matt surface; but that would wash off. Any further information would be thankfully received.—D. R.

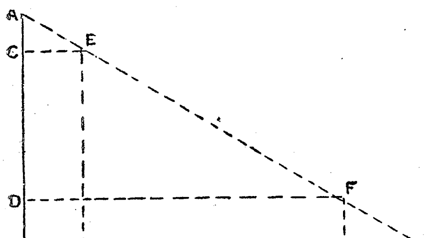
[60055.]—**House Boat.**—TO "PONTOON."—I suggested the boat cut in half on account of the less resistance I believe it offers to the water. It is the principle of the *Calais-Douvres*, now plying across the Channel, on behalf of which it was alleged by her designers that with two complete boats joined by a deck, the water was thrown off from the inner bow of each towards the centre, and being unable to readily escape, was heaped up and compressed between them so as to offer a considerable resistance as compared with the outside, which threw off the water into the open sea. I have not the exact formulæ by me for reckoning the displacement and buoyancy, as, though I have them somewhere, I cannot tell at the instant where to lay my hand on them, so will give you the figures next week.—E. CONRY.

[59762.]—**G.W. No. 9 Locomotive.**—I inclose sketch of the engine with outside eccentrics, but am only able to give a few dimensions. Driving-wheel, 7ft. 8in. diameter; leading and trailing-wheels, 4ft. 6in. diameter; cylinders, 18in. by 26in.; heating surface about 1,250 square feet; wheel-base, 18ft.; weight on drivers, 17 tons 5 cwt. The arrangement of outside eccentrics is not new on the



G.W.R., as I have heard of one of older singles being fitted in the same fashion about 15 years ago. —B.

[60058.] — **Fall of Potential.**— The fall of potential is simply the loss (or fall) of force along the circuit; it depends entirely on the resistance, and is the same no matter the length of the conductor. If you know the E.M.F. and the resistance of the various parts of your circuit, plot it out



thus:—Let A B be the E.M.F. in volts at the terminals of dynamo, and B G the resistance in ohms of the whole circuit (to the same scale), B I the R. of lead to lamps, I H, R. of lamps, H G, R. of return lead; count the number of volts between C and D and it will be the E.M.F. used in the lamps. A C + D B being that used in the leads I E, which equals B C, being the E.M.F. at the first lamp. If this is properly drawn to scale, you can see at a glance how your E.M.F. is used up, and also fall of potential in any part of the circuit. To find difference of potential at terminals of dynamo or lamp, connect voltmeter to terminals when full load is on.—I. LOW, Lenzie, N.B.

[60083.]—**Clematis.**—The following, clipped from the *Journal of Horticulture*, may be found useful to the querist:—These plants (C. Jackmani) can be increased by cuttings of nearly half-ripened wood in the spring of the year, if inserted in sandy soil, and placed until they are rooted under bell-glasses in a temperature of 50° to 55°. This, however, is not a certain method, and layering is never practised by the trade. The best, quickest, and safest method is to propagate them by means of grafting. Strong roots from any other kind must be procured during the winter, and kept moist in cocoanut fibre refuse, sand, or any similar material, until wood is ready for the scions in spring. Plants from which the wood is taken are generally wintered in cold frames, and brought forward in them by keeping the frames moderately close. The young wood should be used for scions, say, after it has attained 3ft. or 4ft. in length, and before it becomes half-ripened towards the base of the shoots. Each scion should be cut off just above a pair of eyes, and the wood between the joints left to each scion should be cut wedge-shape. The strong roots should be cut clean across the top, then split down the centre, and the scion fitted in between. The bark of the scion and the root must be fitted together on one side, and then bound into position by matting or worsted, the first being the best. One pair of eyes is sufficient for each scion. After this the grafted roots should be potted singly in 3in. pots in sandy loam. A gentle watering should be given, and the pots plunged in a propagating case where the bottom heat ranges about 75°, and the top heat 55° to 60°. Attention must be paid to dewing them over daily, preventing the sun from striking upon them, and lifting the lights of the case. Clematises are easy to graft, but unless care is taken with them for the first few days or a week afterwards, they will all go off. Union soon takes place between the stock and scion, and if they can only be kept from damping until they have reached that stage they will be perfectly safe afterwards.—NUN. DOR.

[60097.]— **Vacuum Brakes.**—The ball-valve goes back to its seat again. Perhaps there is too great an incline; that is what it seems to me. Say you have 10in. of vacuum (= 5lb.), and pistons $6\frac{1}{2}$in. stroke. The whole of the brake force is destroyed by the upward stroke of the pistons, and you have no brake left. This is why the brake does not hold.—TRIPLE VALVE.

[60131.] — **Muffin Plate.** — There is nothing very wonderful in a muffin-plate: it is simply a sheet of iron heated by the hot gases from a furnace—a small one—and coke is preferable to coal; while charcoal is better than either. A good recipe is flour, half-peck; warm milk and water, half-gallon; yeast, quarter-pint; salt, $\frac{1}{4}$lb.; mix these thoroughly for quarter of an hour, and add another half-peck of flour. Work up into dough, and put aside in a warm place to rise. Then roll up and pull into suitable pieces, which are baked on the plate or on tins in an oven, turning when half done and dipping into warm milk just before browning off. Crumpets are made by pouring a thick butter into rings laid on the plate.—THE BELLMAN.

[60139.]—**Transferring Prints to Glass.**—Clean the glass thoroughly and keep out of the way of dust. Coat the print carefully with gold size, copal varnish, or (best) Canada balsam, and when completely coated place carefully on the glass, rubbing down so as to exclude air-bubbles, and obtain perfect contact at every part. Allow it to dry, and then with the finger dipped in water rub the paper carefully off, so as to leave only the ink lines adhering to the balsam, which is the best thing to use. A good deal of practice will be required, but much may be done by a little experiment. If the paper is thick, you can gum a piece of wood or millboard on the back of the print after it is dry, and subsequently "split" that from the glass-plate, when it will bring away most of the paper. Apply a coat of varnish or balsam when the paper is removed.—SAML. RAY.

[60140.]—**Tobacco.**—The tobacco leaves when ripe should be cut and allowed to dry partly in the sun on the ground. In practice the stem is cut down and left until the leaves wilt, which will be in an hour or so, according to the heat of the sun. They are then hung up to dry, and afterwards the leaves are stripped from the stem, damped slightly, tied in bundles, and packed between boards, which are weighted down, when a process of slow fermentation commences. This must be watched to prevent mildew, and when complete the leaves will have the true aroma. It is no use for fumigating until after the fermentation—any vegetable refuse would do quite as well if that important part is left out. The Excise can prevent you using tobacco in that way, but as a rule they do not. They may be more strict, however, now that so much attention is being devoted to the subject.—SAML. RAY.

[60155.] — **Gelatine for Clarifying.**—Yes, gelatine and isinglass are used for clarifying beers but wines are generally cleared with white of egg or milk. As to the "process of manufacture," it is not clear what information the querist wants. The brewers' finings are made by dissolving fine-shredded isinglass in sour beer, and diluted with small beer after filtration. A pound of isinglass will make about 12 gallons of "finings."—NUN. DOR.

[60168.]—**Domestic Mincing Machine.**—Messrs. Churchill have a mincing machine in which the meat is really cut, a wheel of blades rubbing over the surface of a plate through perforations in which the meat is forced. You will find their advertisement in nearly every number.—NUN. DOR.

[60173.]—**Rusty Kitchen Boilers.**—The difference is far more likely in the water than in the iron, which is either cast or wrought. An effectual remedy is to boil hard water in it, which will coat the plates with "fur"; but, failing that, it is a good plan to rub the plates all over with paraffin wax when hot. The difficulty is that in the majority of boilers it is impossible to reach all parts of the interior.—SAML. RAY.

[60176.]—**Dyeing Flags.**—This querist should consult a work on dyeing, if he cannot find what he wants in back volumes. Surely he might have stated what material it is he wishes to dye, and what colours he requires.—S. T. N.

[60178.]—**Locomotive Cranks.**—It is advisable to have the driving cranks as long as possible.—C. M.

[60185.]—**L.B. and S.C. Locomotives.**—The dimensions of L. B. and S.C. 4 Mickleham, Class D, are as follows:—Boiler barrel: length, 10ft. 2in.; diameter outside, 4ft. 1in.; thickness of plates, $\frac{1}{2}$in.; tubeplate, $\frac{3}{4}$in. Outside firebox: length outside, 5ft. $2\frac{1}{4}$in.; breadth outside at bottom, 4ft. 1in.; thickness of plates, end, $\frac{5}{8}$in.; sides, $\frac{1}{2}$in. Inside firebox (copper): length inside at top, 4ft. 2in.; bottom, 4ft. 6in.; breadth inside at top, 3ft. 3in.; bottom, 3ft. 5in.; thickness of plates, $\frac{1}{2}$in.; tubeplate, $\frac{7}{8}$in.; distance between crown of inside box and shell, front, 1ft. $2\frac{7}{8}$in.; back, 1ft. $4\frac{7}{8}$in. Crown stays: number, 90; centre to centre, 4 and $4\frac{5}{8}$in.; area of firegrate, 15·2 sq. ft.; surface of firebox, 90 sq. ft. Tubes: number, 177; diameter outside, $1\frac{3}{4}$in.; thickness, 10 to 11 B.W.G.; outside heating surface, 858 sq. ft.; total heating surface, 948 sq. ft.; ratio of heating surface to grate area, 62 : 1; firegrate area to flue area, 6·75 : 1; firegrate area to least sectional area of chimney, 10·8 : 1. Safety-valves (two on dome): diameter, $2\frac{1}{2}$in.; effective load, 140lb. per sq. in. Smoke-box: length outside, 2ft. $6\frac{7}{8}$in.; breadth outside, 4ft. $6\frac{1}{4}$in.; thickness of plates, $\frac{3}{8}$in.; steam-pipe, diameter inside, 3in. Exhaust pipe: diameter at top, $4\frac{1}{2}$in.; height above centre of boiler, $9\frac{1}{2}$in.; above top row of tubes, 2in. Chimney: diameter at top inside, 1ft. 4in.; bottom inside, 1ft. 5in. Cylinders: diameter, 17in.; stroke, 24in.; centre to centre, 2ft. 2in.; diameter of piston rod, $2\frac{3}{4}$in. Ports: length, 1ft. 3in.; breadth of steam, $1\frac{1}{2}$in.; exhaust 2in. Slide valves: travel, 4in.; lead, $\frac{1}{8}$in.; outside lap, $\frac{7}{8}$in.; inside lap, $\frac{1}{8}$in. Valve spindles: diameter, $1\frac{3}{4}$in.; centre to centre, 4in. Valve gear: travel of eccentrics, $5\frac{1}{2}$in.; length of eccentric rods, 4ft. 10in. Connecting rods: length, centre to centre, 6ft. 6in.; diameter of large end, $3\frac{1}{2}$in.; small end, 3in.; diameter of bolts, $2\frac{1}{8}$in.; threads per inch, 7. Diameter of wheels: driving and leading, 5ft. 6in.; trailing, 4ft. 6in. Wheel base: leading to driving, 7ft. 7in.; driving to trailing, 7ft. 5in. Cranks: section of outer arms, 11 by $4\frac{5}{8}$in.; inner arms, 11 by $4\frac{1}{2}$in. Crank axle: centre to centre of bearings, 3ft. $11\frac{1}{4}$in.; length of bearings, 8in.; diameter of axle at wheel-boss, $8\frac{1}{4}$in.; at centre, $7\frac{1}{2}$in.; diameter of crank-pin, 8in. Leading axle: diameter at wheel-boss, $8\frac{1}{4}$in.; at centre, $6\frac{1}{2}$in.; length of bearings, 1in.; diameter of bearings, 7in. Trailing axles: diameter at wheel-boss, $8\frac{1}{4}$in.; at centre, $6\frac{1}{2}$in.; length of bearings, $8\frac{3}{4}$in.; diameter of bearings, 7in.; pumps (2); diameter of plungers, 2in.; stroke, 2ft.; Westinghouse brake; tanks on sides. Frames: distance apart, 4ft. $1\frac{1}{2}$in.; thickness, 1in.; depth, 1ft. 5in.; extreme length over all, 28ft. 7in.; length over buffers, 31ft. $9\frac{1}{2}$in.; height of footplate above rails, 4ft.; width over footplate, 8ft. Springs: driving, volute, diameter, $7\frac{1}{4}$in.; length, $11\frac{1}{4}$in.; section of plate, 8in. by $\frac{3}{8}$in.; leading (17 plates) and trailing (16 plates); length unloaded, 3ft. 6in.; breadth, 5in.; thickness of top plate, $\frac{1}{2}$in.; thickness of remaining plates, $\frac{3}{8}$in.; camber loaded, $3\frac{1}{2}$in. Weight of engine empty: leading wheels, 12 tons 10cwt.; driving wheels, 12tons 10cwt.; trailing wheels, 9tons 7cwt.—total, 34tons 7cwt. These dimensions are taken from *Engineering* for Jan. 14, 1876 (Vol. XXI. p. 28). They are not at all the same as those given by "G. N. R." on p. 20 in No. 1119. Where did he find them?—V. J. B.

[60186.]—**Mathematical.**—It cannot but be plain to "T. C.," I think, on looking at the smallest square holding two circles of 6in. diameter, that it is the face of the smallest cube that will hold four (or three) spheres of that size. If the question had been the least cube that will hold two of the given spheres, it would not have been quite so easy, and this would be worth the attention of those who have answered the other.—E. L. G.

[60194.]—**Strawberries.**—The following notes, extracted from a paper by Mr. J. Muir, of Margam Park, South Wales, in the *Journal of Horticulture*, may be found useful by those who have recently been writing on the culture of strawberries: "It is of no use," says Mr. Muir, "attempting to grow strawberries successfully under the 'odd corner' system. They certainly will cover any 'odd corner' with foliage; but they require a good position to obtain abundance of high-class fruit from them, and the first and foremost thing to do in either introducing them for the first time, or making a new plantation anywhere, is to select a spot well exposed to the sun, and where the soil is of a substantial nature. Strawberries can be grown in light soil; but they do best in heavy material, and a stiff soil will always produce more

robust plants and finish finer crops of fruit than light soil. I have known strawberries planted in very light soil bear excellent crops for a year or two, if the weather happened to be moist at the time the fruit was swelling; but when the season chanced to be dry at that time, they were almost a total failure. It is when the fruit is swelling and ripening that the quality of the soil is tested. Many are heard to complain that their strawberry plants were full of bloom, the fruits formed freely, but most of them were lost before ripening; and that is the evil of planting in light soil, as it is very rarely the crop fails in heavy material, and the fruit as a rule swells to the last berry. In many cases the surface soil of a garden is very fine and light, whilst the subsoil is heavy, and if trenching was done there before the strawberries were planted it would benefit them highly. The subsoil should then be brought well up to the surface, and the whole of the quarter for the strawberries should be trenched before any manuring is done. It is generally understood that strawberries delight in a rich soil; but there is a danger of giving them too much manure, especially at first. I have known beds to be originally composed of almost half-manure, and the plants made astonishing growth in it; but this was all, as leaves took the place of fruit in a great measure, and these strong plants were by no means so fertile as those of medium strength. A very moderate supply of manure will grow strawberries well for the first season, and afterwards they can be easily and advantageously fertilised by mulching in early spring, which is the best of all times for this operation. In dealing with strawberries from this point of view, the newly trenched ground and soil being dug for the reception of young plants should only have a medium coat of manure worked into the surface, but what is used should be as good as possible. It must be remembered that a new strawberry plantation ought to remain in prime bearing condition for four, five, or six years, and if a quantity of weedy manure is introduced to the soil at the first, it will give endless trouble or may lead to the plantation having to be dug up prematurely. There is never any satisfaction to be had from a plantation which is constantly full of weeds, and when these are introduced with the manure, it is a difficult matter to keep them down or clear them out. The best and shortest way of preparing the ground for strawberries is to clear everything from the surface, dig or trench it if necessary from 1½ft. to 2ft. deep, then fork a quantity of good clean manure into the surface and plant. If the soil is inclined to be light, use cow manure; if rather heavy, introduce stable manure. As a rule it is not an advantage to plant strawberries where strawberries were before. Like many other things, a change of soil is very beneficial to them, and they may follow potatoes, onions, or any kind of vegetable crop which is being cleared off about this time. As to the best time for planting, I do not think there is a better than the end of August or very early in September. The young plants have then time to form roots and become well established before November, and once this is accomplished, they will bear a light crop the first summer after planting. It is always a very great advantage to have strong runners to place out, and if these were cut off and lifted some time ago and planted closely in a nursery bed to form roots they may now be transplanted without receiving a check. Secure a ball of soil with each if possible, and plant without breaking this. Newly dug or forked ground is always loose, and as the young roots establish themselves much more quickly in firm soil than loose material, when the whole have been planted the ground around each plant should be firmly trodden down. We find that those of the Black Prince type do very well with a distance of 2ft. between the rows and 18in. between the plants, but the more robust-growing ones should have at least 6in. more room each way."—HORTULANS.

[60197.]—**"Take a Postage Stamp."**—There is one of these machines at the Midland station, Sheffield, and the name of the makers is "The Post-Card Automatic Supply Company, Limited, 13, Huggin-lane, Queen Victoria-street, E.C."—H. GILBERT, Sheffield.

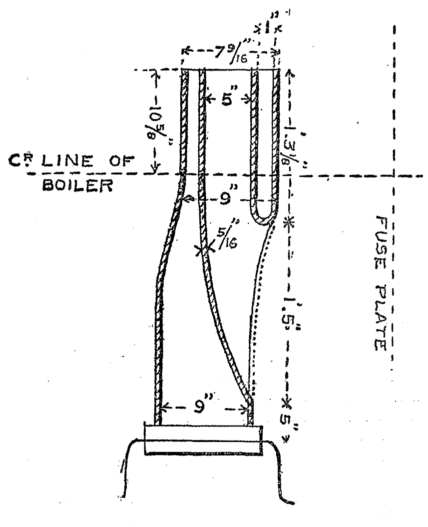
[60252.]—**Gravity.**—If, as "Red Light" states in answering the above that the portion of the earth left behind by the body in its passage through the shaft does not affect the motion of the body, how does he account for the alleged return of the body through the shaft? Has he not been rather too explicit?—G. H. H.

[60255.]—**Hydrostatic Pressure.**—I had not noticed this query until "T. C., Bristol," called my attention to it. I think it may be done without using the calculus. Suppose we have a beam of uniform section, hinged at one end to some object above the surface of a piece of water, and suppose that this object may be raised or lowered at will; if we raise it so that the other end of the beam just touches the water, the beam will of course hang vertically; if, then, we gradually lower it so that the free end of the beam passes below the surface of the water, it will still hang vertically until a certain point is reached, when the beam will then assume a sloping position. Now suppose the beam to be in this latter position, call the length of the beam l, the part submerged x (measuring along centre line of beam), then the portion of beam above water will be $l - x$. Now we have to take moments round the turning point of the hinge. Suppose W = weight of a cubic foot of water, S = specific gravity of the beam (in this case = ·82, water being = 1); also, let c = area of cross section of beam, the weight of portion above water will be $(l - x)$ S W c; this weight suspended at centre of gravity of this portion of beam gives a moment acting downwards, the length of the "arm" being $\frac{l - x}{2}\cos.\ \theta$ (θ being angle between slope of beam and horizontal); multiplying the weight by the arm, we get a moment of $\frac{(l - x)^2}{2}$ S W c cos. θ. Now for the submerged portion, the force tending to push the beam up will be the difference between the weight of the submerged portion and the same quantity of water, or (1 − S) W $c\,x$, applied at centre of submerged portion; the length of the arm is $\left(l - \frac{x}{2}\right)\cos.\theta$; multiplying them together, and equating to the moment already found, and striking out W c cos. θ, common to both, we get the equation—

$$\frac{S\,(l - x)^2}{2} = (1 - S)\left(l - \frac{x}{2}\right)x,$$

from which it will be found that $x = l\,(1 \pm \sqrt{1 - S})$, the lower sign to be taken; from this it appears that x (the length of submerged portion) is independent of the height of hinge above water, so that it will always be the same length. The depth of submerged end is easily found when we have found x; call depth = d, then, by similar triangles, $\frac{d}{x} = \frac{h}{l - x}$ when h = height of hinge.—M.I.C.E., Bath.

[60250.]—**Blast Pipe.**—The accompanying rough sketch will give a general idea of Adams's



blast pipe. I have as yet no details of its working; but I understand that on the L. and S.W.R. it is found to effect a considerable saving of fuel on engines to which it is fitted.—CARSTAIRS.

[60260.]—**The Aneroid.**—The table in the pamphlet named by Mr. Lancaster is not in a convenient form for ready use; but from it one can readily be constructed, which will show the heights corresponding to each tenth or hundredth of an inch of barometrical reading, and as the table is calculated for a mean temperature of 50°, the correction for temperature can be effected with the least possible trouble, and this is fully explained in the above-named pamphlet. I believe that some aneroids are graduated, and the works put together in much the same way as a watch; but the only correct plan must surely be to graduate after the works are in the case. Should an instrument be constructed on this latter principle, the spaces must naturally vary considerably. I imagine that "X." already possesses a copy of the table before mentioned, as his "limits" are peculiar, and correspond with readings given in this table. In the example he propounds, I make the height climbed to be 34ft., temperature being ignored, as it may safely be, in such a small range.—D.

[60263.]—**N.B.R. Engines.**—The engines which formerly had Ramsbottom's safety-valves underwent a slight change, but not a new departure on the N.B. The present standard safety-valve has two discharge tubes as before. In each of these is a spring in compression, coupled above to a bridge across the tube, the ordinary form of valve being used.—CARSTAIRS.

[60268.]—**C.G.S. Units.**—If my esteemed and most even-tempered friend, Mr. E. Conry, cannot perceive the difference between a force of a dyne overcome through one centimètre in a second, and a gramme lifted one centimètre per second, it is quite useless to argue with him; but, for the benefit of the querist, I may say that there is a difference of (only) 981 times in the values. I repeat my statement on page 44, that the latter is not a C.G.S. unit at all; and I will go further now, and say that it is not a unit in any system whatever. It is quite as much the duty of a correspondent to correct glaring errors as to answer queries. I am only surprised that Mr. Conry has not tried to defend his remarkable assertion that "on a frosty day the air is more rarefied than on a warm day," page 563. I promise Mr. C. that if he catches me making such absurd mistakes I will take his correction with much more equanimity than he has mine. *Humanum est errare;* but to persist in error after it has been pointed out is ———?—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60274.]—**Mushrooms and Salt.**—Since penning the reply on p. 21 I have learned that common salt is really a beneficial manure for mushroom-beds—though no explanation is offered of the cause. I have cultivated them for many years in all sorts of odd corners, but never tried salt. The fact mentioned by Mr. Wykes, p. 44, is, I find, corroborated by the practice of those who grow mushrooms for market, and we have consequently an interesting problem—How does salt act as a manure in the case of mushrooms? I do not think it can be merely because it assists in maintaining moisture, but rather because it acts chemically on some constituents of the soil, or of the bed.—SAML. RAY.

[60186.]—**Mathematical.**—It is quite clear that the balls cannot be arranged closer than to touch, and consequently with a minimum of waste room, and in working out the sizes I took the diagonal of the square as giving the size—viz., 14½in. divided by $\sqrt{2}$in.; and "E. L. G." appears to have done the same. But as yours of this week implies, I find the top ball is rather loose (by calculation), consequently the box cannot be the smallest, as one of the bottom balls could be raised a little, and therefore the box be reduced in size to, say, 10in. I also find that it takes me further into mathematics than I can now go, and will leave it to "E. L. G.," who seems pretty well up in these box puzzles.—T. C., Bristol.

[60297.]—**Testing for Faults.**—A detector simply shows, by the deflection of its needle, whether a current is passing or not. Join the instrument up to a cell, and if current is passing a deflection will be produced. If a bell is substituted for the galvanoscope it will ring, providing the current is strong enough. In testing a dynamo—the field magnets, for instance—to ascertain whether the wire with which they are wound is uninjured, the cell would be coupled to the detector, the detector to one end of the magnet wire, and the other end of the magnet wire to the remaining pole of the battery. If the needle deflects, the circuit is intact; if not, there is a fault somewhere, and the magnets must be unwound to find it. The instrument will not point out where the fault is situated automatically, as you seem to suppose.—C. D. R.

[60299.]—**Locomotives—N.B. Railway.**—Mr. Holmes's first bogies have only 6ft. 6in. wheels, not 7ft. as Mr. Seaton puts it. The principal dimensions are:—Cylinders, 17in. by 26in.; bogie wheel, 3ft. 6in.; coupled ditto, 6ft. 6in.; wheel base, 21ft. 4in.; boiler, 4ft. 4in. diameter; 196 tubes, 1¾in.; firebox, 4ft. 10⅝in. by 3ft. 6⅝in. by 5ft. 10in.; total heating surface, 1,030 sq. ft.; firegrate area, 17 sq. ft.; weight of engine loaded, 44½ tons; tender, 6 wheels, 4ft. diameter; base, 12ft.; tank capacity, 2,548 gallons. These engines are numbered 574 to 579, and run the Edinburgh-Glasgow expresses. One thing remains to be said, that as to the complaints of unpunctuality constantly being made about the N.B.R, no one can justly blame the engines, as No. 574 class do very good work, as also do some of the other classes.—CARSTAIRS.

[60301.]—**Electric-Lighting.**—What do you mean by "dimensions of electric-light wires." All wire is known by a certain gauge, the "B.W.G." usually, and the diameter and conductivity supplied by the makers. If you wish to know what current a certain gauge of wire will safely carry, tables are set out giving all particulars—for instance, No. 22 B.W.G. wire, copper, will carry a safe current of [illegible] amp.; No. 20, 3 amp.; No. 18, 4 amp. If you wish to calculate what thickness of wire will be required to carry a current of, say, 150 amps., it will, of course, depend upon the con-

ductivity of the metal used, and under these circumstances there is no help for it but to commence at the beginning. Get a knowledge of algebra, and be in a position to work the equation out. If I can help you further I will.—C. D. R.

[60307.]—**Analysis of Silver Alloys.**—I am obliged to Wm. John Grey for his reply to my query on this subject, p. 44, but should be glad of further information. I look to the ENGLISH MECHANIC as to an instructor of English working men, and I feel free to ask questions, and expect answers which shall help me, as a working-man, to understand the scientific principles underlying my trade or profession. Now, I am by trade or profession an electro-gilder and plater, and not altogether a stranger to some practice in the manipulation of metals, mechanically and chemically. I have been deterred (by lameness) from taking journeys to laboratories and workshops to get a practical acquaintance with my fellow men in analytical work; but I have studied works on analysis at home, and have put the lessons into practice in the workshop. With some of the processes I have been very successful, and can assay gold and silver with tolerable accuracy as tested by duplicates sent to some of the best assay offices in London. I find, however, that the loss of silver in assaying heavy alloys of this metal is variable, and, I think, as a consequence, that the usual checks are not to be depended upon to give strictly accurate results. I have known the variation to be, with the same composition, ·02gr. in a 7gr. sample, which is equal to 20gr. in the lb. avoirdupois. It is manifest that this is a serious variation when one has to determine the exact deposit of silver per pound avoirdupois on copper or brass in samples, where from 1dwt. to 2dwt. of silver per lb. only is allowed. I wish to ascertain the cause of this variation, and to avoid it if possible. I wish also to learn a more accurate method, and thought I could get it by a chemical analysis of the alloy. I find, however, that perfection and strict accuracy cannot be attained in this way unless one "has had a previous training in similar work." This is discouraging to an isolated student like myself. Is it impossible to train one's self by the aid of written or printed instructions? The instructions in the textbooks do not go far enough. The writers of those books appear to have had only a limited experience in assaying *manufactured* articles. I learn from them that alloys of silver can be quantitatively analysed with accuracy; but when I try the methods given in the textbooks I experience failure, as described in my query. I am therefore led to question whether they have ever tried to analyse alloys so poor in silver as those I name. I shall be glad to be set right on this point. I find that silver is always held in solution after NaCl or HCl is added in excess to a solution of copper nitrate containing 2 per cent. of silver.—G. E.

[60308.] — **Sound-Proof Doors.** — Close the doors on one side, and board up the other with match-lining, placing dry sawdust between the boards and doors as the work proceeds. This is most effectual and cheap.—C. D. R.

[60313.]— **Ozone.** — TO MR. BOTTONE AND OTHERS.—The method of producing ozone, described by Mr. Bottone, requires special plant. The trouble and outlay caused by purchasing and working this may be saved by obtaining pure ozone from Brin's Oxygen Co., Connaught Mansions, Westminster, who have perfected means of producing ozone in any quantity at such a rate as brings this hitherto costly gas within the range of practical application to numerous industries.—E. B. ELLICE-CLARK, M.Inst.C.E.

[60324.]—**Terrestrial Telescopes.**—My best thanks to "F.R.A.S.," "Garrison Gunner," and Mr. Nelson. Might I ask a little further assistance? I notice all three recommend a pancratic eyepiece. Has any description of this eyepiece appeared in "Ours"? (I have back Vols. to XXV. inclusive.) If not, how may I know one? Would it be possible to adapt one to my glass, or would the object-glass not be suitable? The instrument is by Bate, of the Poultry (now Potter), and was bought over thirty years ago. It has always been considered a very good glass; but I wish I could submit it to the criticism of a master like Mr. Nelson. Would that gentleman mind saying whether his telescopes are of English make? Any one like myself is rather helpless in purchasing a glass. One has to rely on what one is told about focus, power, &c., and as a rule there is not much opportunity of testing the capability of the instrument at the time, especially for such work as flag-reading.—D. G.

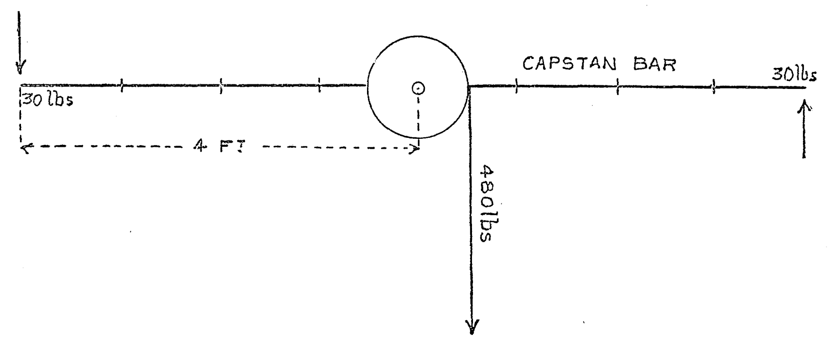
[60336.]—**Keeping a Pony.**—Does J. Low really mean that he would feed a 14-hand pony upon 3 to 4½lb. of solid food per diem, of which one-sixth part, or from 6 to 9oz., would consist of hay? I have read his reply several times, but can make nothing else out of it. It may be my ignorance, but to me such economical feeding is a revelation. I did hear once of a Welshman's mare which was by degrees reduced to a diet of one straw daily, but the historian of this wonderful animal records that she died before the experiment was completed. I have also read of one

"Captain Jinks, of the Horse Marines,
Who feeds his horse on peas and beans";

but in this case the metrical record is defective as to the results of the diet upon the animal economy. I had intended to reply to this querist with a word of warning, but it escaped my memory. I have a number of horses to keep, and have kept horses in both city and country, and unless querist wants some extra worry, he will not think of keeping a pony for pleasure unless he can also afford to keep a man to look after said pony—clean him, feed him, wash harness and trap, and attend to the many other matters connected with the stable. I never was able in a city to keep a horse under 20s. a week, and that was when the one man looked after three horses, and I got bedding for nothing. Even in the country, where I grow all my horses' eat, the food of each costs 10s. per week. Again, I cannot agree with J. Low. If you want a good horse, you are far safer, if you are not a judge, to go to a respectable dealer, tell him what you want, and get one on trial. He will, of course, expect a fair profit; but if he is a man of standing he will not knowingly sell you a screw. Such is my experience, and I have been using horses for 25 years.—DOCTOR MEDICINÆ.

[60337.]—**Small Compound Engine.**—There is such a large difference between my reply and that of "Engineering" that I think it as well to point out to querist that it all depends at what speed the engine has run at as to the power it gives. I have assumed 300 revs., and I think "Engineering" has assumed 150, so as to drive pumps direct; hence the larger cylinders required. Querist should remember that it is always as well to have more power than present requirements.—T. C., Bristol.

[60341.] — **Mechanics.** — The accompanying diagram will show the rationale of the forces



asked about by "Novice." If two ropes were wound round the capstan each in opposite ways, and each diametrically opposite to each other in their "pull," it is obvious that if each were weighted to 240lb. there would be no strain on the axle at all.—PAUL WARD.

[60341.]—**Capstan.**—Your first supposition is correct, $2 \times 4 \times 30 = 240$ being the strain on rope, and by supposing a strain to be applied to the opposite side of the drum to maintain the equilibrium, when the pressure is removed from the arm or bar, you will easily see that it must be 240 also, and, therefore, the shearing force on pin is $2 \times 240 = 480$. I do not think a diagram would simplify the case.—G. H. H.

[60343.]—**Heating Small Conservatory.**—A conservatory, 400 cubic feet, can be heated by an oil stove. A funnel fixed to 1in. pipe placed over the stove is sufficient to carry off the fumes, which cause an unpleasant smell, although not injurious to plants; neither is the light detrimental from the same.—G. O.

[60343.]—**Heating Small Conservatory.**—I would ask "Orchid" if he has ever used a gas-stove without a flue in a greenhouse for a whole winter, when the greenhouse contains plants which are in bloom or in an active growing state? If he has, I am afraid his results will be little, if any, better than doing without heat altogether. When he states that half the heat of a gas-stove is lost by using a flue, he states what is not true, unless the grossest carelessness and ignorance have been present when the stove was fixed. The flue of the stove or boiler should be used in the greenhouse, exactly in the same way as a hot-water pipe, and the products of combustion should not leave the flue at a temperature more than 20° Fahr. above that of the house. As a matter of fact, in my own greenhouse, when the house was at 50°, the products of combustion from the flue averaged 68° for four months in succession, and over 98 per cent. of the total heat was utilised in warming the air of the greenhouse. The only waste of heat necessary is to prevent down-draught: but for this, the whole of the heat could be utilised.—998.

[60346.] — **Charging Accumulators**.—Your cells short-circuit by the sediment you observe at the bottom of accumulators. This causes the E.M.F. to fall so rapidly after having been left some time after charging. To remedy this, cement strips of thin glass tubing at bottom of cells to prevent plates touching the bottom.—ZEMO.

[60346.]—**Charging Accumulators.**— Your plates are very small for practical purposes, and the charging dynamo of very little use. As you do not say what current it gives or the E.M.F., I cannot advise you upon the best method of arranging the cells during charging. The formation of the plates occupies several weeks, and the capacity for receiving charge depends upon the weight of reduced lead in them. It does not appear that you have carried the formation of the plates sufficiently far. You had better examine the cells and see to what depth they are converted into spongy lead. This may be ascertained by cutting a plate or two with a knife. You will probably find that the spongy lead only just covers the surface. If this is the case, you must continue the process of formation until the whole depth is reduced. This must be effected by charging the cells with at least one ampère of current per pair of plates. When the charging ceases to be useful the cells will give off torrents of gas, and if continued the liquid will commence to heat. They must now be slowly discharged through a resistance—a lamp, for instance; after which, connect again to the dynamo and pass in current, but in the reverse direction to that previously, and again discharge. This process of continued charge and discharge must be carried on until the whole of the plates are capable of receiving a full charge. The object of the continual reversal of the charge is simply to reduce the metallic lead to a porous state. After formation, the current must always be passed in from one direction.—C. D. R.

[60348.]—**Testing Gold.**—The test stone is a black slate-like stone of close texture. The studs or needles are bits of gold wire, made up of all the alloys of gold supposed to be required to be tested. The manner of using the studs and stone is as follows: The suspected piece of gold is rubbed on the stone until it leaves its mark thereon; then a test stud is rubbed on the stone by the side of the first mark, and the two marks compared. These rubbings are repeated until the rubbing of the suspected gold and a selected stud exactly coincide in tint. We can then determine that the suspected gold is nearly the same quality as that of the stud selected. It is largely in use by Indian traders.—G. E.

[60359.]—**Freezing Meat.**—I understand the apparatus is simply a steam-engine driving a fan which causes a powerful draught of air to blow perpetually through the chamber where the meat is kept, and thus by constant evaporation keeps the air at freezing point.—E. CONRY.

[60359.]—**Freezing Meat.**—This is effected on board ship by utilising the fact that compressed air is reduced in temperature on expansion. A steam-engine is used to compress the air in high-pressure cylinder, and is again forced into the chambers containing the carcases. In expanding it becomes reduced in temperature, and in its passage through the chambers extracts the heat from the meat until the carcases become cold enough to freeze; the whole principle of the operation can be demonstrated by blowing upon the back of the hand; if we simply breathe gently, we shall find that a feeling of warmth is imparted to the part breathed upon. If, now, we blow forcibly, we shall find the air proceeding from the lips is colder. Previous to issuing from the mouth it is compressed between the cheeks, and on expansion is reduced in temperature, and coming in contact with a warm body extracts the heat from it, and in doing so a feeling of cold is produced.—C. D. R.

[60362.]—**Cold Compressed Air.**—I am much

obliged to "S. G." and E. Conry for their information. They will find my address in Addresses, if they will kindly communicate.—DOCTOR MEDICINÆ.

[60362.]—**Cold Compressed Air.**—Machinery for producing cold air is, or can be, made in any desired size; a special apartment is not absolutely necessary, but is advisable. Power is requisite; but that may be steam, gas, or a hot-air engine, and a good supply of water is a sine quâ non, for the whole thing depends on compressing air and extracting the heat from it, so that when it is allowed to expand it will seize upon heat wherever it comes in contact with it—in other words, will be very cold. For dairy purposes, I should think the cold-air process scarcely suitable, though it may do well enough if it is desired merely to keep the milk and cream cool.—SAML. RAY.

[60363.]—**Cold Compressed Air.**—See reply to 60359.—C. D. R.

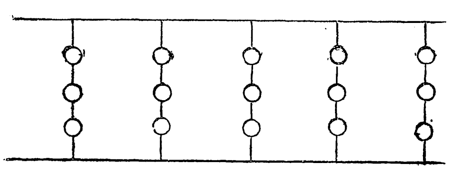
[60364.] — **Beach's Developer.** — TO MR. BOTTONE.—Make up two solutions, No. 1 and No. 2, in the following manner:—(1) Pyro. solution.—Warm distilled water, 2oz.; pure sulphite of soda, 2oz. Dissolve, and when cold add sulphurous acid, 2oz.; pyrogallic acid, ½oz.; mix, and keep in a well-stoppered stock bottle. (2) Potash Solution.—A. Water, 4oz.; pure carbonate of potash, 3oz. B. Water, 3oz.; sulphite of soda, 2oz. After each salt has been dissolved in its own water, A and B are mixed together. To develop an 8½ by 6½, take water 3oz.; No. 1, 4 drachms; No. 2, 3 drachms. If the image is slow in coming out, add more of No. 2. If it comes out too quickly, increase the dose of No. 1 and lessen that of No. 2.—S. BOTTONE.

[60365.]—**Printing.**—It is not easy to understand what "Pica" means by a "dwell" on the type, for all platen machines must, of necessity, have more or less of a "dwell," as the motion of the platen is reciprocatory. It is sufficient if the impression can be said to be perfect, whether it takes one-hundredth of a second or of a minute to produce it. Obviously, the longer the "dwell," within limits, the better the work—that is, some machines which have the merest touch-and-go action can scarcely be expected to do the best work.—A PRACTICAL PRINTER.

[60367.]—**Dry Meters.**—I have had very little experience with dry meters, and what little I have had has not been at all pleasant; the clicking noise which exists more or less in all gas meters will not increase his gas bill, as he appears to think. The objection to a dry meter is that the flexible diaphragms sometimes get hard, and when this happens, the behaviour of a dry meter is usually more curious than satisfactory.—THOS. FLETCHER.

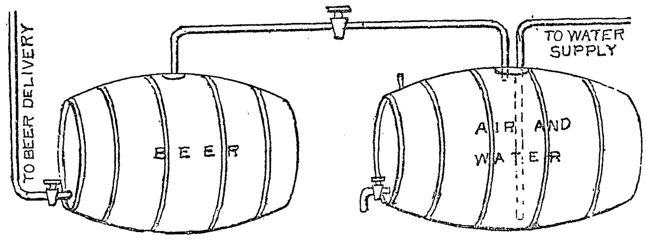
[60368.]—**Exploding Spirit Lamp.**—It does not matter whether the lamp is hot or cold; alcohol gives off vapour at ordinary temperatures, and forms an explosive mixture with air in the chamber of the lamp. The only cure is to make the burner fit better into its socket, so that flame cannot find its way into the reservoir. I have a lamp which frequently exploded until I stopped the air-hole up with a piece of match stick.—PAUL WARD.

[60370.] — **Dynamo.** — TO MR. BOTTONE.—There is nothing the matter with your dynamo; but your lamps are of too low resistance. You can,



however, remedy matters by running five or six sets of the said 14 volt 10c.p. lamps, of three in parallel, as shown above.—S. BOTTONE.

[60369.]—**δ Cygni.**—I see H. Atkinson asks about δ Cygni. He may rest assured Mr. Sadler's figures are not far out. I have seen the *comes* to δ easily very often this year, and on showing it to another person he estimated the distance as little under two seconds. I see it widely apart, and I am sure if Mr. Perry's measure was correct I should never see the *comes* to so bright a principal star. Is not 0·8″ a misprint for 1·8″? I have seen one or two *comes* to double stars which I think are hitherto unnoticed. Near ε Lyræ there is a pair of stars *f.* a little N., similar in position and distance to ε. Close to the S. star of the two is a faint double about 4″. Near P XVII. 200 Herculis are two pairs, one 10′ S. 20′ *p.* 20″ 110° ±, the other 10′ *p.* 9″ and 10″ 20″ 200°; β Cygni has a faint *comes* at 20″, 30° from the smaller star, and the star rather more than 1′ N., a little *p.* forming the apex of an isosceles triangle with β, has also a *comes* about as distant. Σ 2491 has a faint *comes* at 25″ 160° ±.



Star 1° *n.p.* from P XXIII., 101 Cassiopeiæ is double 6″ and 9″ 6″ 70° ±. There is a star on Proctor's maps betwixt P XX. 452 and ν Cygni; 2′ from this star at angle of 140° is a pair 8½—9½ 4″ 30° ±. I think T Cassiopeiæ must be at a maximum at present. On August 28th it was bright and very red. It has a *comes* 1′ distant at 340° and a fainter 10°.—EDWIN HOLMES.

[60370.]—**Dynamo.**—"Trouble" should have stated the E.M.F. his dynamo was made to work at. Probably it is higher than the 14 volts his 10 c.p. lamps take, so that he is running his machine slower than intended. From the facts he gives the machine seems rather to be simply shunt-wound than compound-wound. I suppose "Trouble" knows that if the external resistance of a shunt machine be lowered beyond a certain point the current rapidly drops. It appears likely that the addition of the two extra lamps lowers the resistance enough to do this. Try connecting the six lamps up in three parallels of two in series, or some such combination, to increase the external resistance, and run the machine faster if necessary.—MERE S.

[60373.]—**Battery Zinc.**—TO MR. BOTTONE.—The reason why the bottom of the zincs gets less acted on than the tops is because the zinc salts formed by the action of the acid on the zinc are heavier than the original acid, and falling to the lower part of the vessel as fast as formed, protect the lower end of the zinc from further action. Agitation, the use of a deeper cell, or occasional lifting the zincs will remedy this.—S. BOTTONE.

[60373.]—**Battery Zinc.**—Evidently from some cause the electrical action goes on chiefly at the middle of the plates—probably, I should think, either from the liquid having sunk to that point, or from the top and bottom having got coated with hard sulphate of zinc, while the middle is comparatively clean. It is usually the water line and edges of a zinc plate that wear away. If you get all the zincs properly amalgamated, and keep the plates the same distance from the carbon at all points, they ought to wear away evenly.—E. CONRY.

[60374.]—**Solder for Platinum.**—I have done it with a spirits of salt flux and solder, which I believe was the ordinary sort, using for convenience a blowpipe flame.—E. CONRY.

[60374.] — **Solder for Platinum.** — Ordinary plumber's solder adheres perfectly to platinum; so does silver solder. But all solders are apt to permeate the platinum, and render it readily oxidisable; for this reason it is better to rivet or screw the platinum tips on the screws or springs of electrical contacts.—S. BOTTONE.

[60374.] — **Solder for Platinum.**—Drill the end of the screw, and fit the platinum wire in the hole. Tin the inside of hole with soft solder, and tin the end of wire; heat them and put them together. The platinum sometimes requires a little persuasion to take the solder; but with soldering fluid it can be done. In cheap French work no solder is used.—OS.

[60374.]—**Solder for Platinum.**—For small work and light currents soft solder will do; but for hard work and heavy currents, such, for instance, as the platinum studs in contact breakers of induction coils, the cylindrical block of platinum is silver-soldered on to the brass screw, a small recess having been turned in its (the screw's) tip to hold the platinum central whilst heating. — PAUL WARD.

[60375.]—**Lifting Power of Engine.**—The area is, of course, in favour of the single 36in. cylinder, and it would lift most dead weight if crank were vertical; but the two 24in. cylinders would be able to start where the other would stick, and would lift most dead weight with the same amount of expansion.—T. C., Bristol.

[60375.]—**Lifting Power of Engine.**—If I understand your question rightly, all the practical factors which determine the power of engines are equal, except area of piston, and in the one case there is 24 × 2 = 48 acting sq. inches to 36in. in the other, so that the power of the engines ought to bear the ratio of 48 : 46. Really, however, it would not be quite so much—more like 44 : 46.—E. CONRY.

[60377.] — **Breaking Strain on Cables.**—ERRATUM.—The word "depressing" should be "depression."—SAILOR.

[60378.] — **Beer-raising Apparatus.**—I inclose sketch of arrangement whereby "Vino" can utilise his water-pressure for raising his beer. Let him take an empty barrel and connect his water supply (as shown), letting his pipe go to the bottom of his barrel and connect his beer barrel by means of a tube with a stopcock in it to his empty barrel; on turning on his water supply the air in his water barrel will be compressed sufficiently to force the beer up the 12ft. pipe. At a suitable time, say, every morning, he can turn off the cock between the two barrels, take out the vent-peg of his water barrel, and drain off what water has been used to compress the air in it, and start afresh; of course, he will have the sense neither to let his water barrel get so full as to send water into his beer, nor to burst his water barrel by excess of pressure from his water supply. This is, I think, about the simplest device he can have recourse to.—PAUL WARD.

[60381.]—**L.B. and S.C. Locos.**—Nos. 208 to 213 are alike in dimensions; 214 to 219 have slightly larger boilers and fireboxes, in other respects they are the same; 326 to 350 are all alike, with the exception of Grosvenor, 326, which has 4in. larger driving wheels—6ft. 10in., I think. Lancing and Worthing have been, or are about to be, sold or broken up, as there are some new tanks bearing the names. The Cavendish, I believe, is in the shops. I do not know the dimensions of Caen.—RICHMOND-PORTSMOUTH.

[60382.]—**Balance.**—Assuming the weight to be same side as goods to be weighed, it would have no effect until after the pointer of scale had begun to move, when the process of weighing is really completed; but the effect of the weight being below the knife edges of balance would be to lose part of its power of balancing when scale descended any distance, and so tend to return the beam to a horizontal position.—T. C., Bristol.

[60383.]—**Resistance of Battery.**—Why not make up two similar cells, with plates same size, acting surface and distance from each other, and couple them up against each other? You will thus get rid of all currents, and the resistance of one cell will be half that of the pair as joined up.—E. CONRY.

[60384.]—**Dead Black Lacquer.**—Ivory black ground up with a solution of shellac in methylated spirit is the ordinary dead black lacquer generally used. A better result is obtained by using a mixture of equal parts gum thus and gum sandarac instead of shellac. The proportions vary with the work for which the lacquer is required, and can easily be got at by experiment. The finish of the surface depends on the care with which the ivory black is ground up smooth with the spirit solution.—998.

[60386.]—**Letters on Brass.**—When I have cut these I have heated the plate and filled in with sealing wax, and dressed off smooth when cold.—T. C., Bristol.

[60386.]—**Letters on Brass.**—TO MR. S. BOTTONE.—I should make a thick paste by rubbing up the colours (ivory black for the black, and Chinese red for the red) and a small quantity of good copal varnish on a slab and muller until quite smooth; adding sufficient colouring matter to make a stiff paste.—S. BOTTONE.

[60388.]—**Wimshurst's Influence Machine.**—In reply to the questions by "Influence," I assume that the glass discs are 30in. in diameter. 1. The glasses should not exceed ⅛in. in thickness; smaller glasses should be proportionally less thickness. 2. The bosses should each be from 5 to 6in. in length. The end next the glass should be about 3¼in. diameter, the driving pulley about 2in. diameter in the V-groove. 3. A fair average size for the sectors would be 5½in. in length, the broad end 1in., the narrow end ¼in, 14 or 16 sectors on each glass. 4. The driving wheels ought to be about 10in. diameter. 5. The holes may be bored in the glasses by means of a suitably arranged revolving tube and emery and water; but many of the glass-cutters will cut out the hole when they cut the glass; it takes very little time. If the sharp edges of the glass are rubbed lightly with a file, it is

all that is necessary. 6. The spindles should be of steel, $\frac{9}{16}$ths, or $\frac{1}{2}$in. in diameter. 7. Whether 30in. discs are worth the trouble must be answered by "Influence," for the length of spark depends upon the distances given between each of the parts for the purpose of insulation. Long sparks cannot be obtained from small plates and the correspondingly small distances. Thirty inch plates, suitably mounted, will give thirteen or more inches length of spark. Quantity of electricity depends chiefly upon the velocity at which the plates are driven.—J. W

[60389.]—**Apparatus for Ringing Hand-bells.**—(1) I should think a large edition of the ordinary musical-box mechanism would do—a revolving drum, set with little spikes, meeting the ends of long elastic metal teeth, and twanging them as the drum revolves. If you had large, long elastic teeth, carrying a little metal button, you arrange them to strike the bells and then rebound. (2) You could copy the apparatus which rings the chimes in the clock-tower of "Old London" at the Exhibition; it is perfect of its kind, especially for arrangements where a blow of some force is required. If you like, I can give you a sketch of it.—E. CONRY.

[60391.]—**Inspector.**—Second in elementary is very much elementary indeed. The science and art exams. will not assist you in above appointments. In fact, the companies have a preference (which is well-nigh exclusive) for marine engineers possessing a chief's certificate, and I think they are quite right. In the first place they have to study hard and pass certain—not elementary—exams. by the Board of Trade, and are practical engineers. In addition, they have charge of the boilers in the boat, and are all-round men as a rule.—T. C., Bristol.

[60393.]—**Straight Wires.**—These can be obtained at any metal shop.—C. D. R.

[60393.]—**Straight Wires.**—I think there must be a special machine for preparing the wires for the brushes of dynamo machines; but when I want to so prepare wires in the way you mention, as for a pair of brushes, I do it by fixing one end in a vice, pulling the other out hard, and then cutting off with the pliers to desired length. It is not so long an operation as it might seem to be.—E. CONRY.

[60394.]—**Pocket Magneto Machine.**—To MR. BOTTONE.—What do you mean by a "pocket magneto machine"? I know of no machine having magnets less than 6in. long to be of any use whatever, and these can hardly be called pocket machines. If this is what you want, write again, and I will send in drawings and description.—S. BOTTONE.

[60395.]—**Water Motor.**—If you want simplicity and non-liability to get out of order, you must have a turbine, as a good one will work for years with care, and will not cost one penny in repair. I cannot help you as to the size of turbine as you do not state what fall you have or what quantity of water you have per minute, as these are the two main points of water power. If "F. E. A." will advertise his address, I will help him further.—MILL-MAN.

[60396.]—**Electric Lighting.**—Details of a dynamo suitable for you have been given by Mr. Eaves, and also by "Xero," in these pages. The construction of secondary cells is a long process. See my reply to 60346 this week. You are debarred from using any but Planté cells, owing to the patent rights held by the E. P. and S. Co.—C. D. R.

[60396.]—**Electric Lighting.**—In my book, "The Dynamo, How Made and How Used," you will find full constructive details for a machine such as you require. Some differences, however, must be made—viz., firstly, the machine should be three times the size of the one therein described; secondly, the armature should be laminated, or built up of punchings, instead of being solid.—S. BOTTONE.

[60396.]—**Electric Lighting.**—I am afraid you will not find any work giving what you want. What volts do your lamps take, and can you tell what current is required to light a single one? The latter would be advantageous, and information of the former is indispensable. If you will furnish this, and also say for how many hours each night you would want the light, perhaps I can help you.—E. CONRY.

[60397.]—**Engine.**—The boiler named, with a good draught, is only just large enough, or, I might say, barely enough. Better have one 14ft. by 5ft.—T. C., Bristol.

[60398.]—**Photography.**—Your proposed studio is not long enough (15ft.) for cabinet work. You will require at least 20ft., and if you use the lens mostly in use by first-class photographers (Dallmeyer's 3 A patent) you will require 24ft. Don't put windows in it, but make all your north side and roof of glass, and then you can use screens to modify the light as you desire. Seven feet in height is too low; why not make it 8ft. at the north side, rising to 12ft.?—B.SC., Plymouth.

[60401.]—**Violin Belly** should be $\frac{1}{8}$in. thick all over; or you may graduate it from $\frac{1}{6}$th at centre to $\frac{1}{10}$th at edge.—T. LISLE.

[60401.]—**To A., Liverpool.**—I don't know what is your motive for making a violin belly of cedar wood. I never heard of such, and would prefer a piece of nice grained deal or American pine, but not soft. I would think it would give a deal of unnecessary trouble to work the bass bar out of the solid. I give the thicknesses of a fine old violin in my possession as accurate as I can measure with callipers through *f* holes. Thickness under bridge is $\frac{3}{16}$in. Do. at inside edge upon bass side $\frac{1}{8}$in. bare. Do. on treble do. $\frac{1}{16}$in. full. Do. all round outside of the sides is $\frac{3}{8}$in.—A., Liverpool.

[60402.]—**Violin D String.**—Your violin is probably too thin in the wood, or the ratio between the upper and lower air chambers is not correct. Consult an expert.—T. LISLE.

[60402.]—**Violin D String.**—Of what sort is defect? Examine nut and bridge to see if string is stopped clean and sudden like other strings. If string buzzes on finger-board your bridge is too low, and you must get new one. Look if bridge stands well on both feet, and not on edge of one foot.—WEALD.

[60402.]—**Violin D String.**—It is one of the characteristics of a first-class violin that all tones produced by it are equal, and it mostly happens that an inferior violin is tubby upon its third string. This can often be greatly improved by trying a thicker or thinner string, and at the same time moving the soundpost slightly backwards or forwards, which can be done with a thin 1in. chisel or table knife; but it is essential that said post shall be exactly in a line with the centre of the treble foot of bridge, that it be so loosely up that if all the strings are taken off it would almost fall down, and, lastly, that the E string ought not to be, as is often the case, outside of the vertical line from centre of foot, so that there would be a strain to tilt the bridge over were the other strings slacked up.—A., Liverpool.

60403.]—**Revolving Cylinder.**—I should suggest working them with strong flat coil springs like those of a clock, and if you have any difficulty about making them go slow enough, you could wind on one axis, or on the cylinder itself, a cord sustaining a weight, by increasing which you could regulate the turn of the cylinder to any degree of slowness. I fear, however, you will have some little difficulty about getting it to work as slowly as you want without the aid of clockwork, or very special springs.—E. CONRY.

[60406.]—**Photographic Exposures.**—I would advise "N. Y., Plymouth," to get the "Systematic Exposure Note-Book" (Cartwright and Rattray, Manchester, 1s.), where he will find tables to suit all his queries. (1) and (2), he is right. (3), multiply 1 or 2 by 6 for August. Six o'clock is too late for photography in September.—B.SC., Plymouth.

[60409.]—**Boiler.**—If for practical work, buy one of the many 2 h.p. boilers always in stock, and do not go to the expense of a copper one. You could buy two of above for one of copper, and the difference in steaming is—well, let me say, a fancy. T. C., Bristol.

[60410.]—**Electro-Motor for Boat.**—I think it will scarcely be a "model" electro-motor that "Rochdale" requires. A boat of 3ft. in length will require a fairly powerful motor. I saw one working at an electrical exhibition (at Barrow-in-Furness) in connection with the School of Science and Art. If I remember rightly, it was about 4ft. long, and was sailing in a long tank. Mr. E. Thornton is the maker, and perhaps we might ask him to give us a description in "Ours," so that many of us who have tried and been unsuccessful may know how to proceed. This boat was fitted with apparatus for regulation to various speeds, and also motion for reversing. I believe the speed this small boat has attained is eight miles an hour, and to continue without recharging for six hours. Now this is just what many of us would like. Hope for Mr. Thornton's particulars that I may try my hand.—ANOTHER ROCHDALE.

[60410 and 60411.]—**Electro-Motor and Engine.**—If "Rochdale" can refer to p. 570, Vol. XLI., of the ENGLISH MECHANIC, he will find description and illustrations which I sent in, which will, if carefully followed, enable him to construct satisfactory motor and engine. If he cannot refer, and he will notify, I will repeat information.—S. BOTTONE.

[60411.]—**Engine.**—What sort of electromagnetic engine do you want? A little pump, or mill, or what—or will anything do that shows electricity turning a wheel?—E. CONRY.

[60412.]—**Steam.**—Area of 16in. cyl. = 201in., and of 27in. cyl. = 572in. Ratio of cyls. is $\frac{572 \cdot 2}{201}$, or 2·84 to 1, and if cut off at $\frac{1}{2}$ stroke in h.p. cyl., expansion will be $2 \cdot 84 \times 2 = 5 \cdot 68$ times. The terminal pressure at 50lb. boiler pressure will be $\frac{50 + 15}{5 \cdot 68}$, say 11lb. above a vacuum. At 65lb. it would require to be expanded $\frac{65 + 15}{11}$, say seven times to produce same final pressure, or at $\frac{5}{7}$ of $\frac{1}{2} = \frac{5}{14}$ of stroke in h.p. cyl. The reason of the saving in using h.p. steam is that the latent heat is proportionally less, but the sensible heat greater, the work obtained being represented by the fall of sensible heat obtainable, in working, from boiler to condenser or atmosphere; say in your case from 312° to 100° at 65lb. and condensing.—T. C., Bristol.

[60413.]—**Steam Valve.**—No difficulty in arranging this. Simply a piston weighted to lift at 30lb., say, and connected by a lever to an equilibrium valve to admit steam into the other boilers. No demand for such a thing commercially, as most would use a simple wheel valve, and adjust it as required by hand.—T. C., Bristol.

[60414.]—**Overhead Wires.**—You must obtain permission from the local authorities to cross the streets with an overhead wire, and also from the various owners of lands and houses over which the wires will run. In a majority of cases a rent will be charged for all houses where an insulator is fixed for the purpose of supporting the wire. You will be required to show good cause for erecting the line, and be prepared for a refusal.—C. D. R.

[60414.]—**Overhead Wires.**—Get permission to put up telegraph posts or insulators where necessary from the various householders on whose houses you require to put up the supports, and then run your wire as quietly as possible, without asking permission of anybody else, unless you happen to be in a very small country town, where everybody knows everybody else's business, and there is a fussy vestry to interfere with everybody all round; in which case it would be of no use attempting secrecy, and you would have to propitiate the "powers that be," and get their sanction.—E. CONRY.

[60414.]—**Overhead Wires.**—You must first obtain permission from the owners of houses where you wish to attach the wires. The local boards or parish authorities have no power or control over the overhead wires when carried across streets or highways; but owners of private property (or occupiers) can object to wires passing over their houses or gardens, and can institute proceedings if persisted in. Take care that your instruments are not an infringement of existing Bell, Blake, and Edison patents, or a local telephone company may trace out your line, see the instruments, and bring an action against you or your friend.—ARMATURE.

[60415.]—**Brazing.**—If only required air-tight solder would do; but if it must be brazed file a few notches in plug, which must not fit tight. Use powdered borax as a flux, and drop in some brass cuttings; raise to a red heat, and remove as soon as a blue flame appears in tube.—T. C., Bristol.

[60417.]—**Fish-Plates.**—Yes, they work loose by the vibration, and there are plenty of notions for preventing it, such as split spring washers, nuts with thread part bent, lock nuts, &c. Not possible to say if any railway company would adopt a thing, even if you gave it to them. The patent specifications on railway plant would repay reading, and give you some idea of the number of patents granted for railway matters, and how few are taken up.—T. C., Bristol.

[60419.]—**Clark's Cell** will give a constant E.M.F. of 1·457 volts. Hence, comparison with this gives ready means of measurement. In this cell the positive element is pure mercury, which is covered by a paste, formed by boiling sulphate of mercury in a saturated solution of zinc sulphate. The negative element consists in zinc which has been purified by distillation. It rests on the paste. Contact is made with the mercury by means of a platinum wire, which passes through a glass tube fixed to the interior of the vessel, and which plunges below the surface of the mercury; or, better still, through a little glass tube blown in the side of the vessel, and opening close to the bottom of it (See "The Electrician's Pocket Book," p. 62).—S. BOTTONE.

[60420.]—**Steam Whistle.**—The bell is not indispensable, as it is only used to increase and deepen the volume of the sound. Steam, blowing out against any sharp edge, will produce a loud screech, and if applied to an ordinary metal whistle in the same way as the breath, will produce a similar, only louder, effect.—E. CONRY.

[60421.]—**Carriages.**—It is quite impossible for a pistol thrown from a carriage window to fall on the step board, and if it did, the motion would soon shake it off.—KENTISH TOWN.

[60422.]—**Protection of Life.**—The offices of

the International Association for the Protection of Human Life are at Victoria Mansions, Westminster, S.W., and if your correspondent "Inquirer" will communicate with the secretary, he will doubtless be furnished with the information for which he asks. I may add that I am a member of the Executive Council of the Association.—CLEMENT E. STRETTON.

[60430.]—**Gravity Daniell Battery.**—Several causes have been at work to produce the effects you name. 1. The acid must be too strong to produce evolution of gas. 2. The zinc was probably not properly amalgamated, otherwise gas would not be evolved except on the closing of the circuit. 3. The sulphate of copper solution has been agitated and got mixed with the acid solution, hence the flocculent deposit on the zincs; or, 4. The zinc dips too deeply into the jar, and thus reaches the copper solution. I should strongly recommend the ordinary porous-cell form in preference to the gravity.—S. BOTTONE.

[60430.]—**Gravity Daniell Battery.**—Your solutions are mixing. The black deposit on the zinc is reduced copper, and takes place at all times when the sulphate solution reaches the zinc. You had better empty the cells, and recharge them, using plain water for the zinc; it will take up acid from the copper solution. When hydrogen is evolved it shows that the solution is too strong in acid; a portion, therefore, should be drawn off with a syringe, and pure water added to dilute the remaining portion. Daniell cells consume almost as much zinc on open circuit as on closed.—C. D. R.

[60430.]—**Gravity Daniell Battery.**—Your trouble comes from sulphate of copper reaching zinc. The local action deposits copper in dirty black form, perhaps really copper-hydrogen alloy, and then local action is increased. Open circuit merely encourages the evil; best chance is to let current run free, especially at first, with low resistance. Keep solution on copper plate well nourished with crystals. Clean your zincs now, and start again; fill up cells quietly. When not in use do not break circuit, but connect with high resistance, such as lead pencil, cutting two notches through the cedar for connection.—WEALD.

[60430.]—**Gravity Daniell Battery.**—Your cells are short-circuiting themselves inside—that is, there is some electrical communication between the zinc and copper plates, which ought not to exist. Probably it is caused by the metal strap or wire connected to the bottom plate not being properly insulated from the liquids through which it passes. Perhaps, also, the liquids have become mixed. Have you got sawdust or sand inside the cell, as that is one of the best ways to prevent the fluids mixing? Remake the cells, carefully insulating the metal strap, and using sand or sawdust, and you will not find any trouble. The ordinary form of gravity Daniell cell is as good as any for working an electric pen.—E. CONRY.

[60434.]—**Crank Movement.**—There must be a dead point if the motion of piston is reversed, or how could it reverse? This dead point is theoretically a mathematical point only; but practically it is an inch or two in good engines, and if you have ever tried to oil the crank-pin when running at, say, 100 revolutions a minute, you will know how short an interval it represents. Of course, a direct rotary motion is best, if we can get it without too much complication: but if any reciprocating motion is used to obtain it we had better stick to the crank, I think.—T. C., Bristol.

[60435.]—**B.A. Degree, Dublin University.**—If "Scholastic" would advertise his address in the "E. M.," I would be happy to send him a small calendar. University calendars and their supplements, containing the papers set during each year, can be had from Messrs. Hodges and Figgis, Grafton-street, Dublin, price 4s. each.—T. C. D.

[60435.]—**B.A. Degree, Dublin University.**—The regular examination for this is in December; there is also a special examination for the same in June. The subjects are astronomy, ethics, English composition, and any two of the following—viz., mathematical physics, experimental science, natural science, and classics or languages; the last-mentioned meaning any two out of Greek, Latin, French, and German. The questions for the ordinary examination are not published. "Scholastic" had better procure the Dublin University "Calendar," published by Hodges and Figgis, Dublin, and Longmans, London. Price 4s.—DUBLINIENSIS.

[60436.] — **Telegraph Connection.** — To "E. M."—Do you want the arrangement in duplicate so as to ring from both ends like an ordinary telegraph, or from your own end only? Your words strictly apply to the latter arrangement only.—E. CONRY.

[60437.]—**Zinc Stencil Plates.** — They are made for the trade by a punching machine; but you can cut them out with a mallet and chisel on a block of hard wood, carefully drawing the outline of the letter first, and finishing off with a smooth flat file, if necessary.—E. CONRY.

[60437.]—**Zinc Stencil Plates.**—Make a mixture of Burgundy pitch and beeswax and rub it on the slightly-warmed surface of the zinc. Black Japan varnish will do nearly as well if time is allowed for it to dry thoroughly. Rub the under side with tallow, scratch the outlines of the parts to be cut out deeply and cleanly, and cover the scratches with hydrochloric (muriatic) acid. If done with moderate care the acid will cut out the pattern as cleanly as if done with a chisel or graver.—998.

[60438.]—**Photography.**—The fault in enamelling is in taking the print off the glass *before* mounting; it must be partially mounted on cardboard first. In burnishing, probably your photos. were not sufficiently dry.—B.SC., Plymouth.

[60440.]—**Frogs.**—The best arrangement for keeping frogs is a large rectangular fern-case, the bottom of which is covered to a depth of about 6in. with peat moss. At one end place an enamelled iron pie-dish, sufficiently large to reach from side to side, and let the edge of the dish be on a level with the surface of the moss. In the centre of the dish build a small rockery of stones, &c., for the frogs to climb on. If you intend keeping green tree-frogs as well as the common or garden animals, you must plant a small bush of some kind (myrtle is the best and prettiest) at the end opposite the pie-dish, on which the frogs will bask in the sun. For the tree-frogs flies are the best diet, and the others will thrive well on worms, beetles, or any small insects. Of course, you may put any ferns, bits of bark, or other ornamentation into the case, and if this be tastefully done, the result will be a very ornamental vivarium. I may add that a few green Jersey lizards will add greatly to the appearance of the whole concern. — H. W. EDWARDS.

[60444.]—**Turning Vulcanite or Ebonite.**—Small sharp lathe tools (hand lathe tools, unless the work is very large), three-corner bevel and bird's-beak (i.e., pointed-nosed, more or less) of various sizes, with one or two very narrow, square-nosed tools for cutting with the side edge. A pretty fast speed, a light cut, and no lubricant; an ordinary carpenter's gouge ground down to a rounded nose is also very useful for this.—E. CONRY.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

IN the *Archives de Geneve*, Professor Brun has published an interesting study on the so-called lightning holes to be found in the High Alps. He and other investigators have found them at heights of from 3,348 to 4,000 mètres, or between 11,000ft. and 13,000ft. above the sea level. Usually they are found on summits. Sometimes the rocky mass, which it is supposed has been vitrified in the passage of the electric fluid, presents the appearance of small scattered pearls, sometimes of a series of semi-spherical cavities only a few millimetrés in diameter. Sometimes there are vitrified rays going out from a central point to a distance of four or five inches. Sometimes a block detached from the mass appears as if bored through by a cannon-ball, the hollowed passage being quite vitrified. The thickness of this vitrified coating or stratum never exceeds a millimètre, and is sometimes not more than the quarter of that depth. The varying colours which it presents depend on the qualities and composition of the rock. The same may be said as to its transparency. On the Rungfischhorn the glass thus formed by the lightning is black, owing to the quantity of actinolith which the rock contains. It is brown on La Ruinette, the rock consisting of feldspar mixed with gneiss containing chloride of iron. Under the microscope these lightning holes display many interior cavities, which must be attributed to the presence of water in the rock at the moment of melting by the electric discharge. This vitrified material has no influence on polarised light.

QUERIES.

[60445.]—**G.W.R. Engines.** — Will some correspondent kindly give dimensions of 3202 class, saying for which work they are used, and how many there are?—G.

[60446.]—**Bisulphide of Carbon.**—Will Mr. Grey, or some other competent chemical friend of "Ours," kindly say how many cubic feet of sulphurous acid gas are given off in burning five fluid ounces of the above? Also, what quantity of bichloride of mercury would it be necessary to vaporise to saturate 1,000 cubic feet of air?—IGNORAMUS.

[60447.]—**To Mr. Bottone.**—I am making a dynamo from dimensions given by you in "E. M." of April 23rd. What size should the iron ring for armature be (you give $4\frac{3}{4}$in., which is size over wire)? I intend using No. 18 double c.c. wire. What distance should there be between sections on armature? I propose using an iron ring with grooves turned on the outside.—MCP. M. V.

[60448.]—**Legal.**—Will our legal adviser kindly reply to the following queries? (1) If a married woman having an income under £100 in her own right can claim exemption from income tax (her husband is, of course, liable for his own property). (2) Is a wife's private property liable for any unpaid debts of her husband's at his decease?—THE BARD.

[60449.]—**Music.**—(1) I should like very much to read some good book, English or German, on harmony, "Harmonielehre." (2) Is there any work in existence which "explains" Beethoven's music—his sonatas, symphonies, and concertos? Would some kind friend of music give me some information on these two points? I should be greatly obliged.—MUSIKFREUND.

[60450.]—**Electric Power for Tramcars.**—(1) It is required to work five tramcars upon a line $1\frac{1}{4}$ mile in length, the total electrical power being 200 ampères at 300 volts, the cars on an average being equidistant. Assuming the generating station to be at one end, please state the economic sectional area of the conductors for various sections of the line. (2) Five cars, weighing two tons each, carrying 20 passengers, have to be taken up a gradient of 1 in 15 at a speed of five miles an hour. What is the necessary mechanical H.P. required and allowing for the loss in conversion, leakage, and transmission? What is the electrical H.P. required?—BLACKPOD.

[60451.]—**Pocket Accumulator.**—Will some of our practical electricians kindly inform me how to make a pocket accumulator for a 4c.p. lamp? Also a simple electric motor?—A. W.

[60452.]—**Loco. Question.**—Does the height of a loco. boiler make it run more rough? Should the boiler be kept low down to get steady running?—KENTISH TOWN.

[60453.]—**North British Engines.** — Wanted, dimensions of the new 590 class of N.B. express engines.—ANTI-VAC.

[60454.]—**Wind Motor for Electric Lighting.**—I have lately constructed a wind motor on a somewhat novel principle. Its power in an ordinary breeze is about on a par with an ordinary windmill presenting the same surface to the wind. As the wind increases in force the speed and power of the motor increases in proportion, without any check, except by the work it performs; but the machinery driven by the motor runs at one uniform speed, however much the motor may vary in speed. It requires no attention under any pressure of wind, except to keep it well oiled. My idea was to make a motor that would drive a dynamo to charge accumulators, and do its work automatically, without requiring the presence of an attendant. The motor is left free to start whenever there is sufficient wind to drive it, and when it attains sufficient speed to drive the dynamo safely, the dynamo is started automatically, and not before. When started, the dynamo will run at one uniform speed under any increase in the pressure of wind, and consequent increase in the speed of the motor; but when the wind decreases in force, so that the motor will not drive the dynamo at a sufficient speed to charge the accumulators, the dynamo is stopped automatically, and the same mechanism will break the contact between the dynamo and the accumulators. I should be glad to have the opinions of practical electricians as to the value of such a motor for lighting country houses, &c. I may add that the motor presents none of the objectionable features of an ordinary windmill.—J. G. GWYNT.

[60455.]—**Chemical.**—Could anyone kindly furnish me with a formula by which I could prepare paper, and make a medium in the form of a pencil (not brush) to use upon said paper, which would raise a palpable and permanent mark upon the same? Colour no object.—W. R. S. R. N.

[60456.]—**Balm of Columbia.**—What is the composition of this preparation for the hair?—SALUS.

[60457.]—**Winding Gramme Armature.**—To MESSRS. BOTTONE, EAVES, AND OTHERS.—Will you be so kind as to give an amateur the following instructions as to winding a Gramme armature—that is, the proper way of coiling the wires, so that the coils shall be evenly wound and the two ends of every coil to come on the outside, and to prevent self-induction between the coils?—AMATEUR.

[60458.]—**Old Oak.** — In consequence of wet flower vases having remained for some time on old polished oak furniture, the colour of the oak has in such places been removed. Can anyone suggest a means of polishing or staining such marks, or in any way restoring the colour of the oak?—IGNORANCE.

[60459.]—**Crane Chain.**—Find the maximum stress in a crane chain 30ft. long, which, when raising 25 tons, has to sustain the sudden impulse due to the dropping of the load through 9in. What statical load would be required to produce an equal stress in the chain?—X. Y.

[60460.]—**Telegraph Circuit.**—I have charge of a telegraph circuit of some eight or ten miles long. Six miles of the line wire is carried by the posts that belong to the railway. This same circuit is used for speaking purposes; but owing to the great amount of induction from other wires it is very difficult to hear each other. I would be very thankful for some instructions as to lessen the induction.—AMATEUR.

[60461.]—**Starch in Yeast.**—Would Mr. Grey, or some other chemical reader, kindly give information as to the best method of ascertaining the amount of starch in yeast when mixed with that substance?—ATOM.

[60462.]—**Testing Lightning Conductors.**—Would Mr. Bottone, or other electric contributor, oblige me with how to test a copper lightning conductor on a 60ft. chimney? I am wishful to do it myself; have battery and galvanometer. Can it be done without ladders, &c.?—CHIMNEY.

[60463.]—**Lantern Slides.**—I have a few slides (photos.) which, when looked down upon, have a greenish sort of tint. I think they are made by the "Wet Collod. Proc." Am I right? Is there any special preparation or mode of treatment for giving slides the above mentioned tint? What is it? Can it be used with any process or plates?—B.

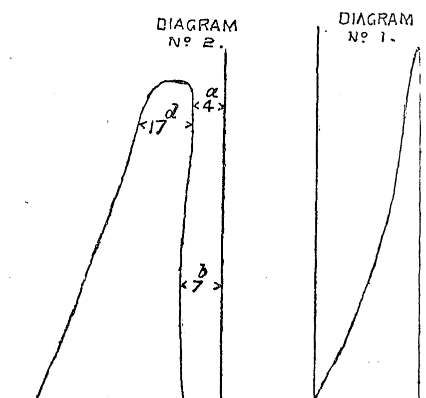
[60464.]—**Coopering.**—Will someone please instruct me through your paper on coopering? I wish to commence in a little way of making small tubs and casks; some knowledge of carpentering.—SOBER.

[60465.]—**Sewing Machine.**—Lockstitch refuses to pick up lower thread; upper thread will work about ten stitches, then seems to catch, and gets cut by needle. Have taken machine to pieces, and cleaned and examined it; but cannot see the fault. Can any reader enlighten me?—F. W. S.

[60466.]—**Emery Wheel.**—Can any of our readers tell me how I can put a good coat of emery on to my wheel that will not get soft when exposed to rain? I have tried all sorts of glue; but when exposed to rain it becomes soft, and dirties any article that I may be grinding on it.—TRAVELLING CUTTER.

[60467.]—**Falke Torpedo Boat.**—Can any reader supply me with the following information about the Falke (the Austrian) torpedo boat? I want to make a model of above boat on $\frac{5}{8}$in. or $\frac{1}{2}$in. scale. I require the position of the two funnels, the conning tower, and the two ventilators behind; also the position of the conning tower in front of the funnels, and, if possible, the length of the turtle deck from the bows, and the distance from the bows of the widest part of the vessel. Please give the height, diam., &c., of the funnels, ventilators, &c.—the size they are in the boat itself. Also give diam. and pitch of propeller.—ISLE OF DOGS.

[60468.]—**Action of Steam**—To "T. C., BRISTOL."—Thanks for your taking notice of my query (60294). The diagrams were taken with the indicator; but I have drawn other two diagrams, not to scale, but so that you will be able to see what I want better. Diagram No. 1;



between the lines of counter pressure and atmospheric line there are 4lb. at A, 7lb. at B, and 17lb. at C. You say the 4lb. at A go to the $2\frac{1}{2}$lb. at E on diagram No. 2. Now where does the 7lb. at B, the 17lb. at C, and the 17lb. at D go to on diagram No. 1? From the atmospheric line to the steam line on diagram No. 1 is 50lb., and not 17lb., as you read it in reply 60294. The 17lb. at D is between the steam line and the line of counter pressure.—YOUNG ENGINEMAN.

[60469.]—**Hygrometric.**—Would one of the readers of the "E. M." kindly give rule for calculating the weight of moist air, say 1,728 cubic inches of moist air at 15° C. and 59° Fahr.; dew point, 5° C. and 41° Fahr.? Also rule for correction of the barometric height for millimètres and centigrade scale?—POSTULATA.

[60470.]—**Malt.**—Could you inform me how to take the bitter and colour from malt after being boiled with hops? I have an idea that animal charcoal will do it; but how to use it, so that it does not get mixed with the malt, is what I want to get at.—THOMAS PEARSON.

[60471.]—**Electric Clock.**—Can any of "ours" give me full particulars and sketch of electric clocks in new schools, Oxford?—W. J.

[60472.]—**Chuck for 3in. Lathe.**—Will any of "ours" kindly give us sketch and full working drawings of a three or four-jaw chuck for 3in. lathe? The patterns is our difficulty for castings. If we can get them out are of opinion could manage other part. Any information will greatly oblige—W. J.

[60473.]—**Resistance Coil or Switch.**—Will someone oblige with particulars for making switch or resistance coil for working strength of battery power of small plating bath for fixing in front shop?—E. T.

[60474.]—**Shirt Collar Studs.**—Can any reader tell me how the metal covering is put on to some of these, and with what tool?—MOSES.

[60475.]—**Gelatine Moulds for Plaster Casting.**—Would some reader kindly give a little information as to the correct method of making gelatine moulds for plaster casting? I have been using good gelatine with as much alum as it will take up; but the gelatine moulds break very readily: they do not seem at all tough enough.—BARIUM.

[60476.]—**Dynamo.**—Would Mr. Bottone kindly give directions for winding and connecting the machine described by him in No. 1100? I have the armature wound with $3\frac{1}{2}$lb. No. 18, and 15lb. No. 20 to put on fields. Also say what number of 20c.p. lamps I would require, and their voltage. Would 2,000 do for speed?—D. B. S.

[60477.]—**Saccharin.**—Would some of our kind correspondents be good enough to answer a few questions in reference to the above? I have read the notices in reference to the above, No. 1115, p. 500, and No. 1116, p. 522, and think that (price there quoted excepted) it could be used to great advantage in my business. Please give address of German Co., or of any English manufacturer of the article in question. What is the present price quoted per pound? Is it soluble in water?—SUGAR BABY.

[60478.]—**Setting out Curves.**—Can any reader give me a hand in this? I want to know how to do it sufficiently for railway contractor's work, and for the present to avoid all theoretical business over the job, that I can go into at my leisure after I know enough for practical purposes. I have Baker's "Engineering Surveying," but that goes into trigonometry. Must I learn this for a start? I have a theodolite, and can set out an angle. What books had I better get for self teaching on this and kindred subjects?—CURVIST.

[60479.]—**Engineering Formula.**—

$$1.—H = \frac{D^2 \times \sqrt{P} \times R \times S}{8500}$$

$$2.—H = \frac{2 \times A \times (P - 16) \times 7 \times R \times S}{C \times 8}$$

I shall be greatly obliged if any mathematical correspondent will kindly transpose the above formulæ. In No. 1 I want the values of D, P, R, and S; No. 2, the values of A, P, R, and S respectively.—ENGINEERING, MANCHESTER.

[60480.]—**Conic Sections.**—In Hunter's book on this subject, there occurs in the early part of the chapter on the ellipse the following:—

$$e = \frac{2a - e\,.\,DA'}{2a + DA'} \quad \therefore a = ae + e\,.\,DA'.$$

Can any of the correspondens of the "E. M." inform me how the value of a is obtained from the first equation?—E. W.

[60481.]—**Polarised Light.**—I am desirous of learning if any improvement has been made in the production of artificial tourmalines (Herapathite) since the papers published by Dr. Herapath, I think, in 1852. Further, why are natural tourmalines so costly? Is it that only occasionally the tourmaline possesses the property of polarising? It cannot be that the working of the mineral presents any particular difficulty. I find that plates but little exceeding $\frac{1}{4}$in. in diam. are charged from £2 to £3 each, £5 being asked for a plate not exceeding $\frac{1}{2}$in. in diam. I am told that some polarising appliances (selenite objects, for example) are much cheaper in Paris than in London. Is it so with respect to tourmalines?—E. W.

[60482.]—**Problem—Carbon in Steel.**—In Eggertz's test for carbon in steel two tenths of a gramme of the steel are taken for testing. Supposing a steel to contain 0·50 to 1·00 per cent. of carbon, what amount of error in weiging the 0·20 grammes of steel would produce a difference of 0·01 per cent. (1-100 per cent.) of carbon, or, in other words, would make a 0·75 per cent. into 0·76, and, consequently, is a very sensitive and accurate balance essentially necessary for the test or not?—ALDEBARAN.

[60483.]—**Electro-Motor.**—I wish to make an electro-motor to be worked by a battery of 12-18 bichromate cells. I require about $\frac{1}{8}$ to $\frac{1}{6}$ H.P., and, if possible, the weight of motor not to exceed 30lb. Would Mr. Eaves, or Mr. Bottone, kindly give me a rough description, dimensions, size and quantity of wire, &c., and best method of winding? I have good appliances for making it, and have made two or three smaller motors before.—MOTOR.

[60484.]—**Twilight.**—Respecting this phenomenon, will "F.R.A.S.," or others of our authorities, kindly inform me how the calculations are made to fix its duration at all times of the year? Whitaker gives the hour it ends for the first of each month; how is this arrived at? We are told that twilight lasts so long as the sun is less than 18° below the horizon. But a degree varies in length with the latitude of a place; and as it is the place, say London, and not the sun, which rotates out of sunlight into twilight and night, slower and through less space as it is more distant from the equator, is the band of twilight, or 18°, narrower in miles at London than at the Equator, or would it be correct, on a diagram of a hemisphere of the earth showing the sun over the Equator (in March) illuminating the upper half for day, leaving the lower half shaded for night, to draw a line parallel to the line dividing day from night (coincident, at this date, with the earth's axis) 18 equatorial degrees wide right across from south to north, or should the width of this twilight band vary from the equator north or south in accordance with the varying lengths of a degree?—because, if not, it would, at London, indicate more than 18°, though of the same width as at the Equator? I am living close to the Equator where twilight is proverbially short; yet it seems to me, theoretically, it should (at shortest) last 72 minutes from sunset to the last streak of light on the western horizon.—LAUKA.

[60485.]—**Waterproofing Double Textures.**—Could any of your readers give the writer any hints about waterproofing double textures? I can make the solution right enough; but on the slightest pressure to make the two cloths adhere, the solution inclines to come through and stain the fabric outside, and, of course, it looks unsightly. The commercial double texture solution appears quite black, as if it was mixed with earthy matter. I have tried it mixed with silicate, magnesia, soot, tar, pitch, &c.; but any of these mixtures seem to destroy the adhesive power of the rubber. The melted pitch, for instance, when mixed with the indiarubber solution, hardens almost immediately, and renders the solution useless.—WATERPROOF.

[60486.]—**Oscillating Engines.**—Will any kind reader who has had experience in Mill's style of oscillating cylinders state whether I can use them for a steamboat to drive a screw of 3in. dia. at a high speed? I have had considerable trouble with the old style of flat faces, working on a block, as they seem to me to waste steam very much. I think of using a pair, $\frac{5}{8}$in. by $1\frac{1}{4}$in., on the diagonal system, only one crank, and at a pressure of 40lb. steam. Will any reader give me some particulars as to working, and if suitable for high speed, and how the steam is admitted to the cylinders?—ENGINE PUP.

[60487.]—**Dynamo.**—Will Mr. Bottone, or some other electrician, kindly say whether a dynamo giving, say, 25 volts and 12 ampères would light 12 incandescent lamps, taking, say, 25 volts and one ampère each, or should the dynamo give 300 volts and 12 ampères to light the lamps? Also, about how many volts and ampères must a dynamo be making to give an unpleasant shock to any person touching the terminals or the leads?—J. H.

[60488.]—**Medical Battery.**—I am constructing a medical battery of several dozen of Leclanché cells. I wish to know if a canvas bag would answer instead of the usual porous pot, and what disadvantages there would be attending it? I have looked through all my back numbers since 1875, and can see no mention of any other diaphragm but the porous pot. Not having a long purse, if the canvas bag will answer it would be a great help to me. At the local chemists I find peroxide of manganese is 1s. 2d. for 7lb. I find electricians want from 8d. to 1s. per pound. Is there any difference in the quality, and would the first-mentioned do for a Leclanché?—CARPENTER.

[60489.]—**Electric Lighting.**—To S. BOTTONE.—I wish to light up four rooms of 10 candle-power each for about six hours a night. I want to light them by storage batteries, and to charge them from a 70 candle-power dynamo driven from a lathe. How many cells should I want, and how long would it take to charge them? I intend using E.P.S. cells.—VOLT.

[60490.]—**Book-keeping.**—I shall feel obliged if any reader will kindly inform me which is the best and simplest method of keeping books in a small engineering firm—whether single or double entry is to be preferred, and what books are really requisite. Information as to the simplest work on book-keeping, dealing, if possible, with the engineering section, would oblige. I am about to commence business on my own account, and would like to know the best system for a place employing, say, 20 hands.—LEDGER.

[60491.]—**Time.**—I have three regulators, all compensated, but cannot get them to run together. Will anyone kindly tell me if there is a simple method of getting true time by the observation of a star passing a given point two or three times a week, so that I could find which of my clocks is going right?—CHRONOS.

[60492.]—**Mechanical.**—Many thanks to "T. C., Bristol," for answers to my past queries. Would he kindly give a rule in figures for finding in wheel works when the same two teeth come into contact again? A wheel of 44 teeth, pinion 28; how many turns will each wheel make to bring the same two teeth together that were in contact when starting? Rules for any wheels will oblige—NOVICE.

[60493.]—**Sewing-Machine Cams.**—Would someone inform me what kind of machine is in use for cutting sewing machine cams, as I am ignorant as to how they are cut?—W. G. PAYNE.

[60494.]—**L. B. and S. C. Locos.**—Can anyone tell the principal dimensions and what letters denote the classes of the following: Goodwood, Norwood, Reigate, Sutherland, Genoa, Silverdale, Chambery, Gipsyhill, 424, 411? Also how many engines are stationed at Battersea and New Cross?—RICHMOND-PORTSMOUTH.

[60495.]—**Britannia Developer.**—Would "B.Sc.," or some of your photographic readers, kindly assist a fellow being driven almost to desperation by the following? I am using pyro. developer with Marion and Co.'s Britannia plates. I have adhered strictly to the formula in mixing. I have used half a gross of plates with various exposures, and I can get nothing except a hazy image. Would some kind reader tell me the cause? "E. Y.," No. 1,069, p. 68, was in the very same predicament; perhaps he can now assist me.—TERRANOVA.

[60496.]—**Telephone Fixing.**—Under the heading "Answers to Correspondents" you say "two wires are better, as earth return is not satisfactory with telephones." As with earth return the paths for the current would be farther apart in most cases than when two wires are used, and, therefore, induction would be less; how can that be so? and is it not entirely opposed to Mr. W. H. Preece's experiments as detailed in his paper "Induction in Telegraph Wires"?—ZINCI SULPHAS.

[60497.]—**Acoustic Telephones.**—I wish to fix one of these for my own use, but find great difficulty in getting the sound to travel round the insulators, of which I cannot do with less than four. I can hear the sound of the voice, but am unable to tell what is said. A musical note is conveyed perfectly. Can any of your readers assist me?—ZINCI SULPHAS.

[60498.]—**Induction Coil.**—I have made one according to directions set forth in "Dyer's" book, and get $\frac{1}{2}$in. spark. I find, no matter which way the primary current flows (I have fitted a commutator), I can obtain the static spark from that end only of the secondary which is farthest from the core. Why are not the ends of sec., from which static spark is obtained, reversed when prim. current and polarity of core are reversed? Is it a fault in construction?—ZINCI SULPHAS.

[60499.]—**Waterworks Pressure.**—Can any obliging fellow reader give the usual working pressure of town's water, giving an example or two, say Glasgow, Manchester, Liverpool, Sheffield, Birmingham, or London? Expressed as pounds per sq. in. preferred, but feet head of water, or inches of mercury will do.—NIAGARA.

[60500.]—**Coil**.—Can any kind reader inform me how to wind a street coil, 9 by 4? I want to have six different powers. What size wire to use, and if c.c. will do?—ONE IN A FOG.

[60501.]—**Inks**.—Will any kind reader inform me what colour I ought to get if I dissolve 3½ of nigrosine in 10oz. of warm water, and state what action sulphuric acid has upon it? Also if some reader will inform me how to make black ink, like Draper's?—NEMO.

[60502.]—**Lattice Girder**.—Should be greatly obliged for dimensions of a lattice girder, 12ft. span, to carry a concentrated load of 5 tons, and method of calculating the strength. Should be glad of recommendations for course of study for calculating strength of materials and structures.—SELF TAUGHT.

[60503.]—**Photography**.—(1) what kind of lens is considered best for both cabinets and c.d.v. portraits? I mean, what diam. and length of focus? (2) What is the quickest time that a portrait can be taken in with a lens described, as of ordinary intensity, by noted makers (in studio)? (3) Will the cheapest dry plates, advertised at 1s. per doz. (¼-plate) produce first-class portraits with a good lens?—H. WALKER.

[60504.]—**Watch Jewelling**.—Would any reader be kind enough to say how watch jewels are set in their places? I see some of them are only stones bored through, and others have collars of brass round them.—IGNORAMUS.

[60505.]—**Salt and Lime in Water**.—How can I precipitate salt and lime in water before putting it into boiler? They stop up the exhaust pipe and small steam pipes.—T. P.

USEFUL AND SCIENTIFIC NOTES.

Primitive Man.—Two Liége *savants*, MM. Marcel de Puydt and Maximilian Lohest, have announced a recent discovery, which may be of scientific importance. In a cave at Spy, a few miles from Namur, known as the Biche aux Roches, they found in the sandstone two human skulls of extraordinary thickness, resembling the celebrated skull found in the Neanderthal, near Elberfeld. They have the same very projecting eyebrows, and the same low sloping forehead of a decidedly simian character. The finders suggest that these are types of the skulls of the primitive race who dwelt on the Sambre. Other things were discovered in the cave by MM. de Puydt and Lohest, among them some thousands of flints very carefully dressed on one side; also some specimens of jasper and agate, minerals not found anywhere in the neighbourhood, ivory breast pins, several red ear pendants, and some necklets of pearls of curious designs. It was noticed that there were no representations of animals. All were found in the sandstone, three layers of which were plainly discernible. It was visible that the remains of flints, &c., deposited in each layer indicated different stages of skill in workmanship. The lowest stratum was by far the poorest in the number of the objects found and in the quality of their workmanship. But it was here that the skulls were found, so that from a scientific point of view it is most important. A drawing has been carefully made of the geological section of the cave, so as to mark precisely the point where the skulls were found.

FROM a paper on "Secondary Electrolysis," by E. Semmola (*Compt. Rend.*) it appears that if a small ribbon of platinum is immersed in a voltameter containing acidulated water, in such a way that its ends are opposite the electrodes of the voltameter, and a powerful current is passed through the latter, hydrogen and oxygen are evolved not only from the electrodes but also from the ribbon. This secondary electrolysis varies greatly with different conditions, and ceases altogether when the current is not strong; but if oxidisable metals are used instead of platinum, it becomes much more energetic. The phenomena are well seen with amalgamated zinc, which is not attacked by acidulated water except when the current passes. When the circuit containing the voltameter is closed, hydrogen is given off from one half only—the negative half—of the zinc, whilst oxygen is absorbed by the other half. If several pieces of zinc are immersed in the water in the voltameter, hydrogen is given off from each of them. This secondary electrolysis is due to a current derived from the immersed zinc.

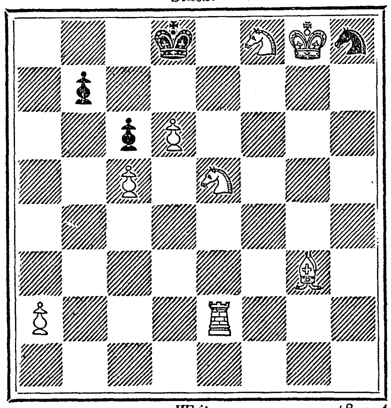
THE unique example of a town undergoing direct transition from oil lighting to electric illumination without passing through the intermediate stage of gas lighting is presented by the little town of Tivoli, near Rome. Upon the occasion of the inauguration a large number of invited guests from the town and from Rome was received by the municipality and citizens. The guests included the representatives of England, Spain, Austria, and other nations, and after the city had been illuminated a grand banquet was partaken of in honour of the occasion, and was followed by a musical entertainment in the town-hall. The success of the lighting is complete. Arrangements are being made for private lighting in Tivoli and for transmitting 2,000 horse-power from Tivoli to Rome for lighting purposes in the latter city.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MX.—BY J. P. TAYLOR.

Black.



White. [8 + 4

White to play and mate in two moves.

SOLUTION TO 1008.

White.	*Black.*
1. Q Q R 7.	1. Anything.
2. Q, R, Kt, or P mates.	

(Six variations.)

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,008, by Link, G. A. A. Walker, A. Bolus, A. Dean, Avon, A Beginner, "——," I. M. B., J. A. M., and J. Mackenzie; to 1,007, by A. Bolus, Link, J. Thompson, and Isca.

E. BONREW.—In your attempt at 1,007, 2. R-K sq. is not mate, as Q covers. In 1,008, you have not given Black his best defence, as 1. ——— Q Kt-Q 2 prevents mate next move.

A. BOLUS.—We had not forgotten; our remark was meant to refer more to two-movers.

BLACK PAWN AND T. H. BILLINGTON.—Thanks for problems.

J. A. M.—In your attempt at 1,009, we think you have overlooked the defence, 1. ——— B-R 4.

A BEGINNER.—We did not intend to convey that yours was considered a *correct* solution; but only that you received some marks for good attempt.

J. M.—The marks refer to a Solution Tourney now going on.

RECEIVED, with thanks, *The Wanderer*, *Chess Player's Chronicle*, and *Cassell's Saturday Magazine*.

THE German Secretary of State has published statistics on the periodicals of the world, from which it appears that there are 34,000, with a distribution of 592,000,000 copies; 19,000 are published in Europe, 12,000 in North America, 775 in Asia, 809 in South America; 16,500 are in English, 7,800 in German, 3850 in French, and 1,000 in Spanish.

THE largest body of fresh water on the globe is Lake Superior, 400 miles long, 160 wide at its greatest breadth, and having an area of 32,000 square miles. Its mean depth is 900ft., and its greatest depth is said to be about 200 fathoms, or 1,200ft. Its surface is about 635ft. above the sea level.

Carbon, or Transfer Paper.—To make transfer paper, mix lamp black with cold lard to the consistency of thick paste: apply to common printing paper (not sized or letter paper) with a rag, and with a piece of flannel rub off all that will come off. For red use powdered Venetian red; for green, chrome green; for blue, Prussian blue. To use transfer paper place the sheet between the sketch to be copied and the paper on which it is to be copied, with the coloured side next to the clean paper. Trace the lines of the copy with a dull pointed instrument, and the design will be accurately transferred on the lower sheet.

Preserving Wood.—The prevention of decay in wood is said to be effectively accomplished by exhausting the air from the pores and filling them with a guttapercha solution, a substance which preserves the wood alike from moisture, water, and the action of the sun. The solution is made by mixing two-thirds of guttapercha to one-third paraffin, this mixture being then heated to liquefy the guttapercha, when it is readily introduced into the pores of the wood, the effect of the guttapercha being, when it becomes cool, to harden the pores.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XI., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words, afterwards 9d. per line. Paragraph advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d.
Twenty-four words	0	3
For every succeeding Eight Words	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Sept. 22, and unacknowledged elsewhere:—

W. A. HUNTER.—C. H. Wingfield.—Orderic Vital.—T. H. Nassau.—T. Casson.—Chas. Penruddocke.—Valve Gear.—W. Roper.—G. D. Seaton.—Goods Fireman.—R. E. F.—E. Conry.—F. P. Otto.—R. S.—E. R. Dale.—Lt.-Col. Campbell.—Mill.—Arthur Mee.

OILMAN. (Illustrations have been published in some of the pictorial papers, but we really do not see how you can make a model, as there are merely erections over the bore-holes with pipes leading to the refining stills.)—SIDNEY AUSTIN. (Make a chloride of silver battery, or one of those mentioned in recent numbers. See indices under head "Battery.")—A LOVER OF THE MECHANIC. (There is the *Journal of Gas Lighting*, published at 11, Bolt-court, Fleet-street, E.C., weekly, price 6d. We do not know whether there is such an association.)—G. J. (Try Allen and Co., Waterloo-place, W. 2. Perhaps Harcourt's "Harbours and Docks," published by H. Frowde, Amen-corner, E.C., will suit; or Wiggins's "Embanking Lands from the Sea," published by Lockwood and Co., Stationers'-hall-court, E.C. 3. Has been

frequently illustrated, and is described in every manual. 4. See "A Catechism of the Steam Engine," by Bourne, and other textbooks.)—PRACTICAL. (See Mr. P. J. Davies's book on "Plumbing," and the back volumes; also the list issued by Mr. Fletcher, Thynne-street, Warrington. You should look in the indices of the Patent records. The stamp duty is not recoverable.)—J. D. B. (Lacquer is inferior work. Blueing was described in No. 1114, p. 489; but the address should be No. 48.)—ENGLISH BARLEY. (Malt is made by damping barley, and when it begins to germinate, drying it in suitable kilns. See any cyclopædia.)—AN OLD READER. (There are no works of the kind. You will find full instructions in back volumes, but as a rule the numbers containing the articles are out of print.)—DARWEN. (The question is of no interest to any one: it simply shows that 6 × 6 is more than 5·5 × 6·5.)—NICKEL. (For articles on nickel-plating, see pp. 96, 117, 139, Vol. XXXIX., and the indices generally. Watt's "Electro-Metallurgy," eighth edition, Crosby Lockwood and Co., Stationers' Hall-court, E.C., price 3s., contains information on the subject.)—G. H. H. (The various methods of gilding frames have been frequently described; see No. 870, for instance. 2. Send to any of our tool-makers who advertise for one of their lists, and you will find sets priced according to the number of pieces, with illustrations of the various tools.)—JUMBO. (You will find it altogether more profitable to purchase the oxygen in iron bottles or in bags from those who make it for the theatres, as it is rather risky for a novice to make it in such quantities as you would require. See illustrations of gas tanks given in some recent volumes, and endeavour to examine some of the burners in use. You want a mixture of oxygen and coal-gas impinging on a cylinder of lime, but the gases must not mix until they reach the cylinder. Aniline dyes for leather in No. for July 16, p. 431.)—LUCIFER. (We do not know of such a book, nor do we suppose there is one, as the sale would not pay the expenses of printing. You can find some information in the cyclopædias, and also in back volumes—*e.g.*, Vol. XXXI. pp. 121, 143.)—R. F. ARDEN. (See the index published with the last number under head "Lamp, wonderful." For a price list, apply to the address given in the advertisement.)—THOS. KERR. (We do not know of any book specially devoted to iron turning; but there are several works on the lathe.)—W. T. BARKER. (Thanks for sending the extract; but we have had all about the ammonia engine some time ago. On p. 551, Vol. XIII., and p. 1, Vol. XIV., you will find something about ammonia as a motive power, and its use on a tramway in New Orleans. We are afraid the new "success" is only an attempt to revive a speculation.)—E. BOTTOMS. (No; they have not been published in book form, and it is scarcely probable that they will be.)—BROSCENICUS. (Read what has been said recently under the heading of a "Wonderful Lamp," and see p. 561, No. 1117.)—W. M. (Some are. An explanation would involve a small article on optics, and you can find that in many textbooks, and over and over again in back volumes.)—POOR ASTRONOMER. (If the tube and stand are worth a first-class object-glass, apply to Mr. Wray, North-hill, Highgate, for his price list.)—JOHN LEE. (We do not know the address. See Hints No. 5.) J. L. H. Y. (Size and coat with a ground colour; but it is cheaper to buy those already prepared.)—A NEW SUBSCRIBER. (See the index published last week, and No. 1062.)—J. SMITH AND CO. (From the bark of willow and poplar, and the green parts of several spireas. 2. Most likely moulded by hydraulic pressure. If any cementing material is used, it is weak gum water.)—ANTI-BEETLE. (Beer and sugar or treacle will attract them. A good method of clearing the house of them is to mix red lead, flour, and a little sugar, and put near their haunts.)—A READER. (The *Berliner Tageblatt* will be as good as any, especially if the advertisement is inserted in the weekly supplement called *Industrieller Wegweiser*. The address is Berlin; but one of the large agents would see to its insertion and quote terms.)—ROBERT RUDGE. (One pound of glue, four pounds of glycerine, and sufficient whiting to colour.)—AMATEUR. (Use plaster of Paris or whiting, mixed with tallow.)—PERPLEXED. (There is not any rule of the kind you imagine.)—YOUNG ASTRONOMER. (Does it not occur to you that we may have already given such information? See Nos. 857, 860, or Nos. 881, 884.)—ANXIOUS. (Full directions for browning gun barrels were given in No. 1035.)—CORNISH. (Almost any work on the steam-engine mentions the Cornish; but we know of none specially devoted to it.)—SAILOR. (The water condenses the vapours, that is all.)—W. H. G. (See what has been said recently, and look through the back volumes, or consult a cyclopædia. Its professed believers claim much more than scientific men can accept.)—R. A. (Yes, we believe so, as far as the separating arrangements are concerned.)—T. H. (Use tinman's solder with a copper bit, and chloride of zinc or rosin as a flux.)—BLACKBURN. (No satisfactory method of brazing without heat. Cold soldering, described in No. 888, p. 81.)—C. A. NEWTON. (Clean out with benzoline or spirit. You mean the oil, we presume—not nicotine. Several methods of cleaning meerschaum pipes have been given. See p. 593, Vol. XXXIX., and the indices.)—F. K. W. (Goodeve's "Principles of Mechanics," Longmans.)—CONSTANT READER. (Apply to the Secretary of the Sanitary Institute of Great Britain, 74A, Margaret-street, London, W., for copies of examination papers.)—J. S. C. (Ferrocyanide of potassium is made by heating nitrogenised matters, such as dried blood, hoofs, horns, &c., with an equal weight of crude carbonate of potash, and about one-third their weight of iron filings. 2. Cyanide of silver is prepared by precipitating it from the nitrate of silver solution by adding cyanide of potassium. 3. Tartrate of iron is made by boiling together equal weights of tartaric acid, water, and iron wire. If potassium is added by means of the carbonate of potash, we suppose that would produce what you mean.)—T. P. (Any query received from you or anyone else has either been inserted or answered—provided it had a signature.)—M. A. S. (You can remove the gold by heating the chain to redness and dropping it into dilute sulphuric acid, when the gold will scale off; or you can dissolve it off in strong nitric acid to which a little common salt has been added; but care must be taken to keep the article on the move, and take it out the instant the gold is off.)—ELECTRO-PLATING. (You can plate with a single Daniell cell, and the Daniell or the Smee battery is as good a form as you can have.)—FREDK. RESTALL. (Why not procure a new rubber washer or cement a piece of thin rubber tubing round which the parts will squeeze into a fit?)—A MECHANIC. (If a medical man who has seen you cannot do any good, how is it possible for anyone to do so by merely guessing at the cause of your ailment? There is no radical remedy for the disease named.)—CUTIS. (There is no preservative for leather that is already "crumbling." You can try castor-oil, which would have preserved it if taken in time.)—ANTIQUE. (It is bichloride of platinum applied while the brass is hot through close contact with a Bunsen flame. The common work is done with a blue lacquer on a tinned surface.)—J. G. (Send the description, and we will insert.)—W. GOWEN. (Sue him in the County Court for their value.)—P. H. MARROW, S. G., W. A. HAREN. (In type.)

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Good Value Offered (cash or instruments) for all kinds of sound or repairable Scientific Appliances.—CAPLATZI, Science Depot, Chenies-street, near British Museum. Established 1862.

Tricycle, 56in., Audax, good condition, roller bearings, very fast machine, offers to £5 value. Stamp for particulars.—J. R., 17, Newland-street, Kettering.

Wanted, cheap modern **Books** on Pattern Making, also on Practical Receipts; or I have two 16-wick Lamps; would exchange; quite new.—W., 78, Viaduct-street, London, E.

Tricycle, Coventry, two-track double-steering, perfect order, newly painted; suit any height of rider. Offers.—FORD, 76, St. Paul's-road, Camden, N.W.

Shafting, 1½in. pulleys and brackets; 28in. single Lathe Wheel, 90lb., 3ft. crank; Chemist Carboys, 1½ gallon each. Offers.—W. SMITH, Bilston-road, Wolverhampton.

Youth's **Tricycle Frames and Fittings**, three ready for wheels, 50 yards Wire Netting, Perambulator Wheels, Axles. Rubbers, Plated Caps, 2½in. Steam Gauge. Exchange.—W. SMITH.

Steam Engine, about 2 H.P., fair condition, in exchange for good 50in. Bicycle, or anything useful.—R. SMITH, Fazackerley-street, Chorley.

Horizontal Tubular Boiler, about 6 H.P., excellent condition. Exchange for good Tandem, or anything useful.—R. SMITH, Fazackerley, Chorley.

Wanted, a pair of new or second-hand **Back-geared** LATHE HEADS, about 5in. centre; must be well fitted; exchange.—12, Mill-street, Nantwich.

Two compound achromatic **Lantern Objectives** by Franks, Manchester, fine definition, would make first-class ½-plate portrait lenses. Would exchange for slides, 5 to 7in. diameter, or what offers.—A. SALOMON, 198, York-street, Cheetham, Manchester.

Will exchange 3in. astronomical **Transit Telescope** for 1 man-power Gas Engine, or powerful Electro-motor.—33, Howell-road, Exeter.

Two **Silver Keyless Watches**, cost £3 each, with cash, in exchange for powerful Electro-motor or Gas Engine.—33, Howell-road, Exeter.

"**Griffin's Chemical Handicraft**," "Intensity Coils," Dyer; "Electric Railways," Ayrton; "Régulation des Galvanomètres," Gérando; 4s. 6d., or two No. 1 Leclanchés with sal-ammoniac.—YULE, Southgate House, Winchester.

Exchange pair 5in. **Condensers** for a Double Dark Slide, take 10 by 8 plate.—H. SHAYLER, King's-hill, Wednesbury.

Cylinder Frictional Machine, 8 by 7, baseboard 16 by 20, and Leyden jar; perfect. Exchange Electric Bell.—ALLMARK, Garden-lane, Chester.

"**Illustrated Journal of Patented Inventions**," wanted, back numbers. Exchange.—A. BOWERS, 34, Carnegie-street, Edinburgh.

3in. **Slide Rest** (Britannia Co.), first-class condition. Exchange.—H. W., 138, Abbey-street, Bermondsey, S.E.

Offers wanted for the following really good articles: Bench Drilling Machine, 52in. Bicycle, Singer pattern medium Sewing Machine, Double Perambulator.—Apply, F. UNDERWOOD, Beverley.

20 solid **Brass Drawer Rings**, with screw and nut, for Volumes XXXIII. and XXXIX. ENGLISH MECHANIC.—LOCKER, 175, Thornley-street, Burton-on-Trent.

Want a good 4-10th or ⅓rd **Objective** for microscope. Exchange.—R. T. DITCHFIELD, Chorley, Lancaster.

Have double magnet **Electric Machine**, pair Telephones, British Bull-dog Revolver. Wanted, offers in Screw Tackle and Chasers.—COLEMAN, 130, Medway-road, Gillingham, Kent.

I want a **London U. Calender** for 1886.—W. STANLEY SMITH, Mount-street House, Wrexham, North Wales.

Type, 24lb Roman, nonpareil and brevier, as new, 8lb. leads, and furniture. Exchange Lantern Slides, slipping, &c.—L. CABENA, Mall Wall, Londonderry.

Water Motor, one horse-power, by Wheeler; of Preston, cost £9, equal to new. Exchange for lady's or gentleman's Gold Watch.—Apply to HENRY WHITEHEAD, 153, Rathmines-road, Dublin.

For exchange, a pair of full size King of the Road **Tricycle Lamps**. Offers.—T. H. M., Errigle, Cootehill, Ireland.

Tricycle Frame, hind steering, parts brazed, fork hind wheel, cone pin seat, guide rod, handles, &c. Exchange Slide-rest or Engine and Boiler.—THOS. ELLINGWORTH, below.

Perambulator Wheels, rubber tyres, with axles, caps, lubricators on hub, brass caps, &c. Set of four, 9s. 6d.; set of three, 7s. 3d.—Below.

Lathe Casting Headstock and Socket Rest 4s. 6d. A splendid Accordion, double bellows, 2 stops, 8s. 6d.—THOS. ELLINGWORTH, Church-street, Leighton-Buzzard.

Horizontal Engine, 1½ bore, 2in. stroke, very high speed. Will exchange for anything useful.—Apply, W. HITCHINS, 21, Paynes-lane, Coventry.

"**English Mechanic**," 13 volumes unbound. Exchange Fret Wood, Photo Apparatus, or anything useful.—11, Brook-street, Crewe.

Wanted, a **Concertina**, 48 keyed, in exchange for Violin, date 1796, bow, and case. A genuine offer.—T. MORRIS, 14, Nechells Park-road, Birmingham.

A 5-cell **Bunsen's Battery**, in tray, Bracket Clock, set of Perambulator Wheels. What offers?—J. COIR, 44, Kimberley-road, Nunhead.

"**English Mechanic**," last 7 volumes, with index, quite clean. Offers requested.—M. CLARK, 28, Blenheim-street, Chelsea, S.W.

Will exchange my new **Dynamo**, 50 c p, and Jones Laminated Armature.—RICHARDSON, Grocer, Chatham.

"**Popular Educator**," Vols. III. and IV. wanted. Will give books in exchange, or offers.—JAMES ALEXANDER, Ythan Wells, Huntly, N.B.

Wanted, Lancaster's **Instantograph**. Will give above value in Electrical Apparatus.—T. MORRELL, 54, High-street, Brierley-hill, Staffs.

Valuable double **Refracting Goniometer**, protractor, and tables, Rothwell's Dividing Micrometer; this cost £15 15s. Surveyor's Aneroid, scale to 8,000 feet. Sympiesometer, by Adie.—9, Ball's-pond-road.

Corn Mill, hand-power, by Nye and Co., London, quite new. Will take good Tricycle or Lathe.—Address, GEO. H. HEAVEN, 8, Oakland-road, Bristol.

Induction Coil suitable for telephone transmitters, in mahogany case, with terminals for secondary. Exchange for No 36 silk-covered Wire.—E. THORNTON, Barrow-in-Furness.

About fifty Lantern **Photo View Slides**, a number Scotch. What offers?—Address, PHOTO, 182, Trongate, Glasgow.

Wanted, **Pocket Battery** or Accumulator, also Magneto Electric Machine. Cheap. Good exchange offered.—CHARCOAL WORKS, Hodson-street, Liverpool.

To Confectioners.—Machine and pair 5in. Rollers, 3 pairs 3¼ and 29 pairs of Rolls, Malster, and Pedestal. Exchange.—Stamp, SEDGLEY, 22, Ryding-square, West Bromwich.

Wanted, **Electric Bell** or American Lever Clock. Offer Grocer's Scales (copper cup pans), or Work on Poisons (Christison.)—BERNARD GREEN, 7, Mountain View, Cockermouth.

What offers in exchange to 4s. for "**Human Anatomy**," by Cloquet, 1828.—BERNARD GREEN, 7, Mountain View, Cockermouth.

What offers in exchange to 12s. 6d for **Gazogene** in perfect condition.—BERNARD GREEN, 7, Mountain View, Cockermouth.

A 2½in. centre **Bench Lathe**, and Motor for above Castings planed of a 5in. Slide-Rest Wanted, or offers.—DOVER, 8, Clifton-street, S.W.

Lot of "**English Mechanic**" and "Photographic News." Offers.—W. SAUNDERS, Dickleburgh, Scole.

Complete **Set of Patterns** for 1¾ Horizontal Slide-valve Engine; also two 3in. Lathe Heads. Anything useful.—J. B., 203, Galapark-road, Galashiels, N.B.

Dynamo, model Brush, 24lb. weight, almost finished, two cylinders, some brass castings, partly finished; "English Mechanic" from Feb., 1885, to present date. Want watch and clock jobbing tools and self-centring drill chuck.—R. PURVES, 27, Mulgrave-terrace, Gateshead.

Bicycle, in good condition, gunmetal hubs, and lamp, worth 50s.; accept half in useful exchange, and half cash.—R. MILNE, 13, Observatory-road, Redhill.

Offers wanted for nearly new 8in. 4-jawed **Independent Chuck**, of Britannia Co., also Drilling Cramp with Drills complete.—LOCKYER, Merstham, Redhill, Surrey.

Offers wanted for good pair 4ft. 4in. French **Burr Millstones** and fittings, also several wheels, &c.—FOREMAN, Merstham Mills, Redhill, Surrey.

Launch Engine, 3¼in. link motion, and new gunmetal pump, wants putting together. Exchange offers.—SMITH, Stanley Villa, High-road, Gunnersbury.

Electrical Machine, 12in. plate, in good working order, strong and portable, with accessories, six pieces; books history, biography, or offers to value of 25s.—J. HULAND, King's-road, King's-heath, Birmingham.

Four dozen **Carbon Battery Plates**, 5in. by 1½in., 2s. 6d.—J., 90, Moray-road, Tollington Park, London, N.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

New Illustrated Price List of **Screws, Bolts, and Nuts** for Model Work, drawn to actual size, sent on receipt of stamp.—MORRIS COHEN, 132, Kirkgate, Leeds.

Fretwork.—Catalogue of every requisite, with 600 illustrations, free for 6 stamps.—HARGER BROS., Settle, Yorks.

Perspective, do you understand? "Knight's Practical Guide," 1s.—SIMPKIN and MARSHALL, or of J. P. KNIGHT, Art Master, Cheltenham.

Mica or Talc.—RICHARD BAKER and CO., 9, Mincing-lane, London.

Hardy's Patent **Safety Benzoline Lamp**, self-lighting, self-extinguishing, and unspillable post free, 1s. 3d.—THISTLETON, Oakham.

FRIDAY, OCTOBER 1, 1886.

NOTES ON THE CHAMBER ORGAN.—V.

By GEORGE ASHDOWN AUDSLEY, F.R.I.B.A.

IN considering the question of the stops most suitable for the Pedal department of the Chamber Organ, the chief difficulty which presents itself is the space they demand for their accommodation. It is this difficulty of finding adequate floor space and height which has, in the generality of cases, prevented the introduction of open stops of 16ft. speaking length, and has caused the almost universal adoption of covered registers of 16ft. tone. It is quite obvious that in rooms of the ordinary size it is impossible to place the lower octave of a 16ft. open Pedal stop, unless some arrangement has been specially made for its reception. If the pipes are of wood, and they are almost certain to be so, all those beyond, say, 10ft. in length may be mitred, and the four or five lower ones may be laid horizontally behind the organ, or in a recess constructed to receive them or partitioned off from an adjoining room. In the latter case, an opening must be made in the wall behind the organ to allow the sound free egress. If a recess or shallow chamber can be formed in the manner hinted at, or, what is better, planned along with the music room or drawing-room, all difficulty in connection with the appointment of an adequate Pedal organ disappears. To further economise room, the C C C and D D D pipes can be made, by a simple arrangement of pneumatic valves, to serve as C C C sharp and D D D sharp also. I have adopted this system in connection with the open Principale, 16ft. in my own organ. There can be no question as to the immense value of an open 16ft. stop in the Pedal department; for its pure, quiet, and dignified tone imparts a grandeur otherwise unattainable in a small instrument; while it supplies a perfect groundwork on which all varieties of manual combinations may rest, enriched, but otherwise undisturbed. The best scales for the C C C pipe are 11in. by 9in., or 10in. by 8in. Except on higher pressures than that previously recommended, pipes of a smaller scale will be too slow of speech and too weak in tone. The stop must be voiced to yield a pure, prime tone of unobtrusive character, which will support rather than overweigh the rest of the organ. At the same time it must be sufficiently clear and self-assertive to render independent pedal passages with distinctness, even when used alone. While the larger pipes of this stop will have to be stowed away behind the organ, and, if possible, out of sight, the chief part of the remaining pipes may be ranged in view, and utilised as an important feature in the general design of the instrument. Whatever the disposition may be, it must be borne in mind that it is imperative that every pipe be placed immediately over or close to its wind. This important consideration will always influence the placing of the pipes.

The stop almost invariably introduced in small organs is of the *Bourdon* or *Lieblich Gedact* species, of 16ft. tone. The chief peculiarity in the speech of such a stop is its tendency to give the second harmonic upper partial tone in addition to the prime tone. This is most observable in stops of small scale, so much so as to earn for them the name "Quintaten." * When there is no open stop of 16ft., it is desirable that the *Bourdon* should be of medium scale, and voiced to yield the prime tone as pure as possible. But when there is also an open register, the stopped register of 16ft. tone may with advantage be a Quintaten in character. When skilfully voiced, it forms an effective stop in imitation of the orchestral double-bass, and materially enriches the full tone of the Pedal organ.

In all instances where space permits it is advisable to introduce an independent open stop of 8ft. This may be a soft-toned Gamba, a *Dulciana*, a Violoncello, or a flute-toned wood register. When space and expense are important considerations, the 8ft. stop may be obtained by adding an octave of pipes to the 16ft. stop, and inserting an Octave coupler. This is an expedient frequently resorted to in small instruments.

A reed stop is a most desirable addition to the Pedal department of a Chamber Organ; but its introduction is attended with certain difficulties. If it is a *striking reed*, of the ordinary construction, it is almost impossible to get it sufficiently refined and quiet in tone. Of course, it must be of 16ft. pitch, and accordingly the vibrations of the larger tongues are accompanied by a rough, disagreeable noise, impossible to be suppressed or even reduced by distance in an ordinary apartment. If it is a *free reed*, such as I have alluded to in the preceding article, it unfortunately demands considerable space for its accommodation. Perhaps it will be as well to explain the last remark. Although the tubes of a free reed of 16ft. tone are not larger in diameter, and are considerably shorter than the corresponding tubes of a striking reed of similar type, the boots are altogether different affairs, being, comparatively speaking, immense. For instance, the wooden boot of the CCC pipe of the Euphonium stop measures about 5in. by 4½in. in cross section, and about 4ft. 3in. in length. The metal tube, of the usual inverted conical shape, is about 10ft. in length; this, as well as all the other larger tubes, can be mitred in any convenient fashion, and generally with advantage to the tone. The tone of the free reed Euphonium, when properly voiced, is of singular purity and roundness; and while the lower notes have a characteristic reedy quality, they are entirely free from the buzz inherent in striking reeds. Such a stop is of great value for melodic use; and if an additional octave is added and an octave-coupler inserted, its value in this respect will be more than doubled. In scheming the Pedal department of a Chamber Organ, every endeavour should be made to provide a stop or stops suitable for solo or melodic playing altogether independent of the manuals.

Having thus hastily touched on the question of the speaking stops most suitable for the Chamber-Organ, I have now to consider the apportionment of such stops in the different departments of the instrument, and the means to be adopted to secure them adequate powers of expression.

Great Organ.—Expressive.

The department of the Chamber Organ which, for the sake of distinction, I call the Great organ, is, under the treatment I propose, by far the most extensive and important one in the instrument. Here should be congregated the chief organ-toned registers, namely, the Principal, 8ft.; Octave, 4ft.; Super-Octave, 2ft.; Mixture, &c., and two or three of the more important reed stops, and a proportion of the chief solo flue stops. To these must be added two or three soft-toned stops suitable for combination and accompaniment. The full tone of this department should be characterised by depth and richness, while its leading combinations are replete with variety of tonal effects. Every endeavour should be made, in the selection of the stops, in the adjustment of their scales, and in voicing, to render it an impossibility to draw an imperfect or unpleasant combination. When the total number of manual speaking stops is about fifteen, it is advisable to place about two-thirds of the number in the Great department, the remaining third being apportioned to the Choir department.

I now come to the all-important question, how to impart the maximum power of expression to all the stops of the Great organ *save one*. The only stop I propose leaving beyond the control of the Expression levers, and, accordingly, outside the swell-boxes, is the Principal, 8ft. The pipes of this important stop should be employed to form the "towers" and other features in the external design. Such salient positions secure for the stop perfect freedom of speech and predominance of tone, placing it at once in the prominent place it is entitled to hold in the general tonal scheme. The remaining stops of this department should be about equally divided, and inclosed in *two independent swell-boxes*. Special attention is directed to this apportionment; for, to the best of my knowledge, I am the first who has suggested the advisability of dividing any *one department* of an organ into *two distinct expressive portions*, while both can be played together or separately on *one clavier*. This arrangement has been followed in the appointment of my own Chamber Organ, and I venture to think with results of the highest value. This is one of the most important steps, in my opinion, towards rendering the organ more flexible in the matter of *expression*, and an instrument better suited for the satisfactory interpretation of the inspirations of great composers. For the production of complex orchestral effects, subtil *nuances*, and a greatly increased range of crescendo and diminuendo, no method, so far as is known to me, can equal the one here suggested.

I must now give some further details respecting this arrangement, so that it can be thoroughly understood, and its peculiar advantages realised by the reader. Let it be supposed that the Great organ comprises ten speaking stops, to be apportioned as above directed; five of these will be placed in what may be designated, for convenient recognition, the *back swell-box*, and four in the *front swell-box*. The Principal, 8ft., will be placed outside the latter swell-box, while it derives wind from the inclosed wind-chest. Five stops are thus apportioned to each of the two divisions of the Great organ. The pallets of both wind-chests must be connected by one train of mechanism with the single clavier devoted to the Great department. This arrangement, however, would be of little use, at least, in one of its important offices, unless means were provided for instantaneously connecting or disconnecting, at the will of the player, either of the divisions to or from the keys. This is secured by simple pneumatic ventils which control the wind separately supplied to each division. The ventils are controlled by small buttons or "pistons" placed immediately under the Great organ clavier.

The selection of the stops to be placed in the different swell-boxes is a matter deserving careful consideration, for much depends on their proper apportionment. This apportionment may, on first thoughts, appear a very simple affair; the most obvious arrangement seeming to point to the grouping of the foundation and mutation stops in one swell, and the solo and accompanimental registers in the others. Such a mode of procedure would, however, result in much disappointment and a serious narrowing of the offices of the twin swells. Indeed, the diametrically opposite course must be followed. If the chief foundation stop (Principal, 8ft.) is connected, as suggested, with the windchest of the front swell, the Octave and Mixture should be in the back swell, and the

* This term is almost invariably incorrectly written "Quintaton." The word is derived from *quintam tenentes*, and should accordingly be rendered Quintaten.

Super-octave (whatever its character may be) should be in the front swell. The solo and accompanimental registers must be about equally divided, care being taken to secure as great a contrast of tone as possible in the two divisions. Thus, if a solo Flute is placed in one division, let a Clarinet be opposed to it in the other. Again, as the Principal, 8ft. is connected with the front swell, place the most powerful reed (the Trumpet) in the back swell. Again, contrast a string-toned stop with a flute-toned one, and so on.

Before going further it may be advisable to put the reader in possession of one or two facts connected with the twin swells. In the first place, it may be pointed out that while the back swell contains about one-half of the stops apportioned to the Great organ only, the front swell should be made sufficiently large to contain all the stops apportioned to the Choir organ as well as the remainder of the Great organ registers. By this arrangement, the back swell-box will contain, say, one-third, while the front swell-box will contain about two-thirds of the entire list of manual stops. In the second place, each swell has an independent Expression lever, of the "balanced" form, placed side by side, in the position previously recommended. So placed, they can be moved one after the other or both together with *one foot;* or in different directions at the same moment with *both feet*, when the Pedal organ is silent. This absolute control over both the Expression levers is essential to the full utility of the twin swells. It will now be seen why I have refrained from applying the usual term Swell organ to any manual department. The entire instrument may, under the arrangement here proposed, be correctly designated a Swell organ.

It may be questioned why the Choir organ should not have an independent swell-box and an accompanying Expression lever? On first thoughts it may appear advisable, seeing that the Great organ has two swell-boxes, for the Choir stops to be inclosed in a third and distinct one; but the additional space required for such an arrangement, the increased number of mechanical parts, and the inconvenience of operating on three Expression levers, are not repaid by the very slight advantage gained by the third independent swell. In an organ of the moderate size contemplated in these Notes, I hardly think the third swell would be found to present a single advantage over the simpler arrangement proposed. Supposing the three swells are adopted, it will be necessary to have a simple mechanical device provided whereby the Expression lever of the Choir may, at will, be firmly linked with one or other of the levers belonging to the Great organ. This is necessary to enable the left foot of the player to open every swell-box of the instrument simultaneously, by simply placing it across the space between the two Great organ levers, and, accordingly, with half the sole on each lever. The combined use of all the Expression levers will only be resorted to in the production of a grand crescendo, with the claviers coupled. Thus united, the entire manual departments may be said to form *one magnificent Swell organ.*

Leaving the Choir department for future consideration, let us see what effects are possible through the agency of the twin swells of the Great organ. A few illustrations must here suffice, for space is too restricted to admit of any branch of my subject being more than briefly touched upon.

1. Suppose all the Great stops are drawn, and the wind is admitted to both the back and front divisions; with both the swells closed the effect will be that of a Principal, 8ft. (*Open Diapason*), at its full value, with a richly-toned, but subdued, background, to which the closed swells impart the effects of distance and restrained power. Now, the slightest touch of the foot on either of the Expression levers materially enriches the combination to the ear, by bringing one half of the background, if I may continue to use the phrase, nearer and more prominent. Leaving the lever thus first touched where it has been placed, the foot may be shifted to the other lever, and sufficient pressure used to open its swell rather more than in the previous case, and, accordingly, bring the tones of the inclosed stops still more prominently forward. Marked differences of tonal effect are thus produced. The mode of proceeding may be carried on step by step, until the full Great peals forth at its maximum strength. Numerous tonal effects may be produced by skilful management of the twin levers before the full power is reached.

II. Suppose the Principal, 8ft., Flute, 4ft., and Super-octave, 2ft., are drawn in the front division, and the Trumpet, 8ft., Octave, 4ft., and Mixture are drawn in the back division, and the wind admitted to the front division only, to begin with. With a closed swell the effect will be that of a full-toned unison in combination with a very soft Octave and Super-octave. Let the tone be brightened by a partial opening of the swell, and then, at a favourable moment, let the pneumatic button be touched, and the wind admitted to the back division. Instantly the ear is arrested by the addition of a mysterious and distant chorus effect, filling up and enriching the more prominent combination.

The front swell may now be fully opened, for the harmonic series is practically complete, and the back swell operated upon at the will of the player. The wind of the front division may be cut off at any desired moment, leaving the Trumpet, Octave, and Mixture at the disposal of the organist and under perfect control. I cannot help feeling how poorly words, however concise, convey any idea of the complex and charming effects hinted at here; they must be heard to be fully realised.

III. Suppose the Clarinet and a string-toned stop are drawn in one division, and a flute-toned combination (say, Orchestral Flute and Piccolo) in the other, and the wind admitted into both divisions. While the organist is engaged in playing a florid composition, he can, with one foot only, bring a hundred *nuances* to enrich his performance, now subduing the flute tones and swelling the reed and string tones, and *vice versâ.* And when he can spare both feet from the Pedal keys, he can, by placing them on the twin levers, produce marvellous orchestral effects, replete with light and shade, and unusual crossings of diversified tones.

The above simple illustrations must suffice to show what is gained by the division of the Great organ speaking stops, and the inclosure of both divisions in independent swell-boxes. If the reader is an organist and a musician, in the true sense of the word, he will have no difficulty in realising what such a treatment is capable of doing in the sphere of expression; and how, by its aid, musical ideas may be intelligently rendered which are at present obscured by the limited power of expression in the ordinary instruments of the organ builders.

(*To be continued.*)

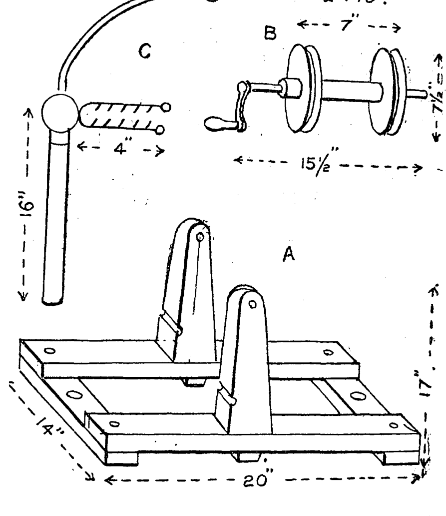
ELECTRICAL INSTRUMENT-MAKING FOR AMATEURS.—XI.*

By S. R. BOTTONE.

IT is with considerable diffidence that the author ventures to place before the readers to the ENGLISH MECHANIC the following instructions concerning the construction of the Wimshurst machine, since the machine has been so fully and ably described in these pages by the inventor himself. However, to render this series of papers complete, a brief sketch of the mode of making two simple forms will be given.

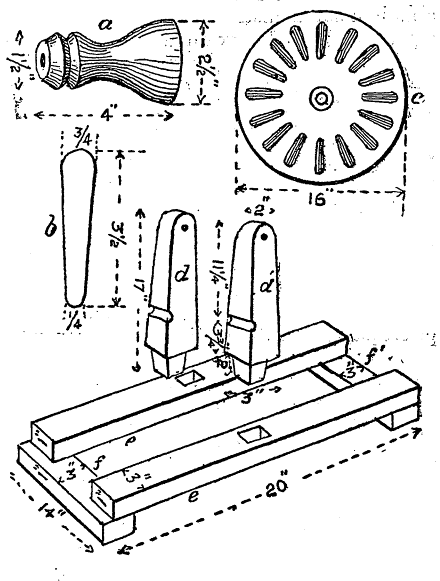
§ 34. *The Wimshurst Influence Machine.*—The portions that first demand our attention are the *plates.* These should be of glass—good window-glass—as flat as can be got, and not too green in colour (as it is apt to be poor in insulating power) is to be preferred. This is to be cut into two discs, each 16in. in diameter. The thickness of these discs should not exceed 1-16th of an inch. As in the Carré and Bertsch machines, it will be actually better *not* to have holes drilled in the plates, but to fasten the bosses to the plates as described at § 20.

FIG. 13.



These bosses consist in two circular pieces of mahogany or other well-seasoned wood, not less than 4in. in length. (It is a great mistake to have these too short, as then the glass discs come too near the standards, and much electricity leaks away.) It is best to turn these up in the lathe, of the form and dimensions shown in Fig. 18*a*. While in the lathe, a perfectly central hole nearly ½in. in diameter must be bored in the small end of the boss (as shown in

FIG. 18.



the cut), reaching *nearly*, but not quite, to the thick end of the boss. This hole must be bushed for its whole length with ½in. brass tubing, and some stout steel wire which just enters the brass tube, selected and straightened out, to serve as spindles on which the bosses are to turn. Mr. Wimshurst, in his directions, says: "I must impress upon those who make a machine that they cannot give too much care in selecting the tubes to fit properly, or the steel wire; it will save trouble throughout the making, and the machine, when made, will work more smoothly." The centre of the glass plates having been obtained as described in § 20, the bosses are attached to the plates

precisely as described therein. When quite set and dry, the plates should be varnished, in a warm dry room, on both sides with good shellac varnish, and the varnish dried by the fire.

§ 35. As shellac varnish is in constant requisition for insulating electrical apparatus, I give Mr. Wimshurst's recipe for the preparation and preservation of this useful compound. Take a large, wide-mouthed bottle—say, a pickle bottle—fit to it a soft wooden bung, bore a hole through this bung, and in this hole tightly fix the handle of a rather large brush (the brush end being in the bottle); then about half-fill the bottle with good shellac, cover the shellac with methylated spirits, and shake the bottle occasionally. In about 24 hours it will be ready for use. By this means the brush is always clean and serviceable.

§ 36. While the varnish is drying on the glass discs the operator may strike out on a piece of paper a circle of the same diameter as the discs, and, by means of the compasses, divide the circle into sixteen equal parts, drawing radial lines at each division, from centre to circumference. This divided circle will, if placed on a flat table under the glass discs, enable the operator to fasten down the tinfoil "sectors" or segments, at equal distances from each other.

§ 37. These sectors consist in wedge-shaped strips of tinfoil, slightly rounded at the top and bottom, as shown at *b* (Fig. 18), 3½in. in length by ¾in. wide at top, diminishing to ¼in. wide at bottom. These sectors are easily attached to the glass plates by placing these latter in turns upon the paper circle (§ 36), and, having rubbed a little *thick* shellac varnish over *one* surface of the tinfoil sector, placing it (shellac side downwards) on to the glass plate, just over one of the lines, care being taken to leave about ½in. of clear glass between the periphery of the disc and the circle of sectors. The line showing this distance had better be struck out with the compasses on the paper, as the perfect regularity of the circle of sectors adds much to the neat appearance of the machine. One disc, mounted on its boss, and fitted with sectors, is shown at Fig. 18, *c*. When the sectors are firmly stuck down to the glass, and the varnish quite dry, it will be well to run a brush charged with varnish round the inner and outer extremities of the tinfoil sectors. These rings of varnish may extend ½in. inwards, but not more. They serve to increase the adherence of the sectors to the glass, and also to insulate slightly the extremities. On the centre of each disc, exactly opposite the bosses, must now be fastened with hot marine glue or Prout's elastic glue, a small ebonite washer, punched out of sheet ebonite 1-32in. thick. These washers are to prevent the rotating glass discs from actually touching during rotation.

§ 38. *The stand* next demands our attention. It should be made of mahogany, walnut, or some other well-seasoned wood. Six pieces will be required—viz., two pieces 20in. long by 3in. wide and 1in. thick; two pieces 14in. long by 3in. wide, and two uprights 17in. in height 3in. square. These two latter must be cut round the lower end to form a square tenon 2in. long by 2in. square section, and two of these sides must be made to slope away 2in., this forming the top end, which must be rounded, as shown at Fig. 18 *d d'*. A hole of exactly the diameter of the steel spindle on which the plates are to run must be drilled through each standard, at about an inch from the top, care being taken that these two holes come exactly opposite each other and at the same *height* in the standards, otherwise the plates will not run opposite each other. At about 3¾in. from the tenon, and on the same side of each standard, a long semi-cylindrical slot is cut, about ½in deep; this serves for the spindle of the driving-wheels to run in. All these pieces are shown in Fig. 18, where *d d'* are the uprights, *e e'* the long cross pieces, and *f f'* the lower pieces of the stand; these pieces must be planed up so as to fit accurately; mortice holes cut in the centre of the 20in. strips to take the tenons of the uprights. The whole is then joined together so as to make a strong frame, with glue and screws; the long strips being screwed *over* the 14in. pieces at each extremity so as to form a square 14in. by 20in. As the two short pieces are placed *below* the larger ones, and as the uprights are morticed into these, it is necessary to make the ends of the uprights project 1in. through the holes, so as to afford a support to the centre of the frame. With a spokeshave, or similar tool, the sharp edges should be taken off the frame, so as to prevent dispersion of electricity. The frame and standard being put together, as shown at Fig. 19 *a*, it will be well to cut out the holes in the centre of the shorter pieces of the frames, which holes are to receive the glass rods or jars (as the case may be) which support the conductors and combs. These holes may be begun with a centre-bit, and should be 2in. in diameter if jars are to be used, or 1in. if glass rods only are to be employed.

§ 39. As the glass discs, when mounted, must rotate in contrary directions, it is necessary to have two driving wheels on a spindle wherewith to drive them, and to connect one driver with one boss (§ 34) by means of a straight band, while the other transmits its motion by means of a crossed band. These driving-wheels may be turned out of any suitable wood, 7½in. in diameter; they should have a centre-bit hole, 1¼in. in diameter, put through the centre; a length of some good hard wood should then be turned up to make the spindle, on which the two wheels must be tightly fitted and glued. Care must be taken that the edges of the wheels, when glued to the wooden spindle, should come exactly opposite the V groove in the bosses (§ 34) when the glass discs are in their places. These wheels must have a groove turned in their edges, to take the driving band.

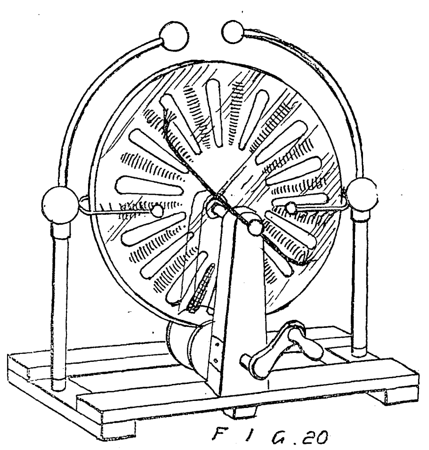


FIG. 20

The length of the wooden spindle must be such as to just *not* reach from standard to standard, say 7¾in. A central hole, about ½in. in diameter, is now made through the entire length of this wooden spindle, and through this wooden spindle is driven an iron rod 15½in. in length, ½in. diameter, projecting 3in. at one end, and 4in. at the other. At the longest end this rod is squared up to take a driving handle. If the wooden spindle does not fit quite tight upon the metal rod, it will be better to drill a hole through wood and iron and drive in a metal pin. The driving spindle is placed in the two semi-cylindrical slots cut in the sides of the standards (§ 38), and is kept in its place by means of two small rounded cleats screwed thereto. These driving wheels, with their spindles, &c., are represented at Fig. 19 *b*.

§ 40. The next step is to mount the combs and conductors on to the glass pillars, which are to insulate them. These pillars, of which two are required, should be 1in. in diameter and 15in. in length. Good white glass that becomes readily electrical on friction should be chosen. They must be fitted with brass collars 1in. long, at the upper extremities, and to these collars are soldered brass balls 2in. in diameter. At the upper portion of these balls is drilled a hole ¼in. in diameter, into which are fitted, but not *fixed*, brass rods ¼in. thick, about 16in. long. These rods are bent into quadrants, and terminate in brass balls. It must be noted that the two brass balls terminating these rods must be of different sizes to obtain the best effects. In the sized instrument under consideration, one should be ⅝in. and the other 1¼in. in diameter, and nicely polished. By not having the rods as fixtures in the top of the glass pillars, it is easy to exchange the rods if the direction of the flow of the current in the machine is reversed, either accidentally or intentionally. The combs, which must be screwed to the centre of each 2in. ball that terminates the glass pillars, consist in ¼in. brass rods 12in. long, terminating in brass balls about ½in. diameter, and bent into the shape of a horseshoe, so as to embrace both the plates. In the interior of the horseshoe are soldered, or otherwise affixed, four or five ½in. brass points. The whole arrangement of the glass pillar, with its collecting comb, large ball, movable end, and terminating ball, is shown at Fig. 19*c*.

§ 41. The plates can now be mounted on the standards. To this end, each plate in turn is held with its boss against the small hole at the top of the standard, on the steel rod, which was chosen as running freely in the bushing of the boss (§ 34) pushed through this hole and into the hole in the boss as far as it will go. The rod is then cut off, leaving an inch projecting on the outside of the standard. With a file, a nick is cut in this steel rod at about the centre of the portion that is to remain in the standard, then a round-headed screw is driven into the top of the standard to enter this nick and keep the steel rod quite firm and immovable. To the projecting ends of the steel rods are affixed the bent rods carrying the brushes. These rods are technically known as the "neutralising rods." They are made from ¼in. brass rod, about 17in. in length. A hole ⅜in. deep and about ⅛in. wide, is drilled at the two extremities of each of these rods. A little tuft of about a dozen short lengths of the fine wire used by the gilt ball manufacturers, is made into a brush by binding at the bottom end with a little of the same wire; this same end is pushed in the holes in brass rod, and wedged firmly into its place by means of a little wooden wedge. There are two such rods; and each rod must have a brush at each end. A short length of brass tubing, fitting tightly on to the projecting pieces of the steel spindles carrying the plates, is now procured, and cut into two pieces 1½in. long. With a round file, a slot (sufficiently deep to take the brass neutralising rods just finished) is produced in these pieces, and each rod having been placed in this slot, at its centre, is soldered thereto. At the same point, to give a finish, and prevent dissipation of electricity, is also soldered a small brass ball. Each rod is then bent slightly in the shape of a bow, so that the "brushes" shall come into contact with the sectors, when the neutralising rods are put in their places on the steel spindle.

The appearance of the complete machine, with the "brushes" in their right position for a right-handed person to drive, is shown at Fig. 20.

ASTRONOMICAL NOTES FOR OCTOBER 1886.

The method of finding the Sidereal Time at Mean Noon at any other Station will be found on p. 353 of Vol. XLII.

Spots and faculæ still diminish, though fine isolated ones occasionally appear.

The Zodiacal light may be seen in the East before Sunrise.

The Moon

Enters her First Quarter at 10h. 33·6m. at night on October 4th, and is Full at 3h. 23·9m. a.m. on the 13th. She will enter her Last Quarter at 2h. 40·8m. o'clock in the afternoon

of the 20th, and be New at 7h. 15·5m. a.m. on the 27th.

Day of Month.	Moon's Age at Noon.	Souths.
	Days.	h. m.
1	3·6	3 9·5 p.m.
6	8·6	7 21·9 „
11	13·6	11 1·7 „

21	23·6	6 33·9 „
26	28·6	11 6·3 „
31	4·2	3 35·2 p.m.

The Moon will be in conjunction with Saturn at 7h. a.m. on the 20th; with Jupiter at the same hour on the 26th; with Venus at 1 p.m. on the 26th; with Mercury also at 1 p.m. on the 28th; and lastly with Mars at 10 a.m. on the 30th.

Mercury

Is an Evening Star throughout the Month, but is most indifferently situated for the observer during the whole of it. His angular diameter increases gradually from 4·8″ to 5·4″ between the beginning and End of October.

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	12 41·4	3 20·1	0 0·8 p.m.

26	15 9·8	19 29·8	0 50·5 „
31	15 38·6	21 42·0	0 59·6 „

The path indicated in the above ephemeris commences in Virgo, and extends to, and terminates in, Libra. On the evening of the 7th Mercury will be rather less than 3° N. of Spica Virginis, and some 2° South of α Libræ on the 22nd. He will be in conjunction with Jupiter at 2 a.m. on the 4th.

Venus

Is a Morning Star during the whole of October, but is also very poorly placed for the observer, and is an insignificant object to boot; her gibbous little disc diminishing in diameter from 10·2″ at the beginning of the month, to 9·8″ by the end of it.

Day of Month.	Right Ascension.	Declination.	Souths.
	h. m.	° ′	h. m.
1	11 34·2	4 21·5 N.	10 53·8 a.m.
6	11 57·2	1 54·9 „	10 57·0 „
11	12 20·0	0 33·7 S.	11 0·2 „
16	12 43·0	3 2·7 „	11 3·4 „

26	13 29·3	7 56·2 „	11 10·3 „
31	13 52·8	10 17·4 „	11 14·1 „

Beginning on the actual confines of Leo and Virgo, this path is practically entirely performed in the last-named Constellation. Venus will be very close to η Virginis on the morning of the 10th, and on the 14th some 2° South of γ Virginis. She will be 3½° north of Spica on the 23rd. She will be in conjunction with Uranus at Noon on the 14th, and with Jupiter at 9 p.m. on the 22nd.

Mars and Jupiter

Have both left us for the season.

Saturn

In the sense of his Southing is a Morning Star; but he rises at about a quarter to Eleven at night at the beginning of October, and before 9 a.m. at the end of it. He is in quadrature with the Sun at 3 p.m. on the 15th. His equatorial diameter increases imperceptibly from 16·2″ on the 1st to 17·1″ on the 31st. But little change will be noted in the opening of his rings, and he still presents an all-repaying

It will be seen from the above ephemeris that the very short arc described by Saturn during October lies in Gemini. Regarding the planet as stationary (which we may do for our present purpose) he may be said to lie very approximately at the right angle of a right-angled triangle, whereof δ and κ Geminorum are at the extremities of the hypothenuse.

Neptune,

Although, as far as his passage over the Meridian is concerned, a Morning Star, yet is visible during a considerable part of the ordinary working hours of the amateur's night; in fact, towards the end of the month he rises before 5h. 30m. p.m.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	3 42·9	17 55·5	3 3·8 a.m.
6	3 42·6	17 54·1	2 43·8 „
11	3 42·2	17 52·6	2 23·8 „
16	3 41·8	17 51·1	2 3·8 „
21	3 41·3	17 49·4	1 43·6 „
26	3 40·8	17 47·6	1 23·4 „
31	3 40·2	17 45·4	12 59·2 p.m.

The short retrograde arc thus described by Neptune lies some 6° or so to the South of the Pleiades, in a perfectly barren region of the sky.

Uranus

Is now invisible for the purposes of the Observer.

Shooting Stars

May be watched for from the 1st to the 6th; and again from the 18th to the 21st, inclusive, with the best chance of rewarding the Observer.

Greenwich Mean Time of Southing of Fourteen of the Principal Fixed Stars on the Night of October 1st, 1886.

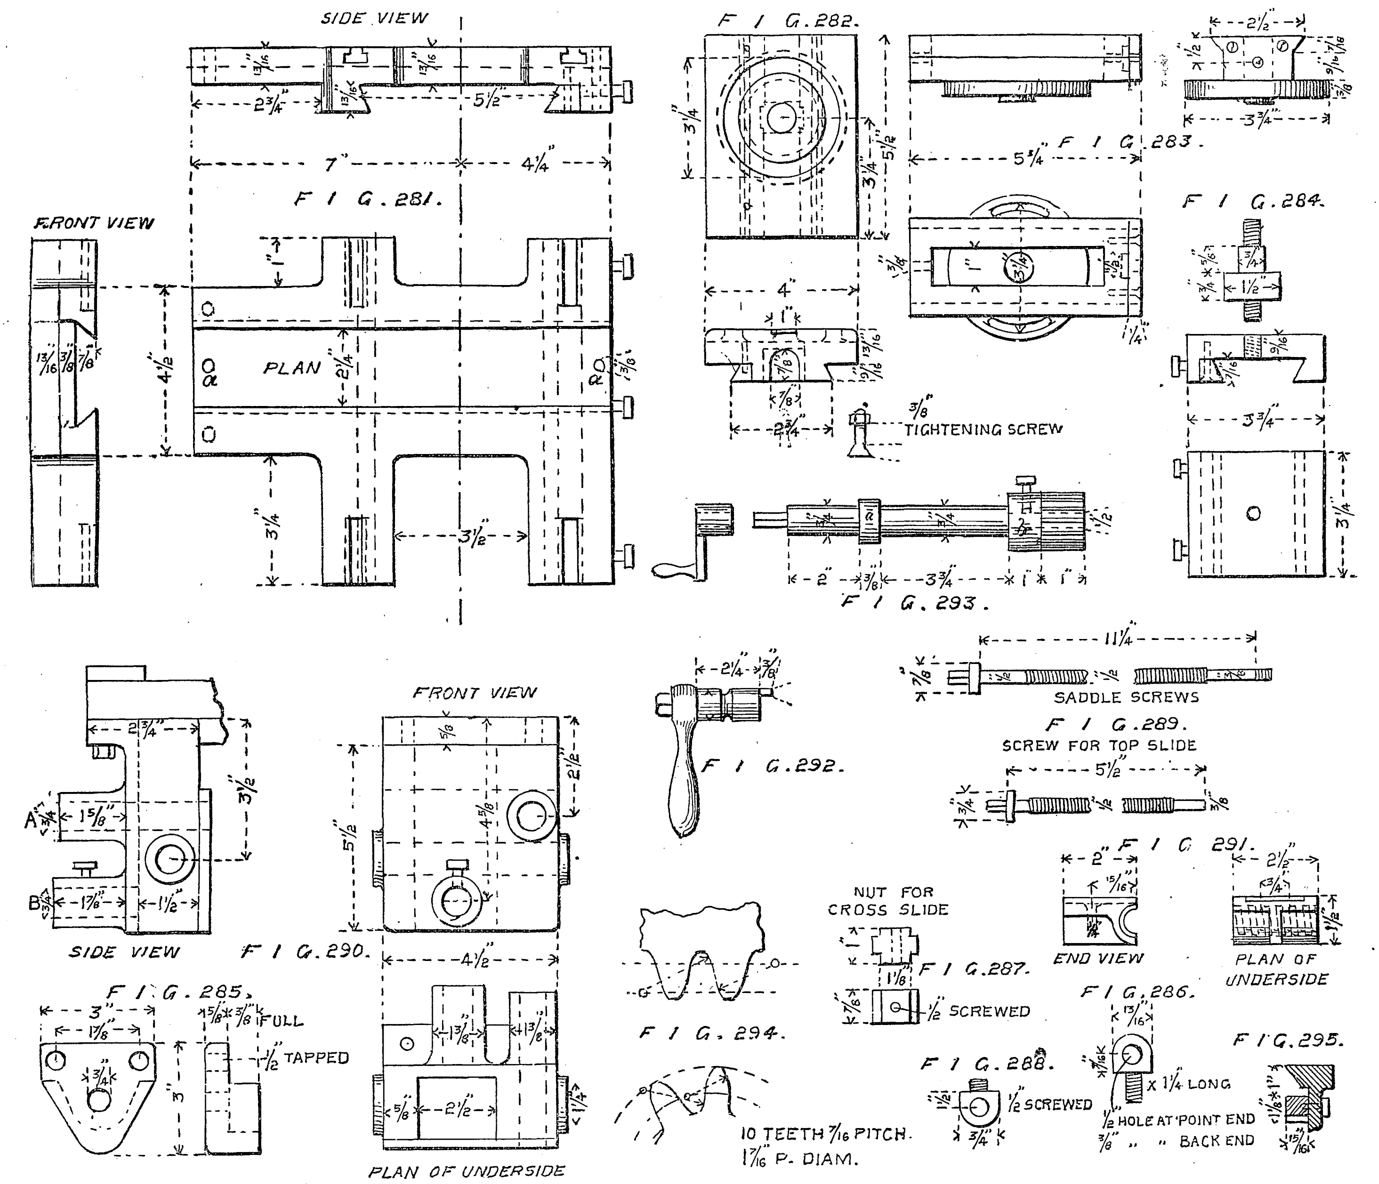
η Piscium	12 42 46·95 „

The method of finding the Greenwich Mean Time of Southing of either of the Stars in the above list for any other night in October; as also that of determining the local instant of its Transit at any other station, will be found on p. 355 of Vol. XLII. It must, however, be reiterated that the rules there given are not rigidly accurate as applied to Polaris, or any close circumpolar star; though they will probably be found quite sufficiently so in practice.

RECENT experiments by Professors J. J. Thomson and Threlfall have brought them to the conclusion that, just as ozone is formed by the passage of electric sparks through oxygen, so an allotropic modification of nitrogen is formed by sparking in nitrogen.



THE AMATEUR WORKSHOP.—XXVI.

Self-acting Lathes.—(*Continued.*)

THE annexed figures represent in detail the slide-rest shown in the general views (Figs. 263, 264, 265, page 546 of Vol. XLIII.) And since in those views the principal parts are seen in their relative positions, I have in these, to render the construction as clear as possible, taken the rest apart, and dimensioned almost every item of detail separately, so that there can be no mixing up of dimensions and views in a structure necessarily somewhat intricate. Keeping those general views at hand, there will be no difficulty in assigning to each matter of detail its proper place.

There is no unnecessary work about this rest; on the contrary, it is as simple as one of this type can be, though of course, a compound slide and screw-cutting rest cannot be a very simple affair in itself. It consists of saddle (Fig. 281), cross slide (Fig. 282), middle slide (Fig. 283), top slide (Fig. 284), tool-holder (Fig. 285), while the remaining figures embrace the apron and its parts, and the various minor details, as screws, rack-and-pinion arrangements, &c. Let us take these in succession.

The saddle (Fig. 281) consists of a plain plate having vee'd edges above for the guidance of the cross slide, and one vee'd edge below to embrace the front edge of the bed, and also a rectangular strip at the back to receive the loose adjustment strip with its set, and clamping screws. The main plate can either be prepared from solid stuff, or narrow cross strips can be halved together. Upon this plate come the remaining parts. The space within which the cross slide travels can be cored out, as being the best job, in which case the main plate will be $\frac{13}{16}$in. thick (see end and front views), or can be made to deliver in the pattern, when the main plate will be only $\frac{3}{8}$in. thick (see front view). (Note that throughout I quote finished dimensions, that is taking no account of pattern allowances for fitting.) Strips are nailed on the bottom (which should be top in moulding), the one being the rectangular piece which carries the loose vee strip, the other a piece which is similarly rectangular in the pattern, but which forms a backing for the vee strip skewered against and cast with it. The shouldered underside becomes the base for the attachment of the apron shown in Fig. 290, and the holes in the apron flange and in the saddle, therefore, are marked one from the other. Four prints are nailed on the top next the ends to carry T-shaped cores, whose section is seen in side view, to receive both for miscellaneous attachments of work to the saddle. The $\frac{3}{8}$in. holes at *a a* are for the bearings of the leading or traverse screw, the bearings being shown in Fig. 286.

The cross slide (Fig. 282) is preferably cored on the under face, the core embracing the arch for the traversing screw, and the square recess for the nut. The top ring recess for the circular slewing motion is also cored out to $\frac{5}{16}$in. deep. The vee which is cast with the slide is loosely skewered on.

The middle slide (Fig. 283) is cored out and the strips cast on, being skewered to the sides of the main body of the pattern. (See end view.) A circular flange is made fast to the body, and curved prints and cores provided for the swivelling motion, the clamping studs passing through these slots. There is also a central stud to insure steadiness, turned to fit the recess in Fig. 282.

The upper slide (Fig. 284) is a plain pattern having a parallel edge on one side to form the backing for the strip, and a vee on the other, the latter loose as in the other cases. The tool-holder (Fig. 285) is of the triangular pattern, and requires no detailed description.

In the fitting of these various sliding portions there is, of course, no difficulty where surface plates, squares, and accurate planing machines and angle plates are available, since the parts are machined independently of one another with the aid of templets, and when brought together require nothing but a trifle of easing and scraping. But it is different in the case of amateur work, and the obvious way to proceed with such a saddle as this would be, bearing in mind the principles already laid down and previously discussed, to fit and check it in the first place independently with scribing blocks and calipers, and finally upon its own bed. This is a laborious task in a saddle of this description having large surfaces, and hence I should advocate having the flat surfaces, not only of the saddle, but of all the slides, at least planed to a parallel thickness, by which the labour of filing would be reduced to the mere fitting of the edges, strips, and screws. Proceeding in this way the saddle as being the basis of operations would be first fitted to the bed with its loose strip. The latter should be of wrought iron, and screwed as shown, and the fit of the saddle should be such that there should be no difference in the degree of tightness or slackness of the sliding fit when the saddle is thrust along by hand. If there is a difference the bed is not of equal parallelism throughout, and if the bed is parallel and the slides are not parallel, there will be tightness at one end and slackness at the other in any position of the rest.

After the saddle is fitted thus, the next most important portion of the work is the groove which guides the transverse slide, and this should be marked by direct measurement from a face plate, care being taken in the first place to be assured that the plate itself runs true,

and that the headstock is in a condition of perfect parallelism according to the method to be presently described. At the same time it will be proper to check the transverse edges by means of a long and true square carried over and parallel with the edges of the bearers themselves. Assuming the transverse edges once got true, there can be comparatively slight difficulty experienced with the fitting of the others. The edges of the cross traverse slide can be fitted to the grooves on the saddle, the fast and loose vees being first marked off on their ends symmetrical or central with the circular groove and stud. The circular groove for the nut must be skimmed round in the lathe and the stud turned.

The fitting of the top slide (Fig. 283) is a repetition only of the work previously done, and since it is revolved and rendered adjustable at any angle by means of the circular groove, the edges of the slides are not regarded in reference to other edges, as was the case with the saddle. The upper plate (Fig. 284) which carries the tool-holder, and the latter also (Fig. 285) are very plain, and dimensions being given for screws (Fig. 289), vee's, and central stud, no further details are necessary.

It will be desirable to try the parallelism of each successive sliding piece directly from the bed itself with scribing block, since although each separate piece may show fairly true for thickness alone, yet on the whole a slight discrepancy may be apparent.

The centres of the holes for the traversing screws will not be marked off until the various bearings and nuts are fitted in place,—viz., Fig. 286 for the saddle, Fig. 287 for the cross slide, Fig. 288 for the top slide. These being all in place, the centres of the holes in the lug bearings (Fig. 286) and in the ends of the slide (Fig. 283), will be scribed off and drilled, preferably with a small drill first of all, being, say, $\frac{1}{32}$in. or $\frac{1}{16}$in. smaller than the sizes of the actual holes, and afterwards the faces of the nuts in the slides will be brought opposite to these, and scribed off therefrom, moving the slide with its attached nut first to one end, then to the other. Supposing a slight variation to exist in the centrality of the end holes, it will be apparent on marking off and drilling the central nuts; and the difference in the holes can then, having them under size, be easily adjusted by filing to one side, and finally finishing with another drill, or with a broach to the exact size. The diameters of the holes are given in each case. The central nuts are screwed either with an angular or with a square thread, as is most convenient, square threads being cut by the lathe makers on account of their more durable wearing surfaces.

Before going farther, and while on the subject of fitting the slides, let us anticipate a little, and suppose the rack and pinion in place, and see how we may check the accuracy of our lathe parts with a view to final adjustments.

When checking the truth of a lathe there are three points to be attended to—the parallelism of the headstock mandrel with the bed cheeks, the exact right angles therewith of the transverse groove in the saddle which guides the slide for surfacing, and, lastly, the parallelism or alignment of both headstock and poppet in relation to the bed cheeks. In the business of setting and checking, the base of operation is of course the vee'd-edges of the lathe bearers. To those the saddle is fitted with as fair an approximation to accuracy as can be obtained by direct measurement, and the headstock is similarly set with its screws. Now sliding the saddle bodily along with a boring-tool clamped in the tool-box, bore out a bush attached to a chuck on the headstock mandrel, taking a very light cut so that there shall be no possible forcing or springing of the tool. The hole will probably not be parallel when tried carefully with calipers. Assuming that the rest fits truly to the bed, the inference is obvious that the headstock mandrel is not set parallel: hence adjust its set screws until by repeated trials we find that the headstock is in such a position that a hole can be bored perfectly parallel, or a pin turned similarly; then, and not until then, can we be sure that the axis of the headstock is in perfect alignment with the axis of the bed. Then, as regards surfacing, we have presumably taken all reasonable precautions to get our vees for cross traverse at exact right angles with the bed slides, according to the directions just now given; but the probability also is that they are not quite so—in fact, not sufficiently accurate for the requirements of good work. Therefore we must try for surfacing by putting a face-plate, known to be true, on the mandrel thread, or by turning a plate of metal true, and then running the cross-slide over the centre, try the turned face to see if the tool or any other point set in the tool-box touches the turned face on the far side precisely as on the side towards the front. Supposing there is not exact correspondence, the only way to remove this source of inaccuracy is to readjust the edges of the saddle vees by filing or scraping the required parts, with consequent resetting of screws, until the vees for cross-travel carry the cross-slide over with a practically perfect approximation to the conditions requisite for true surfacing. Lastly, though we have a true headstock, and true rest for boring, turning, and surfacing, we are not sure now that the headstock and poppet are perfectly in line in relation to the axis of the bed—in fact, we may presume that they are not, spite of all our previous care in lining out. Take, therefore, a round bar, the longest convenient, place it between centres, and turn down a short bit at each end, say an inch inward to the same precise diameters. Shift the saddle of the rest to each turned end in succession, and test by means of a gauged thickness bit of metal interposed between the turned diameters and a tool point or any similar bit of metal clamped in the tool-box. If the space between the turned part and the point is exactly the same at each end, the position of the slides on the saddle meanwhile remaining unaltered, the saddle and the slides being racked bodily from one turned end to the other of the rod without interfering with their relative positions, well and good. If the interspace is not exactly the same at each end, the headstock must be set over in a perfectly parallel position with that which has already been imparted to it by the set screws, and to the precise amount of the difference in the spacing at each end of the rod as gauged by the thickness piece. This can be done by scribing lines with dividers at a little distance away from the edge of the headstock upon the bed, and using these lines as a guide for parallel adjustment.

With this we may consider the essential work of the upper portion of the rest (polish excepted) finished, and devote our attention to the apron and its parts. There are numerous forms of apron and clasp-nut made; but I shall content myself with describing one alone, and that not the most common form. This is convenient, compact, and easier to make than the ordinary double nut with cam plate, and is quite as good for a lathe of small size.

The main casting of the apron is shown in Fig. 290. It is bolted to the underside of the saddle by means of the return flange, is furnished with a groove to take the sliding-clasp nut, a plate being screwed against the face of the groove to retain the slide in place, and two bosses A for the pinion spindle Fig. 293 and B for the eccentric spindle (Fig. 292) for actuating the slide. This casting delivers itself very well, so that its pattern is precisely like the casting, plus the allowances. It should be fitted and screwed in place previously to machining, and the groove scribed with due regard to parallelism and square setting while so screwed up. The sliding nut (Fig. 291) is afterwards fitted to this groove, the labour of fitting being diminished by the use of narrow chipping strips. The screw will be cut in the lathe while the nut is yet solid—that is, the nut will be screwed in an entire circular hole just as though it were a common nut, and then the one half slotted away and discarded, leaving the half-clasp nut as shown in the figure. Or if the slotting presents any difficulty, cast the top half which is to serve the temporary object, as a separate piece, and fit, and solder or "sweat" it on the other, bore and cut the threads, and afterwards separate the halves by the application of warmth. The oblong, round-ended slot is to be cut to the dimensions and in the position shown, to take the eccentric-pin on the spindle (Fig. 292), by which the nut is thrown into and out of gear. This spindle, it will be observed, is prevented from slipping endways by the pin fitting into its circumferential groove (Fig. 290).

The spindle of the rack pinion is dimensioned in Fig. 293, and is maintained endways by the collar *a* at the front and the boss and set pin *b*, which forms an integral part of the pinion, at the inner end. For notes on the making of spur pinions see Vol. XLI. p. 160; information relative to racks will be found on the same page also. Two teeth each for this particular rack and pinion are drawn to full size in Fig. 294, and the section of the rack in Fig. 295. It is 2′ 5″ long, reaching to the gap at one end, and 4″ inwards from the end of the bed at the other, and is preferably cast in two lengths. Its position relatively to the bed in the other direction is shown in the transverse view, and also its mode of attachment by means of stud bolts put in from the inside of the bed.

HOW TO MAKE VARIOUS COLOURS.*

Being frequently asked by young aspirants for fame, in the ranks of the carriage painter, for formulas, by which they could be guided in making certain colours, I have concluded that others might be interested in such matters, and will therefore give here a few of the most popular recipes employed for producing various colours. It must be understood, in the first instance, that all the colours we see on carriages are not simply pigments or pigments mixed and applied as paint. The application of certain colours over certain grounds will produce colours not to be obtained in any other way. The term glazing is applied to this method of painting.

Brown.

Brown, according to scientific authority, is a warm, broken colour having red for its prominent ingredient, and possessing a slight yellowish tinge. Now we make what is called brown with red and black, or red and blue; but it is not really a brown. It is a dark red, and to make a brown we must add a little yellow. Mix Indian red, Tuscan red, or Pompeian red (all the same pigments) with black, to make a colour as light or as dark as you desire, then add a little chrome yellow. To make a richer brown take English vermilion and ivory black, and tinge with yellow. A richer brown, known as japan brown, is made by mixing any deep red with black japan until the required shade is produced. Another and still richer brown is made by mixing carriage-part lake and ivory black and a few drops of yellow. Carmine and such colours as lake, rose pink, &c., give a sort of maroon colour of various shades, according to the amount of black or blue mixed with them. Chocolate brown is a very handsome colour—the colour of prepared chocolate cakes. It may be made by adding a little red and black to burnt umber. Mix the umber and grind it, then add the red and black in small quantities until the desired shade is obtained.

Maroon.

A maroon colour is quite different from brown, yet many call it by that name. It is made in several ways, generally with lake and carmine. To make a good maroon colour add a little black to carriage-part lake, and put over a black ground, then glaze with carmine darkened with blue, not very strong. Carriage-part lake is purchased ready prepared.

Carmine.

Carmine, though an expensive pigment, may be used with economy in making lake colours. By preparing the ground with red, darkened to various shades, then glazing with carmine, we can make a handsome lake colour, and one that will not fade so readily as the real lake. German vermilion (sold at 35 cents per pound) mixed with white lead makes one of the best foundations for a carmine job. Next lay on the German vermilion darkened with a little carriage-part lake, after which colour-and-varnish with carmine, to which is added a little of the vermilion.

Green.

The handsome bottle greens, seen on carriages, are mostly "glazed colours." A ground is made of Dutch pink and black, then a glazing of yellow lake is put on, which gives that rich "depth" so much admired. Rich greens for express work are generally made by adding Prussian blue to Milori green. Chrome green may also be used for such work, but it is not so rich.

Grounds.

All delicate or expensive colours are put on a ground as near the colour of the finish as is possible to make with inexpensive pigments. This lessens the danger of patches and streaks occurring, and reduces the quantity required to make a solid covering. Most lakes have a ground of drop black, tinted with Indian red to the desired shade. For

* By F. B. Gardner, in the *Blacksmith and Wheelwright.*

purple lake, use a ground of Prussian blue with a little white added. For vermilion use a pink, made by adding red to white lead. For green use lead colour. It may sound strange to many, but I have demonstrated in a number of cases that ultramarine blue laid over a lemon yellow ground will be far more brilliant and durable than when put over any other ground. Why this is so I am unable to tell. This goes to show that the ground has an effect upon colours to a greater degree than is generally supposed, and the painter should take pains to get his foundation and groundwork as near perfect as possible. The ground for laying colour over is best when mixed to dry with an egg-shell gloss, not flat or dead, as some are in the habit of making it; then it will require no sandpapering, nor rubbing, which might destroy its evenness.

A PRACTICAL USE FOR LEIDENFROST'S DROPS.

WATER, placed upon a red hot metallic plate, springs into the form of a drop, and evaporates without coming in contact with the plate, as is known to all. It is equally well known that by using a concave vessel the drop continually rotates. To Bohlig belongs the credit of suggesting the practical use of the Leidenfrost experiment, more especially in water analysis for determining the solid residue of natural water. Where hitherto this determination has been effected by evaporating the water to dryness without boiling, in a platinum dish on a sand or water bath, and afterwards weighing the already tared dish, Bohlig proceeds as follows:—He brings a shallow platinum dish to a bright red heat over a gas lamp, measures out 50c.c. of the water to be analysed, and by means of a pipette lets single drops of it fall into the capsule, where they gather into a fluid globule, or spheroid, which begins to rotate. The evaporation proceeds quietly, without any spurting, and new quantities of water are added drop by drop, so that the spheroid always preserves a suitable and comparatively unvarying size. The operation can be carried out successfully with little practice, and is extremely elegant and precise. It is only necessary to be sure that the vessel is kept at a red heat, and that too many drops are not added, nor in too rapid succession, as otherwise the sudden cooling would cause a spurting of the fluid. Too rapid a rotation of the globule is prevented by letting the next drops, when it is time to add them, fall in a direction opposite to that of its rotation, so as to keep its movement in check. When the 50c.cm. of water are in the capsule, the operation is soon ended, the globule rapidly grows smaller, darker in colour, until it resembles a pea, the rotation slackens, and eventually ceases. The flame is then removed. The globule of residue lies perfectly loose on the capsule, without showing any adhesion. Thus there is obtained the solid residue of 50c.c. of water, which has been evaporated without contact with the sides of a vessel, without loss, and without contaminating mixture, in the shape of a little globule, which is exposed for a good while to a temperature of 180° C., until dry, and then is rolled directly upon the scale pan of a chemical balance, and weighed within ½ milligramme. The advantages of Bohlig's method may be thus summarised. The residue is in the shape of a little bead, with so small a superficies that, even if it contains chloride of calcium or chloride of magnesium, the absorption of water from the air is almost nothing, especially as the time of exposure is soon over, on account of the small weight to be weighed. Moreover, there is nothing to prevent the weighing of the globule in an air-tight, closed tube, well-dried beforehand. It is unquestionable that this new method can be adopted for the evaporation of all sorts of fluids to dryness, without loss, and for a large class of cases, if one includes different modifications of the method. For example, the platinum may be replaced with equal or greater advantage by silver, copper, or even pure nickel, and the method is not limited merely to solutions in water. There is no true contact of the fluid to be evaporated with the sides of the vessel, so that no chemical action can affect them. Hence aqua regia, sulphur compounds, &c., can be treated in red hot silver vessels without the latter being at all attacked.—*Rundschau für Pharmacie.*

Edison's Carbon for Transmitters.—Edison has recently devised a modification of the carbon button in his transmitter, which is said to greatly increase the efficacy of the instrument. He takes a textile or woven fabric, preferably that known as "veiling"; he forces lampblack or powdered carbon into the meshes under a strong pressure, and then carbonises it. Or, instead of this, he employs a disc of thin paper perforated with a large number of very fine holes, and treats it in the same way.

SCIENTIFIC NEWS.

WE learn from the American papers that the Lick Observatory, with its big telescope, will be in full activity in the latter part of next year, unless some unforeseen delay should occur. A correspondent informs us that the extra crown lens, which it was intended to use with the 36in. refractor for photographic purposes, has been cracked in the grinding; but we will hope that the Messrs. Clark will overcome that disaster. The amount bequeathed to the observatory was 700,000 dollars, and only about 200,000 dollars will remain as the nucleus of an endowment. Every effort has been made to keep current expenses low; but that sum will not be sufficient to support a staff capable of utilising the various instruments to the fullest extent. To quote the words of Prof. Holden, the Americans do not mean to jealously "guard the immense scientific opportunity for ourselves, for California, or even for the United States. The real gift of Mr. Lick was to the world. We mean to put the large telescope at the disposition of the world by inviting its most distinguished astronomers to visit us, one at a time; and to give to them the use of the instrument during certain specific hours of the twenty-four. Each day there will be certain hours set apart when the observatory staff will relinquish the use of the equatoreal to distinguished specialists who will come from the United States and from Europe to solve or to attack some one of the many unsolved problems of astronomy. In this way we hope to make the gift of Mr. Lick one which is truly a gift to science, and not merely a gift to California and to its University."

In a paper by Dr. B. A. Gould, read at the meeting of the American Association, held recently at Buffalo, N.Y., the author gives an interesting account of his photographic work at Cordoba. The only Northern stars photographed were the Pleiades and Præsepe, and it is notable that on all the Pleiades' plates all Bessel's stars within the limit of the field are found, with one exception, a 9½ mag., whilst others down to the 11th mag. are clearly depicted. Dr. Gould has frequently photographed about 70 of the southern clusters, and more than a hundred double stars.

The death is announced of Alessandro Dorna, director of the University Observatory, Turin. He was in his sixty-second year.

Prof. Cohn has lately delivered a lecture on "The Action of the Electric Light upon the Eye," in which he stated that it sometimes induced inflammation. Arc lights should be surrounded by a globe of ground glass, or even opal, notwithstanding the loss. He quoted the conclusions of Voit and Ranke, of Munich, that the light from an Edison incandescent lamp is seven times brighter than that of an Argand gas-burner, and therefore excites the retina more. On the other hand, if the electric light is weak, books and work are apt to be held too close to the eyes—a fertile cause of myopia. Prof. Junge, of Zurich, informed Prof. Cohn that the local reading society had given up the use of the incandescent lamps, as the illumination was too weak, and to have increased it sufficiently would have made the cost double that of gas. So far as the eyesight is concerned, the incandescent lamp is to be preferred to the arc light, but in either case the light should be steady and strong.

It is stated that a resident of Sydney has brought under the notice of the Governor an electrical machine-gun which is said to be capable of firing 120 rounds "every few seconds," from any position and in any direction. It is stated to have the further advantage of being easily portable.

At the Fourth Semi-Annual Convention of the National Electric Light Association, held recently at Detroit, Michigan, an exhibition of novelties was organised, and amongst them was an incandescent lamp of 400 candle-power, which was stated to need only 425 watts—a very economical lamp of the kind if it answers the test.

A "transportable electric lighthouse" has been lately invented by M. Beduwe, a builder in Liége. The idea is to furnish the light in any place on short notice; and it is thought the apparatus might prove useful in public works, cases of accident, gatherings in public places, fêtes, &c. The constituent parts are (1) a telescopic system of copper tubes bearing the light; (2) a three-cylinder steam-engine to drive either a Gramme machine, or a suction and force pump; (3) a vertical boiler on the tubular system; and (4) a reservoir for water. The whole is mounted on a four-wheeled carriage. The light is raised by hydraulic means.

A Mr. F. Rohart has recently presented a note to the French Society of Agriculture in which he briefly describes a method of utilising wool grease. He has not given a full account, but states that the wool grease, having first been melted down, is treated with "a certain sulphur compound," with which it enters into combination. The substance thus produced is a true chemical compound, and contains in combination at least 100 times its volume of hydrogen sulphide. If it be now treated with an alkali, it is immediately saponified, even in the cold. The soap thus produced smells neither of the grease nor of the hydrogen sulphide, and the conversion takes place with great rapidity. It is, however, essentially a cheap soap, and is not adapted for toilet purposes. This should, if true, prove good news in America, where in New England and the Middle States it is calculated that 40,000,000lb. of the non-drying viscous grease are run into the rivers every year. The subject came up at the Farmers' Convention held recently in Boston, when it was pointed out that the wool grease might be saved, and utilised instead of European degras by the tanners. If M. Rohart can make a soap out of the wool grease, he ought to find plenty of occupation in America.

Mount Lyell, about seventeen miles north-east of Macquarie Harbour, on the west coast of Tasmania, is believed to be extraordinarily rich in gold. Its formation resembles that of the famous Mount Morgan in Queensland, and it is stated that some assays already made have yielded the precious metal at the rate of 164oz., 187oz., and 348oz. to the ton.

The celebrated fossil tree at Clayton, upon which a paper was read by Mr. Adamson at the recent meeting of the British Association, has been purchased by Prof. Williamson, F.R.S., for Owens College, Manchester. It is the most gigantic carboniferous fossil yet discovered.

The Egyptian obelisk, or Cleopatra's Needle, in Central-park, New York, is showing slight signs of disintegration, in spite of the paraffin dressing it received. It is now suggested that ultimately it may be necessary to inclose the stone in a light glass structure.

The Marquis Benzoni, accompanied by Count Savicoux, Major Piano, and a Modenese engineer, Sig. Salmitare, will attempt to penetrate Harrar by way of Assab. They were to start at the beginning of October.

The Canadian salmon, hatched at the South Kensington Aquarium last April, are thriving well, and many of the Indian fish lately imported seem to find their surroundings suitable.

At the Royal Victoria Hall, on Oct. 5, Mr. W. L. Carpenter will lecture on "What may be Done with a New Lantern"; Dr. W. D. Halliburton will discourse on "The Germs of Disease" on the following Tuesday; and on Oct. 19 Prof. Judd will lecture on "A Piece of Pumice-stone."

M. Lecoq de Boisbaudran has communicated to the Paris Academy of Sciences some interesting experiments on the "Fluorescence of the Compounds of Manganese subjected to Electric Effluvium in Vacuum." The fluorescence of some of the compounds of manganese is an extremely sensitive reaction, by means of which imponderable traces of this metal may be detected in natural or artificial substances which might otherwise be supposed to be free from its presence.

M. Ch. V. Zenger has recently brought before the Paris Academy of Sciences some notes on "Phosphorography Applied to the Photography of the Invisible." He has often observed that the bluish-green glow at night on the ice of Mont Blanc would affect a sensitised film, and he therefore concluded that Balmain's luminous paint spread over collodion might also be acted upon. The idea is not novel, but M. Zenger found that in a few seconds a photo-

graphic impression was produced, and that if the plate was removed from the camera and placed in contact with a dry sensitive surface, after the action had continued about an hour the object appeared in all its details as in the ordinary case of photographic impressions. He thus proved that images of objects invisible in the dark may be fixed by simple contact or by the photographic apparatus.

The *Mineralogical Magazine* and *Journal* of the Mineralogical Society, No. 2, contains a paper by Prof. T. G. Bonney on a rare rock from the Val d'Aoste, illustrated by chromolithographs of a couple of microscopic slides: it is a glaucophane-eclogite. Amongst the other papers there is a suggestion for a new classification of the hydrocarbons, and a useful account of the diatomaceous deposits in Skye.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. Passmore Edwards.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

STELLAR MAGNIFICATION — SPURIOUS STAR-DISCS—STAR-LIGHT.

[26307.]—Whenever the subject of stellar magnification has been discussed in these pages it has generally, in substance, been stated that stars are not susceptible of magnification, as contradistinguished from planets, which, though to the naked eye presenting no characteristics that enable one to distinguish them from the fixed stars, are nevertheless susceptible of magnification. This idea, presented to the mind of the struggling amateur (interminable are his woes!) must appear extraordinary to say the least: it does not appear plausible to him, that a telescope should be endowed with the faculty of distinguishing planets from fixed stars in order that it may magnify only the planets (for stars won't magnify); nor is it comprehensible to his mind that one is expanded into a surface with detail, whilst the other is converted into a spurious disc of a definite size, without detail however; this disc, though round and planetary in appearance, having no reference at all to the ultimate star, which is a point of no dimensions whatever! and which no magnification, however great, can give dimensions! Thus it is said. A very meagre attempt is, as a general thing, made to grease this bolus somewhat thoroughly so that it may go down easily and not grate too harshly; but, though the trusting student resists slightly, he, as a general thing, takes it in, and it glides down softly; but it scarcely ever digests—it never can be clear to his mind that any distant object viewed with a telescope is not magnified in the exact proportion of the focal length of the object-glass to that of the eyepiece. Now, why not acknowledge that this is certainly the case even with the star, that the star is as certainly not a point, that it presents a true surface, that the surface presented is $(500)^2$ times greater with, than without, a telescope magnifying 500 times, that with a sufficiently great magnifying power (would our atmosphere and our instrumental capabilities permit it) the surface of a star would present a disc not unlike that of the sun.

To make this clear to a person who has contended with the various conflicting peculiarities of the images of stars and planets, a few simple considerations will, I think, make them all very plain and perfectly harmonious. It is, of course, utterly hopeless to conceive the distance of the stars or to measure this distance with magnitudes such as those with which our minds are accustomed to measure earthly ones: we have actual figures which, within reasonable approximation, represent this colossal distance; but these figures represent no definite idea of the remoteness of the stars to a mind endeavouring to picture it for contemplation. It is conceivable though that no matter how large a sphere may be, it is possible to place it at so remote a distance that its dimensions may shrink to any assignable smallness. Let us suppose that a solar globe is withdrawn into space until its disc presents to the eye a diameter of 0·00001″, such a disc would, of course, present no sensible area to the unassisted eye. Would it in the telescope? Let us see! Since a telescope increases the angle which an object subtends at the eye, directly in proportion to the magnifying power, a telescope capable of magnifying 500 times on being directed to this object would present a disc having a diameter of $500 \times 0{\cdot}00001'' = 0{\cdot}005''$. It appears then that after having magnified the object or the angle which it subtended in the first place 500 times, it still presents a surface that is not recognisable as such by the eye (leaving for the moment out of consideration the spurious star disc, which is an optical phenomenon inseparable from focal images). Hence, what appeared as a point to the naked eye appears still to be a point in the telescope, notwithstanding that it has really been magnified 500 diameters. There would be no perceptible variation in this result if we increased the magnifying power still further to 1000 diameters, when the diameter of the true disc would be 0·01″, representing an undiscernible area, vanishingly small and comparable only to a point, though in truth it has definite dimensions, for it may readily be seen that if the magnifying power be still further increased to, say, 100,000 diameters, our distant globe would then subtend an angle of 1″ and would be visible in a telescope whose object-glass is of large diameter as a small, a very small, disc; but such a magnifying power being—with our present facilities, and with the obstacles that lie in the way of overcoming the image-annihilating properties of our atmosphere—impossible, we may never hope to see the true disc of a fixed star.

If, now, instead of a star we consider the effect of magnifying power applied to a planet, say Jupiter, which at opposition subtends an angle of 44″, an angle which, though many times greater than that of the star, when received on the background of the sky does not sensibly differ from a point in apparent size, and as far as any impression it will make on the retina is concerned, will not differ in its effects from the impression left there by a star subtending 0·00001″.

I exclude from consideration the tendency to enlarged retinal images from superior brilliancy, and hence assume that the quantity of light from both sources is the same. This would result then in an apparent equality in size of Jupiter and a fixed star giving the same quantity of light, notwithstanding their very considerable difference in angular diameter. Though the difference between these diameters is too small for retinal perception when received with the naked eye, this is, however, not the case when it is assisted by the telescope, for when we magnify 44″ 500 times we obtain an angle of more than six degrees, which will allow ample space for possible detail. We have thus applied the same reasoning to both planet and star, and have obtained consistent, comprehensible results: the planet from a point has expanded to a wide disc six degrees in diameter, the star, however, has remained an apparent point, though we have truly magnified the angle under which it is seen; showing that an object may be so small, or rather subtend so small an angle, that a large multiple of that angle may still be a small quantity.

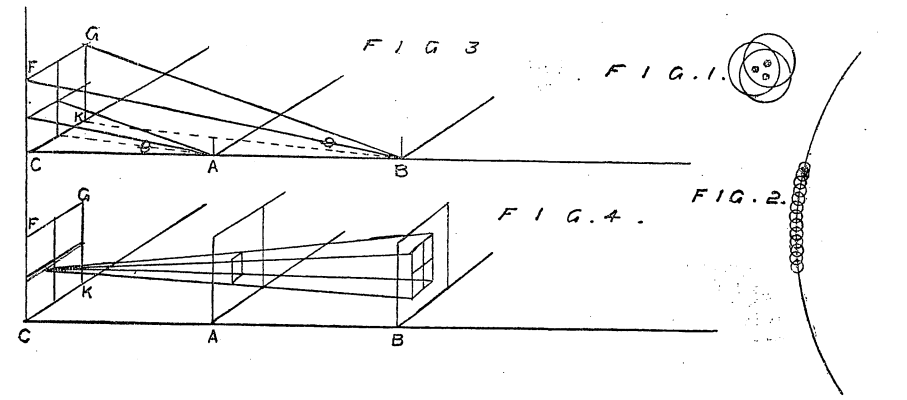
Thus far we have left out of consideration the spurious star disc, which, as is well known, is an inherent property of every image-forming instrument: it is a necessary part of the very nature of light that every point in the object is represented by a minute disc in the image. A star then being as far as dimensions go, when viewed either by the eye or through a telescope, a mere point, will be represented in the image by a disc which the eyepiece may magnify at will, the disc being formed by the o.g. or mirror; the disc then is of determinable dimensions for every o.g. or mirror, depending only on the aperture and decreasing as it increases. If three points be conceived in as close proximity as one can see them in any object, yet distinct and separate, such points being elements of detail of the surface of the object, an image of them formed by an o.g. will consist of three overlapping discs whose centres will be the positions corresponding to the three elementary points (see Fig. 1). It is clear therefore that the spurious disc of every point in an object has a direct tendency to blot out, or at least to modify, the images of neighbouring elementary details, and it follows from this that the smallest possible detail that may be observed in an image must be of the size of the spurious disc; whence it follows that masses of detail cannot possibly be viewed, being of a less size in the object than the focal image of a single point, consequently all detail observed in an image must be formed out of elements of that size, all of them more or less overlapping the discs of numerous elements in the immediate neighbourhood. It thus becomes manifest that the smaller the spurious disc the greater will the image resemble the object, the greater will be the quantity of detail that will be formed in the image, and the greater in general will be its usefulness. Such a decrease in the size of the spurious disc can only result, however, from an increase of aperture or diameter of the image-forming surfaces, and hence the value of large telescopes for the production of images in the greatest possible degree resembling the objects they portray.

A very striking comparison may be useful here to perhaps render the formation of images by aggregation of discs clearer to some. Let it be supposed that an artist is engaged in the production of a mosaic. It will be quite obvious that he will be better enabled to reproduce the original, the smaller the separate pieces are, out of which he purposes to produce the image—and that there are matters of detail in the original, for the production of the image of which his pieces will be too large; and, further, that no matter how small these separate pieces may be, the image can never be identical with the original, since its elements will always be smaller than those of the mosaic can ever be. In the comparison no account is taken of the overlapping feature of the spurious discs.

We have seen that a star disc or the disc formed by any point on a planet's surface is the image of a point which, if it were accurately reproduced, would be in the centre of the spurious disc; this point then is the limit to which a disc would at length diminish if the o.g. were indefinitely increased in diameter. It is manifest therefore that the image of the limb of a planet being formed of discs, the centres of which are the places corresponding to similar points on the limb of the planet, must be too large in diameter by exactly the diameter of the spurious disc, which extends beyond the true boundary of the image by its radius; it becomes necessary, therefore, in making measurements of planetary diameters, or even details, to make allowance for the redundancy in the image in order to obtain the true value sought. (See Fig. 2.)

And now a word or two concerning the brightness of stars. Assuming non-extinguishable properties for the medium filling space beyond our atmosphere, a star shines with undiminished splendour intrinsically, be it ever so remote in the recesses of space; that is to say, for the same angular area of true star disc, the same quantity of light reaches us, as would reach us from the same angular area were the star any distance, however near or remote, say at only a million miles, or only a thousand miles, where its disc would subtend an angle of nearly 180 degrees.

This seems improbable at first sight; but a little consideration will establish this truth firmly. Imagine a plane C A B (see Fig. 3) on which at C there is erected a high and wide surface C F G K; let an observer at A note the extent of surface included within a certain solid angle θ, then having retired to the position B just as far again from the erect surface, let him again note the area included within the same angular space, and it will be observed that having doubled the distance from C, the extent of surface visible in the solid angle will be quadrupled, that is, the areas included within a certain angular subtense are proportional



to the squares of the distances. In the above diagram, supposing the surface C F G K to be a luminous one, we will obtain four times as much light included in the angle θ in the position B as will be obtained in the position A; for, as we recede from A the squares in the diagram, into which the surface C F G K is divided, will contract in apparent size until when we reach B, four squares together with all the light they radiate towards B will be included in the angle θ, which only included one square in the first position; it follows then that the intrinsic brightness of the surface has increased fourfold in doubling the distance. But the quantity of light that will fall on a given surface will also diminish as the square of the distance as we recede from it, as will be seen by inspecting Fig. 4, where a point in the erect surface is shown to radiate in the direction of our observer; clearly the little square in the position A is one fourth of the projected surface at B, and hence the light at B being spread out over four times the area at A will for each element of surface be four times less bright; hence, having increased and diminished the brightness of a source of light, in the same proportion by doubling the distance, its intrinsic brightness cannot have changed at all; it is obvious therefore that the intrinsic brightness of a surface does not change by reason of a change of distance. The observer in moving from A to B has condensed the light of four squares into one, but he has thereby also diminished the brightness of each element of surface, and hence of each square to one fourth its brightness at A, so that the quantity of light entering his angle at B remains exactly the same as that at A.

Applying this result to the stars we learn that viewed from the earth a star is intrinsically as bright to us in the remotest depths of space, there, where the sounding lead of the star-gazer has never penetrated, where its glorious radiations in their almost infinite journey through the endless vistas of space become so enfeebled, that when they reach our earth, a mere mote in the glare of another star, neither eye nor telescope can gather up a pencil whose converging intensity is sufficiently powerful to excite an optic nerve, as it would be were it no further away than the moon—*i.e.*, the same angle including a varying extent of star surface will, however, receive the same quantity of light at all distances; but consider what a small angle we have been dealing with, and the necessarily small quantity of light it represents. I have for illustration assumed the angular diameter of a star to be 0·00001″. May we not, by simply enlarging this disc, produce a sun of no mean splendour, without altering its intrinsic brightness, or even its distance, one particle? Let us try. Our sun is about 32′ = 1920″ in diameter, then $\frac{(1920'')^2}{(0{\cdot}00001'')^2}$ = the number of times the sun's area surpasses that of, say, a star of the first magnitude as seen from the earth, then having ascertained that this equals 36,864,000,000,000,000, we deduce the result that the star, were it recalled from space until its diameter grew to that of the sun (when their discs would be equal in diameter), would be 36,864,000,000,000,000 times as bright as a star of the first magnitude.

Of course, this result is based on the purely arbitrary assumption that a first magnitude star subtends an angle of 0·0001″, the truth of which I can by no means vouch for, though no one can say it is neither greater or less. It is, in fact, one of the great problems of astronomy of the future to determine this quantity, and though our present means of attacking the problem are to all appearances inadequate, there can scarcely be a doubt that the future will develop new means, perhaps a new science to cope with it, and that in time the unknown measure of the unseen, the true star disc, will be determined with accuracy, and lead on to renewed speculations in the vast outer expanse of the ethereal wilderness to which the first magnitude star is but the gateway.

St. Louis, Mo., Aug. 30. **Wm. A. Haren.**

T CASSIOPEIÆ.

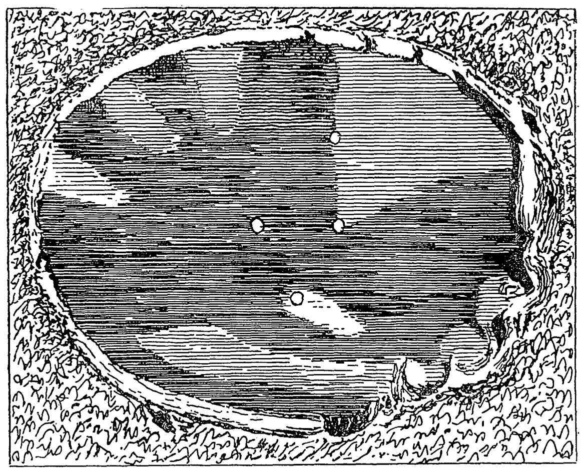
[26308.]—WITH reference to Mr. Holmes's remark about this variable, I may tell him that the star will not be due at a maximum until Dec. 26 of the present year. Observations are, therefore, desirable, as the coming maximum may prove to be a bright one. At the maximum of last year, Mr. Baxendell estimated the magnitude only 7·8.

J. E. Gore.

PLATO.

[26309.]—STARS, double, coloured, and variable, have been for long the rage in your columns. Lunar observations are comparatively unfrequent, save when Mr. Peal expands that most interesting theory of his, or Mr. Elger delights us with one of his splendid drawings.

Time was when views of Plato and its curious interior were frequent; but years have elapsed

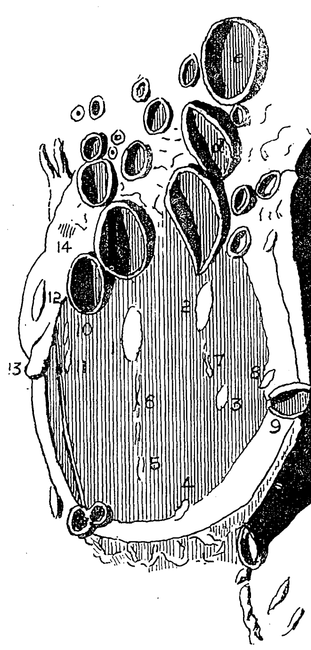


since the last appeared. I therefore take the liberty of sending a sketch of the floor as it appeared to me with an 8½in. Calver mirror on the night of the 17th. Would some observer, blessed with better air and a more accurate pencil than I, tell us what he sees of Plato? I appeal especially to Messrs. Elger and Franks.

Llanelly. **Arthur Mee.**

CLEFT IN CAPUANUS.

[26310.]—THIS important ring-plain contains a few details on its floor which seem to have escaped the attention of observers generally. Neison says it appears level. I observed it on Sept. 8, 1886, for about one hour, when the moon passed across a



gap between two buildings. Though very low, the air was good. The cleft η, along the W. portion of the floor, was very plain. It runs in a N.—S. direction from the foot of peak 13 to the double crater B on the N.W. border. This cleft seems to have been first seen by Mr. E. Stuyvaert, of the Brussels Observatory, on Nov. 29, 1884; 1 is a mound, the largest on the floor, given by Schmidt; 2 another mound, somewhat smaller, but not very difficult; 3 and 5, two other mounds, seen with difficulty. Between 1 and 5, and 2 and 3, are two irregular ridges, 6 and 7, which seem to connect the mounds. Moreover, the plain is not level, as depressions are faintly seen here and there; 4 is generally given as a craterlet—it looked more like a hillock on the present occasion; 8, a hillock; 9, a crater on the E. wall; 10 and 11, two hillocks; 12 and 13, peaks on the W. wall; 14, a slight depression on the S.W. wall. **C. M. Gaudibert.**

STATIC ELECTRICITY.

[26311.]—" A., LIVERPOOL " (26284, p. 85), wishes me to explain some points he refers to in my " Electricity: its Theory, Sources, and Applications." I wish that he, or anyone similarly disposed, would not content himself with merely quoting a few words upon which explanation is desired. With every paragraph numbered in order to facilitate reference, it is very easy to indicate the exact position of the words, instead of leaving me to hunt them out. My writing is generally studded with suggestive sentences, which may be either left to set the reader thinking, or which may be found developed and worked out elsewhere. My chapter on " Static and Frictional Electricity " occupies 77 pages, and I do not know whereabouts the words quoted—" static electricity is understood to mean that produced by frictional means "—may happen to occur. But I am quite sure that this definition is not " laid down " by me anywhere, either as held by myself or suggested to my readers. In § 20 of my second edition, I say distinctly, " Static electricity is, however, a misnomer: it has no existence; all the phenomena are due to static strains, but there is always a gradual loss, called *leakage*, which is, however, the current due to the actual conductivity of all circuits; and every motion set up by so-called 'static' electricity implies a transfer of energy and action occurring in a field of force set up in the form of strains in the particular 'inductive circuit' in which the motions occur."

It is rather hard to take a sentence or two out of a systematic book through which a continuous train of theoretical explanations is worked out, and deal with those sentences apart from the whole train of thought. But this becomes more difficult when the sentences dealt with form no part of the author's own ideas, but are even statements of something which he considers imperfect or erroneous, and then proceeds to correct.

Now " A." quotes me as laying down " that static electricity is only to be found on the external surfaces of bodies," and asks me to explain, on that view, certain experiments which he details. Well, as he does not supply page or section, I refer to the Index, and find " Surfaces and Electric Distribution," p. 62. There, in section 81, I say, " Most electrical works occupy many pages and numerous illustrations to show that *static electricity is formed and exists only on the surfaces of bodies*." I add that Faraday made numerous experiments to prove " that the force is to be found only on *external* surfaces." Then I go on to say that these old theories were destroyed " as soon as it was found that electricity could be placed upon an *internal* surface," which is just what the experiments stated by our friend go to illustrate, but which also has been known to everyone this many a year.

My own statement is: " The static actions of electricity are manifested at surfaces, because these are the boundaries of the field of force in which the electrical charge exists. The law and its reason are obvious—electricity in its static manifestation *must be formed only on surfaces* where the polarised circuit passes from one body to another." In fact, the old theories taught that a charge of electricity was put on the surfaces, as a coat of paint might. The theory (which I was plentifully abused as a heretic for maintaining years ago, but which is now adopted by pretty nearly everyone) is that the (imaginary) electricity is not on the surfaces at all, but in the intervening di-electric, air, glass, &c. If " A." will read pp. 72—75 on " Inclosed Spheres and the Leyden Jar," he will find all his experiments explained, and the whole subject fully worked out; but I may add that he appears to have made a discovery. He says: " I find that if any part of a piece of glass be rubbed, the whole of it is electrified simultaneously." Now, if he means only that the whole surface will manifest some small electrification, no doubt he is right, because the glass surface will conduct slightly; but it is a well-known fact that we can use a rubber to write or make marks, upon a glass surface which are invisible, but if we dust a fine powder on the surface, it will adhere to those marks, and render them visible. Of course, also, if a glass tube is rubbed externally, the inside is electrified (with a charge opposite to that of the external surface): the reason is obvious, on the principles which I have fully explained. **Sigma.**

CONCERNING CHAMBER ORGANS, HARMONIUM PLAYING, AND HOME STUDIES.

[26312.]—I HAVE read the letter by "Country Solicitor," in last week's issue, with not a little interest; and as my name appears therein, in reference to more than one subject, I may be pardoned for essaying a short reply.

It is almost needless to remark that I feel highly gratified at his kind assurances that my "Notes on the Chamber Organ" afford him and others pleasure, and are of "the deepest interest" to him, as he courteously puts it.

Firstly, with reference to his opinion of the Programme I ventured to include in my letter (26103), I can assure "Country Solicitor" that no one of my guests, on the occasion of its performance, complained that so much of the "music of the future" was included therein; and I only wish "Country Solicitor" had been with us on that delightful evening. Does he know the chief numbers from Wagner's pen which were performed —viz., Isolden's Liebestod; Walther's Preisslied; and the Steersman's Song, from the Fliegende Holländer? From his rather slighting remarks I should guess not. If he has amongst his friends a first-rate violinist, I strongly recommend him to obtain copies of the instrumental pieces; but let them not be judged by the way even a good amateur would render them. On the occasion of their performance at my house, the violin was in the able hands of Herr Ernst Schiever, leader of the Richter Orchestra. "Country Solicitor" must be aware of the difficulty of securing variety when one arranges numerous programmes; indeed, one is sometimes so much at a loss for something new, that one wishes one could really get a leaf or two from the veritable *music of the future*. There are vast stores of classical compositions at one's disposal, but few pieces that readily lend themselves to the humble means of rendition at an amateur's disposal. Personally, I always feel there is a danger of grossly misrepresenting or misinterpreting the thoughts of the great composers; and the old saying, "fools rush in where angels fear to tread," comes with unpleasant force to the mind when one is contemplating the performance of a movement from any of the great Symphonies or other complex orchestral works. This consideration has always had great weight with me; and has led me to prefer music specially written for the instruments at my disposal, or such compositions as readily lend themselves to a chamber treatment.

I have read with much interest the programme so kindly given by "Country Solicitor"; and, while one can find no fault with the selection therein displayed, one cannot help feeling disappointed that the true king of instruments—the violin—took no part in its rendition. Now, seeing that the programme I have already given has so greatly offended "Country Solicitor's" musical taste, let me give one other example from my bundle of programmes, in the hopes that it may disabuse his mind of the impression that my mind is lost in admiration of the "music of the future."

"The meaning of song goes deep. Who is there that, in logical words, can express the effect music has on us? A kind of inarticulate, unfathomable speech, which leads us to the edge of the infinite, and lets us for moments gaze into that."—*Carlyle.*

PROGRAMME. PARTE YE FIRSTE.

OVERTURE (A Midsummer Night's Dream) Mendelssohn.
Done on ye Organ alone.

CREATION'S HYMNE... ... ... Beethoven.
For ye Contralto Voyce with ye Organ.

FANTASIE ... (Hungarian Airs) ... ... Liszt.
For ye Pianoforte alone.

DUETTE ... (Marriage of Figaro) ... Mozart.
By ye Pianoforte and Organ.

LARGO ... (Sonata in D major) ... Beethoven.
Played on ye Fiddle, Bass Viol, Pianoforte, and Organ.

AVE MARIA ... ... Gounod.
For ye High Voyce, with Fiddle, Pianoforte, Organ, and ye Horn sparinglye.

PROGRAMME. PARTE YE SECOND.

ITALIAN CONCERTO (F major) ... ... Bach.
Allegro Moderato—Andante—Presto.
On ye Pianoforte alone.

ANDANTE CON VARIAZIONE (Grand Septuor) Beethoven.
Rendered on ye Fiddle, Pianoforte, and Organ.

SONATA YE FORTH ... ... Mendelssohn.
For ye Organ alone.

AVE MARIA ... ... Schubert.
Given on ye Fiddle, Bass Viol, Pianoforte, and Organ.

ANDANTE RELIGIOSO ... ... Lefébure-Wely.
On ye Horn, two Bass Viols, and Organ.

DUO DE CONCERT (Aida) ... ... Verdi.
On ye Pianoforte and Organ.

It will be seen from the heading given that it is also my practice to append to the programmes some quotations having reference to music. The practice is a good one, and I am glad to see that in this respect "Country Solicitor" and myself agree.

I regret to hear that any remarks of mine anent the Chamber Organ, has "struck sorrow into the hearts" of himself and others who may have a limited purse, and, accordingly, cannot afford to purchase a Pipe Organ; but it surely is not my fault that a properly appointed Chamber Organ is so costly an affair. To those who can neither afford to purchase such an instrument nor contrive to make one, I say let them be content with "Country Solicitor's" favourite, the Mustel. Indeed, if "there is as much music in it" as his friend said there was in his church organ of some fifty speaking stops, and more power of expression in it than in a Pipe Organ of any kind, what need is there for any opinions of mine, in favour of the true Chamber Organ, to "strike sorrow into," or even disturb the heart of "Country Solicitor"?

His Mustel must be far superior to my Chamber Organ; yet, strange to relate, I do not envy his instrument. I have never yet seen or heard a Reed Organ which I would care to possess, and I fear the same sentiment will be found in the breasts of all others who love the Pipe Organ, and are fortunate enough to possess good instruments.

I disagree entirely with "Country Solicitor" in the following remarks:—"In even a moderate sized drawing-room a Pipe Organ seems entirely out of place. I even make bold to say that the organ proper is fit only for a cathedral or other building where the 32ft. pedal notes have room to speak." The contrary is really the case so far as the true Chamber Organ is concerned; and I most unhesitatingly affirm that a properly constructed Pipe Organ, schemed on the lines set forth in my "Notes on the Chamber Organ," is in all respects perfectly adapted for a moderate sized drawing-room. Space will not permit me to enlarge on this subject here; but I may just remind "Country Solicitor" that there is no necessity for a Chamber Organ to produce the 32ft. notes. With the 16ft. pitch, the bass is as deep as the lowest bass of the orchestra, and surely that is sufficient for all practical purposes.

Again, I disagree with "Country Solicitor" when he says:—"After all is said and done, even Mr. Audsley must be contrained to admit that even his pet organ is a soulless intrument, devoid of all expression." Where have I acknowledged that the pipe-organ is "a soulless instrument, devoid of all expression"? I have admitted, and do admit, that the organ, as usually made, is *deficient in powers of expression;* and one purpose, as will be clearly seen from the instalment in this issue, of my "Notes on the Chamber Organ," is to show how *increased* and, indeed, *satisfactory powers of expression* may be given to the Pipe Organ. The *portamento*, *sforzando*, and certain subtle *nuances*, or refined effects of light and shade are certainly difficult on the best appointed organ; on the ordinary type of Chamber Organ they are impossible. But, on the other hand, they are still more difficult on Reed Organs which are fitted with a pedal department; for the blowing of such instruments has to be done by hand or by some motor, just as in the case of the Pipe Organ. It is, accordingly, only on the Reed Organs with manuals and no pedal department that the maximum of expression can be obtained. Such one-ply instruments must always be deficient in grandeur, at least they altogether lack the dignity and impressiveness that the Pedal stops impart.

Now the crowning glory of the true Chamber Organ is the magnificence of its bass: this is of untold value in all varieties of *ensemble* music. In short, for all purposes of chamber music the true Organ is unrivalled by any instrument of the Harmonium type. I wish I could let "Country Solicitor" hear the effects produced by my Chamber Organ, either in such a solo as the Overture to "A Midsummer Night's Dream," or in such a concerted piece as the Largo from Beethoven's Sonata in D major; for if he once heard the effects, he would never consider the Pipe Organ "a soulless instrument, devoid of all expression." If he will communicate direct with me, I shall be happy to give him an opportunity of judging whether *his opinion* of the Pipe Organ or *mine* is the correct one. I presume he often pays a visit to London.

I am sorry "Country Solicitor" does not place music on higher ground than as a simple "recreation." I give it credit for being one of the most elevating and refining agents which can be brought into our high-pressure daily life, and within the confines of the home circle. I may be wrong in this, as in many of my other beliefs and opinions; but if I am, I certainly do not desire to be convinced of my error. **G. A. Audsley.**

Devon Nook, Chiswick, W.

[26313.]—THE borrowed Quint of $10\frac{2}{3}$ft. mentioned by your correspondent is not an example to be followed. The fifths are *tempered*, and the acoustic note comes on and off in great waves of sound. That is my experience at St. Mary's, Denbigh, where the experiment was first tried (February, 1884).

The Great Quint is useless and ever offensive in the upper range unless accompanied by an actual 32ft. stop. For the upper range the best way is to borrow from the Bourdon, beginning at the CCC pipe, thus getting the *actual* 32ft. note as at St. Mary's, Denbigh. For the bottom octave 12 truly tuned pipes should be used. This method was advocated in my "Modern Organ," 1883 (invented 1881), and shown in my "Inventions" organ.

Denbigh, 20th Sept. **Thomas Casson.**

SPECIFICATION OF ORGAN, ST. MARY-LE-BOW, LONDON, E.C., BY J. W. WALKER AND SONS.

[26314.]—GREAT ORGAN (COMPASS C C TO A IN ALTO, 58 NOTES).

	Ft.	Pipes.
1. Double open diapason, metal, to tenor C, lowest octave, wood stopped	16	58
2. Open diapason, metal	8	58
3. Horn diapason	8	58
4. Wald flute and stopped bass, wood	8	58
5. Principal, metal	4	58
6. Harmonic flute, metal and wood	4 tone	58
7. Twelfth, metal	$2\frac{2}{3}$	58
9. Mixture (3 ranks), various		174
10. Trumpet	8	58
		696

SWELL ORGAN (COMPASS C C TO A IN ALTO, 58 NOTES).

	Ft.	Pipes.
1. Double diapason, wood	16 tone	58
2. Open diapason, metal	8	58
3. Echo Gamba	8	58
4. Vox Angelica, tenor C, undulating with No. 3	8	46
5. Stopped diapason	8 tone	58
6. Principal, metal	4	58
7. Spitz flute, wood	4 tone	58
8. Fifteenth, metal	2	58
9. Mixture (3 ranks)	various	174
10. Horn "	8	58
11. Oboe "	8	58
12. Clarion "	4	58
		406

CHOIR ORGAN (COMPASS C C TO A IN ALTO, 58 NOTES).

	Ft.	Pipes.
1. Salicional, metal	8	58
2. Dulciana, metal	8	58
3. Lieblich Gedact, wood	8 tone	58
4. Gemshorn, metal	4	58
5. Flute, wood,	4 tone	58
6. Piccolo, wood	2	58
7. Clarionet and bassoon, metal...	8 tone	
		348

PEDAL ORGAN (COMPASS CCC TO G) 32 NOTES.

1 Open diapason, wood	16	32
2 Bourdon	16 tone	32
3 Mixture	12 tone	32
4 Principal	8	32
		128

COUPLERS, &C.

1 Swell to Great	4 Great to Pedal
2 Swell to Pedals	5 Choir to Pedals
3 Swell to Choir	

Three composition pedals to Great; three ditto to Swell; Tremulant to Swell.

SUMMARY.

	Stops.	Pipes.
Great organ	10	696
Swell	12	800
Choir	7	406
Pedal	4	128
Couplers	5	—
Total	38	2030

The case of the organ is of handsome design, with two frontages of gilt speaking pipes, facing south and west. **E. R. Dale, F.S.Sc.**

EARTHQUAKES AND VOLCANOES.

[26315.]—IT is well known that before an earthquake or volcanic eruption takes place there is a strange stillness in the atmosphere, an oppressive something that can be felt, which has led people in all countries and at all times to believe that the volcanic force was the cause of it. Only to-day we find writers accounting for long drought by volcanic agency. They have found that there is a connection between the atmospheric changes and volcanic action, but have mistaken the effect for the cause.

Say, for instance, that the barometer rises $\frac{1}{2}$in.

over an area of 5,000 square miles, the pressure on that area is increased by, in round numbers, 2,130,000,000 tons. If a wave of atmospheric pressure passed over a country in such a way that over the eastern part the barometer were first ½in. lower than in the western half, and then ½in. higher, the effect would be as though a mass of hundreds of millions of tons were shifted from the Western to the Eastern half. If the mercurial column rises 1in., it corresponds to a weight of 650lb. to each square foot, or about 850,000 tons on each square mile of surface. That such a strain must be an important factor in earthquake phenomena must be very evident, but it will not account for volcanic activity. Another agent that may be mentioned is the rise and fall of the tides, which may play a more important part even than the atmospheric pressure. For atmospheric pressure is so distributed that though the weight of air is constantly changing, there are no sharply defined lines, which separate regions of less density from regions of greater density. It is otherwise with the sea along a shore line. Here the sea acts with constantly varying pressure, as its level changes on the seaward side of the shore, while on the landward side of the shore line there are no such variations of pressure. "It has been shown by an American writer that if with a tolerably straight shore line 500 miles in length, and that along this shore line a region of ocean 100 miles broad rises through a height of 3ft. under the combined action of sun and moon raising a tidal wave, and favouring strong winds urging the water shorewards, that 50,000 square miles of sea-water, 3ft. deep, are added as so much dead weight to that part of the earth's crust which underlies the seas along that shore. Each square mile contains about 3,000,000 square yards, or 27,000,000 square feet, the additional weight corresponds, then (as the added layer is 3ft. deep) to 50,000 times 81,000,000 cubic feet of water, each weighing 64½lb., or to 116,000,000,000 tons."

If pressure alone would cause an earthquake, we have in these two forces energy enough to bring about the most stupendous shocks. Pressure alone is not enough; other factors enter into the case, and are all important to the successful effort which terminates in an earthquake.

The question of how earthquakes and volcanoes are caused must be put to nature herself, and in an orderly manner, and must be answered with like order, and I think that we have an amount of information that will from inference enable us to speak with certainty on this point:—

1st. What are the products of volcanoes?
2nd. Where is volcanic action most active?
3rd. When is volcanic action most active?

Taking the questions in order, we find that the products of volcanoes are lavas, which are composed of silicates of alumina, potash, soda, lime, iron, &c., in varying order, forming acidic or basic compounds, as the case may be; the volcano also emits sulphur, water, &c. The energy necessary to melt silicates such as our modern lavas are is very great under ordinary conditions. But when we come to consider that the fusion point would be raised by the pressure, then is the amount great indeed.

It is found that volcanic energy is most active on the coast lines, and that with one or two exceptions all active volcanoes are near the coast.

Volcanic action is most prevalent and active during atmospheric disturbances, and when tidal pressures and atmospheric influences act together it has also been noticed that earthquakes occur in greater numbers during the winter months (or when the earth is nearest to the sun.)

To apply any one factor singly would be unreasonable, seeing that we know the results of volcanic action. For instance, pressure alone gives great heat, but at the same time makes the material acted upon harder to melt. But suppose we apply them as they are, then we get with but a slight effort all the elements necessary for an earthquake or a volcano. Thus the water percolating into the earth finds its way down to great depths, becomes heated, and takes up in solution great quantities of mineral matter. This water sometimes comes to the surface as hot springs, but the greater portion of the deep-seated water is retained under ordinary conditions. The boiling point is raised in proportion to the pressure; it cannot flash into vapour, but is retained in a liquid state, and is under such conditions as makes it a very powerful solvent and agent in bringing the rocks into a state of hydrous-fusion or hydrothermic fusion. On examining a lava stream we find that it is not so much a molten mass as a partially melted rock flowing by means of its contained water; it is in a state of hydrous-fusion only, and not, as is generally supposed, like molten metal. The mud that fell in New Zealand, the mud and water, or ash and water that buried Pompeii, and many other cases show the action that water takes in these convulsions. (That water does find its way into the earth, and is there heated, and carries solutions of minerals, is, or rather was, beautifully shown in the white and pink terraces at Tarawera. The silicious terraces being the product of this volcanic water, it came to the surface with its solutions, there undergoing evaporation, deposited the silica, &c.) The water from the lakes of the Tarawera district found its way into the earth, became heated, dissolved the silica, which is slightly soluble in hot water, and brought it to the surface, evaporation disposed of the water, and left the silicious materials, which, owing to the configuration of the ground, formed terraces, which were coloured by metallic salts. The same action goes on to-day in Iceland, around every geyser, the deposition of what is known as silicious sinter. But the water that we have chiefly to consider does not reach the surface in this condition; it is retained in the earth in the form of a liquid. It cannot flash into steam, the pressure being too great. By a coincidence it happens that the tides are in the spring. This would add a greater strain on the coast line. The energy generated by such strain, acting with the internal water of the rocks, brings them into a state of hydrous-fusion. The forces that caused the spring-tide, acting upon this imprisoned semi-fluid, would draw it in a given direction. Now, if the atmosphere were under such conditions as we have already considered, greater force would be placed upon the mass. If the crust overlying is strong enough to resist this tension, we have no knowledge of volcanic activity. But if a line of weakness anywhere occurs the pressure is at once relieved, the water flashes into vapour, and owing to the great pressure under which it was generated, it will carry everything before it. Such is the evidence of the past and present volcanoes. The ring of Somma was blown out with a crash, and a great amount of water and mud buried Pompeii. The side of Tarawera was served the same way. These old volcanic lines being the lines of weakness in a country, offer the least resistance to the forces at work, and are, therefore, liable to activity under the conditions mentioned at any time.

Where the earth's crust offers sufficient resistance, these forces will not be suspected; but that they are ever active is well shown in what is geologically known as metamorphism. The energy has been expended in rearranging the materials of our rocks, bringing igneous masses into partial fusion, and reconstructing them as gneiss, &c.; turning mud banks into slates, granites, and gneiss, and chalks, limestones, &c., into marbles.

Such is some of the work done by these mighty agents, water and pressure, which, acting over large tracts of country, have given rise to regional metamorphism, which may be taken as a measure of energy distributed over large surfaces with a resisting superincumbent strata. The same forces where the overlying strata are weak and break away give us volcanoes, earthquakes, and contact metamorphism. **P. H. Marrow.**

PERMANENT WAY.

[26316.]—THE following particulars of a new system of permanent way which has lately been brought out in this country (Prussia), and patented throughout the civilised world, may perhaps be of interest to the readers of the ENGLISH MECHANIC.

The perishableness of timber sleepers and their almost utter worthlessness after service, and the lightness and instability of metallic sleepers hitherto in use, as also their probable early deterioration and ultimate valuelessness, except as old iron (after, perhaps, as brief a lifetime as their fellows—the timber sleepers), has given rise to the idea of using old rails, unfit for further service as such, as sleepers for all kinds of permanent way.

It is, of course, a fact patent to everyone, that very large quantities of rails are taken up and replaced by new ones in all our railways, from year to year. How large the quantity may be, I cannot say; but I should think, on the whole system of British railways, scarcely less than 130,000 tons per annum, as they are considered, I think, unfit for further service after serving for the passage of 50,000,000 tons of rolling weight. These rails are generally sold, against public tender, at a very low price as compared with their original cost—perhaps at not more than 40s. per ton on the average.

On the other hand, it is probable that not less than 1,000,000 of new timber or other sleepers are required per annum to replace such as are unfit for further service, and this, of course, at an enormous cost and great inconvenience, not only as regards their bare provision, but in breaking up the old and laying down the new ones.

I am not sufficiently provided with particulars and details as to these matters in order to state other than approximate figures; but it is, I should say, undoubtable that the direct cost per annum in maintenance of sleepers on the lines of the United Kingdom is scarcely less than from £8 to £10 per mile, whilst the loss in value of material (old as compared with new), must be quite as much again, in addition.

Now, if, as is here proposed, the old rails were used as sleepers, it is evident that, whilst the cost of maintenance would unquestionably be very much reduced, the loss in value of material would be almost nil; as, in the first place, such sleepers would have a lifetime of, perhaps, 80 or 100 years, and even then be worth, or nearly so, their original old-iron value; and, secondly, the loss in value of material as now used accruing every twelve to fifteen years, and sometimes very much oftener, in replacing old with new, would practically be all but eliminated.

The 130,000 tons of old rails exchanged from year to year would, in the course of from fifteen to eighteen years, suffice to replace all the transverse timber sleepers at present in use with those of old rails, from which period onwards a positively permanent way would be provided, requiring but very little attendance, and possibly no renewals in the shape of sleepers for, perhaps, fifty, or even one hundred, years to come.

The invention assumes the cutting of the rails into lengths of 7ft. 6½in. for intermediate, and 8ft. 2½in. for joint, sleepers; so that, as a rule, one rail would yield four single lengths, or two compound sleepers.

They would be laid flat on their sides, head to head, forming thus a bearing surface of from 10in. to 11in. in width, according to the depth of the rails. At points corresponding to gauge of line, the heads and flanges would be notched or recessed to within ⅛in. or $\frac{3}{16}$in. of webs, for taking in properly-fitted and bevelled iron packing plates (bevelled to secure cant of one to 20 for the main rails) of about 10¼in. by 8⅝in., and averaging ½in. thick, with raised edges on the two sides parallel to track. On these packing plates (which correspond in the one dimension to the width of the compound sleeper) the main broad flanged rails (or chairs, where these are used) are placed, and the whole secured by four 1in. bolts, a nut passing through both sleeper members, the packing plates, and the clip plates, and thus binding the two members of the sleeper, and all the other parts, permanently and firmly together.

Accidental gauge alterations, or spreading of the rails, is absolutely prevented by the recesses planed out in the sleepers, and by the clip plates abutting, on the one side against the raised edges of the packing plates, and on the other against the rail flanges, suitable forms of clip plates being of course provided for curves.

The joints are of the suspended class; the sleepers being in these instances 2ft. 1⅝in. apart from centre to centre (the intermediates being 3ft. 5¼in. apart), and well fished with strong, angular fish plates reaching from sleeper to sleeper, notched to fit and to abut against them and held by four strong bolts.

The bolt holes are throughout on the one or head side: and the bolts are provided under their heads, with corresponding lugs, so that all turning or movement is avoided.

The weight of such a compound sleeper will ordinarily be about 3cwt. or 1cwt. more than ordinary oak sleepers, and 2cwt. more than the usual light and flimsy metallic transverse sleepers now in use.

There will be no difficulty it is confidently apprehended in packing such sleepers, less, in all probability, than with timber ones, owing to their greater stability and steadiness, and very much less, as a matter of course, than with the light, hollow, and ever-shifting metallic sleepers now employed, and whilst sufficiently heavy to insure perfect repose, there will be elasticity enough for all purposes of traffic and safety of rolling stock.

Although originally in the main intended for single-headed, deep-flanged rails, resting immediately on the foot or packing plates, as described, the same general arrangement, with very slight modifications, is equally adapted for chairs and ordinary double-headed rails, the sleepers made of such being probably even better than with those having very broad flanges.

The cost of preparing the sleeper for the reception of the packing plates is very little—at most, 10d. per compound sleeper, in the matter of cutting, planing, drilling, and fitting, at any of the railway workshops, and when carried out on a large scale would probably not exceed 6d.

The fittings being somewhat heavier than ordinarily—corresponding to the heavier sleeper and intended permanence—would doubtless be a fraction dearer, although perhaps not more so, than in the case of the heavy English lines.

A trial section has been down some six months on one of the State lines of Prussia, and has been reported upon most favourably by the local engineer. He thinks the question of permanent way solved by this invention.

Its general introduction would render our railways independent of foreign wood supplies, and save the country at least £300,000 per annum in the matter of purchasing timber from abroad. On the other hand, the output in the manufacture of metallic sleepers by home industries would be balanced by the increased demand for heavier fittings, and especially by the demand for beams, girders, &c., for building purposes, now largely supplied by merchants and factors in the shape of

old rails, and would then (finding a more lucrative employment) have to be supplanted by new manufactures.

It will be very interesting to learn the opinion of friends of the ENGLISH MECHANIC upon this novelty in permanent way; but I may remark, along with the engineer before mentioned, that it requires to be seen in order to fully appreciate its unquestionable merits.

Rhine, 17th Sept. **S. G.**

LOCOMOTIVES.

[26317.]—I ALSO agree with Mr. Grey, "T. C. S.," "M. R.," and others, that if we are to do any good in locomotive discussion we must know all details about engine, train, coal, water, gradient, and speed.

Will anyone tell me what is the proper heating surface for cylinders 18 by 26 and 7ft. wheels?

In reply to W. D. Thompson, p. 86. no one knows what is to be done with the 1,667 class of 19in. engines. They have gone from London and from Nottingham, as they can't even run those short expresses with two vans and three little bogie coaches.

What they want is a new large boiler; but look at the disgrace of having to rebuild new engines. It is a strange thing to me, and I should like it explained. How is it that no engines can be built now on M. R. equal to Mr. Kirtley's 800 class made 1870.

Will "Kappa" and others who see Midland trains kindly note for our information the Midland *double* engine work? How many pilots a day work to and from London? Is it true that some days every train has two engines, and many of the loads are not more than 12 or 13 coaches? How is this? Why use two engines, when one old 800 would do the work?

Leeds. **Engineer.**

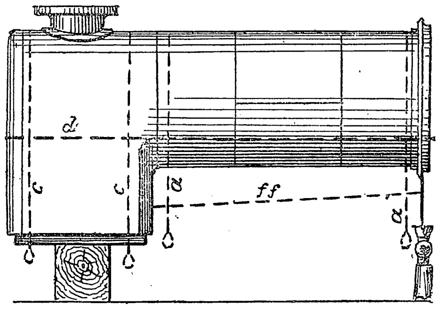
G.W.R. LOCOMOTIVES.

[26318.]—MANY disparaging remarks have been lately made in the "E. M." with regard to these engines. It is stated (Vol. XLIII., p. 528) that "the 2201—2220 class have proved complete failures." I have lately had the opportunity of learning the views of the men about them, and am told that when they first came out they steamed badly, but having been "in shop" are all right now and are doing good work. New and larger boilers with domes are being put to many of the narrow-gauge engines—*e.g.*, the 160 and the Prince Christian (No. 1118) class. Most of the 8ft. singles B.G. have had new boilers within the last few years, and the driver of a N.G. engine, pointing to one of these B.G. singles, said, "Those are splendid engines; there are none that can beat them on an ordinary road." There is a new N.G. four cylindered compound No. 7 with coupled wheels 7ft. in diam., the eccentrics and connecting rods of all the four cylinders working on the same crank axle; the pressure of steam in the high-pressure cylinders is 180lb.; and in the low-pressure cylinders, 90lb. A B.G. compound No. 8 has also lately come out. No. 10 is similar in appearance to No. 9, but the eccentrics are inside. When it is said that the speed of the Dutchman and Zulu to Plymouth and Penzance compare unfavourably with expresses on other lines, it is forgotten that below Newton Abbot it is impossible to run fast; there is scarcely a mile level or straight all the way, and the trains are worked by 8-wheeled saddle tanks, with 5ft. 9in. coupled-wheels, mostly built at the Avonside works—"Noble engines," so the driver of the engine said, "for the work they were built for, but no use for fast running." I do not think the engines are often to blame for unpunctuality, but delays at stations; no extra time is allowed in the time tables for stoppages during the summer months, when traffic is heavy. I asked a signalman at a station where the Dutchman was allowed four minutes if he had ever known it start four minutes after arrival? He answered, "Yes, he had known such a thing to happen; but it was sometimes nearer fourteen than four."

I have recently photographed No. 2203, about which "G." inquires on p. 95. She resembles the 800 coupled class, and as she has no dome and the injector is not fixed as in the more recent engines, I do not think she is new; in fact, on examining the photo with a magnifying glass, I see the date is 1881. The driving-wheels are 6ft. 6in., I cannot give other dimensions. **T. Perkins.**

HOW TO ERECT A LOCOMOTIVE ENGINE.

[26319.]—THIS is the second time I have troubled you with the sketch how to erect a locomotive engine; the last time was about twelve years ago. But as an old apprentice of mine has written me for such information who is now on the other side of our globe, and as he tells me they are about to commence making their own engines, and he has forgotten the way I went about such work, I have told him I would send the required information to the MECHANIC, that it might be useful to other young men as well as himself. The rough sketch I give is of a locomotive boiler as they come from the boiler shop. You first place your boiler in position in sketch with the tube plate resting on a screw jack so that you can set it level. You then get four lines marked *c c* and *a a*; you put one at either end of the boiler, also one at either end of the firebox. You then look at your drawing, and you will see what distance the centre of your cylinders wants to be from the bottom of the boiler, and also the incline they want to be. Then place a line *ff* through each cylinder. Then see that your four lines *c c* and *a a* are equal distance from your cylinder lines; but mind and have your boiler quite level and square with the four lines over the firebox and boiler. When you have done this, pack up your boiler under the barrel; but mind and have an opening through the packing so as to keep your cylinder lines clear, and if on piece work, to save time, it is the best way when you have got your lines *ff* right in every respect, to get two pieces of iron, say $1\frac{1}{2}$ and $\frac{1}{2}$, pointed. Drive them into the floor, one on either side of the boiler; then cramp a straight edge on, then level with the cylinder lines also at the firebox as well, then mark on the straight edge the lines, and you can



then take the lines away, but let the straight edge remain until you have got your cylinders in the required position. Then you look to the frame line marked *d* on your drawing, which will give you the height of foot plate from the cylinder lines, which will give you the position of your brackets for the outside frame—that is, if such is an outside framed engine; if not, it will give you the height of the inside or single-framed engine.

Sheffield. **Ch. H. Nassau.**

CONTINUOUS BRAKES.

[26320.]—IN letter 26297, "L. and Y." has undertaken to answer the ten questions of "Railwayman." The answers given are incomplete, and therefore inaccurate and misleading. No doubt "L. and Y." has based his answers on the brake arrangements in use on *one* railway, possibly the Lancashire and Yorkshire.

Question 1. "Can the engine and tender, &c., be fitted with a complete apparatus for each system?" Answer. "The engines are not provided with a reservoir," &c. Evidently this question was misunderstood. Taking the answer as it stands, it would imply that it is impossible to fit an engine and tender with a complete apparatus for the auto. vacuum brake. In further reply to the question, I would direct your readers to the *Engineer* of Oct. 19, 1885, where a full description of the apparatus fitted to engine and carriages is given, as exhibited at the Inventions. And if a more practical demonstration be asked, I would recommend a visit to Cardiff to see the auto. vacuum brake applied to tank and tender engines in daily use on the Taff Vale Railway. This will also apply to the answer to question 2.

The third question refers to the possibility of shutting off the brake on any carriage when out of order without affecting the rest of the train. It is not the general practice to do so; but it is quite feasible. In fact it is done on the L. and N.W. Ry. The only qualification is that the brake as now used on that railway is a simple vacuum; but were this converted into an automatic brake, which I believe will be the case shortly, the valve to disconnect the cylinder from the train pipe could be used in that event, as well as it is used now.

Question 4. The tap fixed at the end of each carriage in the Westinghouse brake is a constant source of danger. "Railwayman" evidently thinks otherwise; but let me ask him what might happen in the event of a train being made up with the tap at the front being left *closed*, while at the same time the guard in the rear fails to notice the fact from the indicator. The train starts, the driver, trusting that the full brake-power is available, may on any emergency find that he is quite powerless, with the brake acting on the engine and tender only. If shunting is to be facilitated by any such tap between the carriages, it should be made to operate as part of the coupling, so that it should be impossible to forget it in making up a train. One of the most important features of an automatic brake is that it should give warning whenever it is not in working order. What warning can the Westinghouse give when one of these taps is closed? True, the guard in the last van might detect. But guards have many duties to attend to beside looking at the indicator.

Question 7. Perhaps some of your correspondents can say if any difficulty is experienced in taking off the vacuum brake on the long trains, such as the S. Wales express on the G.W. Railway?

Question 8. Perhaps "L. and Y." will give some data to enable us to judge of the correctness of the answer to this question. On the G.W.R. a pump attached to the crosshead maintains the vacuum when the train is running. Why should this pump cause extra consumption of coal more than the Westinghouse pump, which maintains the pressure in the air brake?

In his answer to the tenth question, "L. and Y." very properly suggests certain improvements. No doubt some companies have adopted the vacuum brake in an efficient form. The simple vacuum should be discarded at once. The *leak-off* brake has also proved itself unreliable. **Œdipus.**

RAILWAY SIGNALS.

[26321.]—REFERRING to Mr. Stretton's letter, page 15, I cannot see what cost has to do with where a signal should be placed. Surely Mr. Stretton does not believe that they are put in wrong positions to save posts. I have never considered such a thing, but have always placed signals, after carefully sighting for them, in what I believed to be the best positions.

A "Lancashire Driver" does not apparently know the system adopted with regard to signals by the London and North-Western Railway. On that line, before any new signal is fixed, or the position of any old one altered, representatives of the Signal, Traffic, and Locomotive Departments meet on the ground and decide what shall be done. The particulars are entered on a form supplied for the purpose, and the representative of each department signs it. This is for future reference, and in case of any complaint or dispute arising.

Replying to "Anti-Vac" and "Ajax," my opinion is that the arm should never be allowed to drop right into, or in front of, the post, as the driver might suppose it was out (missing), and treat it as a doubtful signal. An angle of 45° is unsatisfactory, as it appears to be more up than down. I think the clear width of the arm outside the line of the post is the best. I do not see any advantage in the signals in use on the G. N.; in fact, I think they are less distinct than the ordinary semaphore. I have long since condemned all such distant signals as those in use on the Midland. Junctions should have on the facing side as many distant signals as there are home signals—*i.e.*, one for each direction. I agree with a different coloured light for sidings and goods lines. There are some places where distant signals are fixed simply for uniformity, and to mark the distance, and are not intended to be pulled "off." It is an open question whether distant signals are not better fixed in this manner for terminal stations. There are few cases of back lights in line with other signals, but owing to curves it occurs as often where the signals are fixed on the right side as where they are fixed on the wrong side. In the case of four roads, if you put the signals on the left side, which is two roads away, why not put them on the right (when necessary for sight), which is only one road away.

Mr. Stretton says the Binegar accident was due to the line being worked by "crossing orders." "Ajax" says it was due to the bad signalling!

A word or two to "A Lancashire Driver" and "Signalman." Drivers and signalmen do not consider all the conditions to be fulfilled in fixing signals. The drivers' view is the all-important thing; but there are other conditions which must be met (see my last letter, No. 26146, page 577.) I cannot see that it matters to signalmen on which side of the line signals are fixed, and as I have before pointed out, if the Amalgamated Society of Railway Servants have made it one of their *twenty-three requirements*, they have only given room for evil-disposed practical and experienced men to laugh at and ridicule them, as it is impossible to carry it out without rendering a great many signals useless.

A settlement of the colours for signal lights is necessary. Tall signals (with us 40ft. and upwards) are usually fitted with lower arms working simultaneously with the upper arms. It is a rule for home to precede distant signals. It would not, in my opinion, be wise to fix an arbitrary rule that all siding signals should be ground discs. Where there are more sidings than one, the view of disc signals would be sometimes obscured by waggons standing in the sidings.

I do not think eight hours too long a day's work in any signal cabins I have seen yet, and I know one or two where in 18 consecutive hours the lever movements average over four per minute.

Libra.

LAUNCH ENGINES.

[26322.]—IN reference to the latter part of "Ingeniero's" letter, No. 26254, page 63, wherein he states that no benefit can result by placing the cylinders tanden fashion, I may state that one of the great benefits of this type over the simple expansive engine, is that the strains on framing and rods are not so great, consequently a reduction in the diameter of the shafting may be made. The friction of the two cylinders is certainly greater than the one cylinder; but then again you must look at the fact that the friction on slides and journals is greatly reduced, as they may be made much lighter than in the expansive engine. To compare the two engines, take a single-cylinder expansive engine, area of cylinder 804 square inches, rate of expansion 5, steam pressure 80lb., and assume the back pressure to be 4lb., we have $80\,\frac{1 + \text{hyp. log. } 5}{5}$

$= 80\,\frac{1 + 1{\cdot}6}{5} = 80\,\frac{2{\cdot}6}{5} = 41{\cdot}6 - 4 = 37{\cdot}6$lb. = effective mean press. on piston, and the effective initial load on piston $= 80 - 4 \times 804 = 61{,}104$lb.

Now take a tandem compound, ratio of cylinders $3\frac{1}{2}$ to 1, the rate of expansion the same as before. Referring to the l.p. cylinder, we have 37·6lb. as the mean effective pressure. The initial press. in the l.p. and terminal in h.p. will be $80 \times \frac{3{\cdot}5}{5} =$ 56lb., and the effective initial load on the h.p. piston $= 80 - 56 \times \frac{804}{3{\cdot}5} = 5{,}496$lb. Effective initial load on the l.p. piston will be $56 - 4 \times 804 = 41{,}808$lb. It will thus be seen that the total pressure on the crank is 45,024lb. on the compound, and 61,104lb. on the expansive engine.

In actual practice with compound engines there is always a drop in the pressure to the large cylinder, which varies from 5 to 10lb., and, of course, is increased by this amount in the small cylinder. It may safely be put down that there is 20 per cent. less strain on the framing, &c., of the compound. The single-crank compound has been fitted in a large number of vessels in the mercantile marine, and with most successful results, and I have heard it said that they are much steadier in a seaway than the double-crank engine, owing to the fly-wheel, which considerably reduces the racing and consequently enables them to run at a higher speed without much loss of power, also that they are equally as handy as the double crank, on account of them very rarely stopping on the centre.

Engineering, Manchester.

ON SEVERAL OPTICAL MATTERS.

[26323.]—THERE are several matters in the extract from Mr. Madsen's paper on specula-working which seem new, and I trust our experts in this department—Mr. Wassell and Mr. Linscott—will have something to say thereon.

The speculum appears to have been kept uppermost all through the processes, which is rather unusual in so large and heavy a disc of glass as $18\frac{1}{2}$in. diameter. Nothing is said as to whether the glass tool was a plain or facetted tool; apparently it was of the former kind, as no grooves in the grinder are mentioned. To avoid concentric rings, Mr. Madsen advocates a new method of graduation, which I hope "our" experts will try and report upon. If it will render the side motion unnecessary, it will remove some complications from the specula machine.

I am sorry Mr. Madsen's paper was not printed in full, as it would have been very serviceable to many amateur workers; and moreover, we can form no definite judgment of the value and extent of applicability of new methods from so short an account of them.

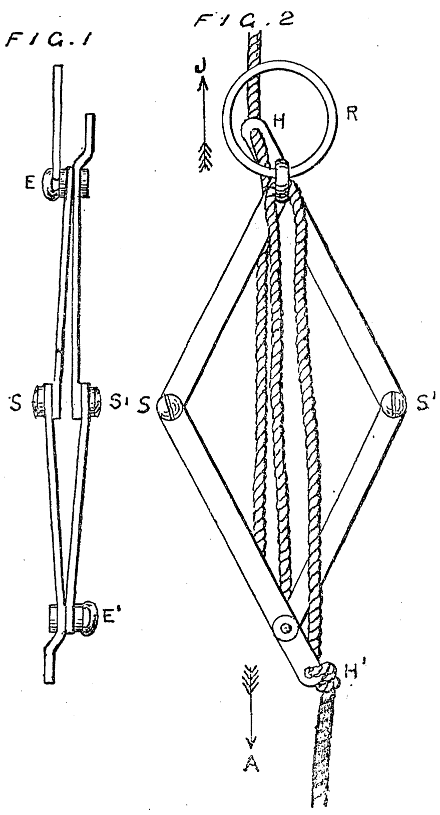
I trust the controversy on English v. Foreign Optical Work will lead to some good result. It is much to be wished that some optical brassworker would give a series of articles showing how to make and fit up the mechanical parts of telescopes, microscopes, and eyepieces in the usual sizes used in the trade.

With reference to *field* glasses, may I ask "Prismatique" what proportions of aperture and focus of o.g. and eye-lenses has it been found possible to achromatise and aplanatise to the best advantage in the two triplet forms figured by him in a letter which appeared some time ago. What is the most serviceable magnifying power for such combinations?

Orderic Vital.

INDICATOR CORD ADJUSTER.

[26324.]—THE mode of connecting the indicator with the reciprocating part of the engine by means of a cord, which has to be disconnected every time the card produced is to be removed, has led to the invention of a disconnecting drum fitted now to all the latest instruments. Those of your readers who, like myself, have to be content with their old instruments, will find the following device of some use in effecting a rapid and safe connection; moreover, they will find themselves suddenly in possession of an advantage hitherto not, to my knowledge, found in any indicator. The sketch (about $\frac{3}{4}$ size) shows a brass frame, the jointed limbs of which are secured by two eyelets E E, and two tightening screws S S; two of the limbs are prolonged above and below the joints E E, and bent as shown in Fig. 1. All joints move firm and smoothly; the eyes and holes where the cord passes through are well rounded. The instrument is reversible; the split ring (R, Fig. 2) being always on the top. Assuming the indicator fixed in position, and the cord fixed to that part of the engine from which the motion is to be taken—say air-pump lever, we lash the cord to the indicator in such a manner that part, or the whole, moves vertically, or nearly so. In marine engines this can usually be done without much trouble. We now reef the vertical part of



cord through H (Fig. 2), and secure it by a knot from thence through the top eyelet to the bottom one, and up again through the hole H, as shown clearly in the annexed. The adjuster being extended to its full limit, it follows that we must have three times the length from E to E, or $10\frac{1}{2}$in. of cord stored up. Taking hold of the instrument by S and S, and opening the limbs we release the cord, the other end of which now must be secured to the hook of the indicator permanently. Placing the forefinger in the ring we resist the down action of the air-pump lever, taking up by this the formerly released cord, and bringing the indicator in action. When once adjusted the indicator and reciprocating part of engine need never be disconnected, except by the mode above explained. The adjuster will remain in any position, in consequence of which two or three diagrams may be taken on the same card by simply placing your finger in the ring, and taking a little more cord up. Where cards have to be frequently taken in all sorts of weather, the adjuster will find, I hope, a place.

Liverpool. **P. F. Otto.**

PHOTOGRAPHIC LENSES.

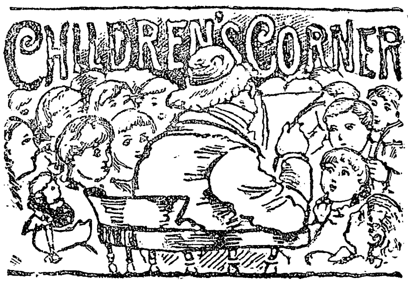
[26325.]—THERE is a manner of using photographic lenses which, though known to some, is not known to all, and which I have not seen mentioned in any handbook. If you have, say, a wide, angled symmetrical of 4in. focus and another of 6in. focus, and if you remove the front combination of the 6in. doublet and replace it by either of the combinations from the 4in. doublet, you get a useful lens of focus intermediate between the two. Theoretically, no doubt, there is a slight distortion of marginal lines; but practically this is so small it may be neglected. I have also found that a similar result may be obtained by removing the back combination of the wide-angled symmetrical of 4in. focus and replacing it by one of the combination of a rapid symmetrical of 6in. focus. It is important that the short focus lens should be in front, or the size of the field is diminished, and when practicable the shorter mount should be used, and it is well that the focal lengths of the two lenses should not differ too much. In the cases I have mentioned, if the chemical focus is displaced at all, it is by so small an amount that a stop of $\frac{f}{23}$ or $\frac{f}{32}$ belonging to the shorter focussed doublet—equivalent to about $\frac{f}{29}$ or $\frac{f}{40}$ on the construction—covers a half plate sharply if the subject is an ordinary landscape.

T. Perkins.

"UNCLE SAM'S" APPEAL.

[26326.]—MAY I ask any of your readers who are willing—especially clergymen, Sunday-school teachers, and others having influence with large bodies of children—to help me?

I am allowed a column in the *Weekly Times and Echo* called the "Children's Corner," in which I endeavour to enlist the children of the readers of that widely-circulated paper into an association for the promotion of kindness to animals and each other. I know, from my own experience, how desirable it is that these lessons should be instilled *very early* into the minds of children, and I think I am doing some little good. Will any readers do what they can to induce children to join, and send me their names and addresses? I send to each child a card of membership, and the children are encouraged from time to time to send me stories about animals and other communications. Here are our rules:—



1. To defend the weak against the strong.
2. To be kind to dumb creatures.
3. To avoid all cruelty to human beings, or to bird, or to beast.
4. To be guilty of no rudeness to the poor.
5. To be friendly to one another.

There is a motto as well—a verse that every child should know:—

"He prayeth best who loveth best
All things both great and small,
For the dear God who loveth us
He made and loveth all."

I will gladly send specimens of the "Membership Card" to anyone interested.

Uncle Sam.

Weekly Times and Echo Office,
332, Strand, London, W.C.

THINGS OLD AND NEW.

[26327.]—I AM not much given to politics; they always appear to me like a game of peg in the ring. If one member sets his top up with evident belief in its spinning powers, another considers it his immediate duty to try to split it, and thereby to insure its destruction. Conservatism says "As you were!" Liberalism says "Right about face!" and so I suppose matters will continually go on to the end—the bitter end—top and bottom sawyer periodically changing places, but ever and always kept apart with a sharp cutting instrument with teeth. Wandering at my own sweet will through a big and flourishing workshop, and passing from lathe to planer, from drilling machine to shaper, I was brought up all-standing by the formidable rival of the last-named appliance, the milling machine, of which there were several at work, quietly executing their appointed tasks with a precision which left nothing to be desired. When these machines first ventured upon the scene of their labours, mechanical conservatism was against them. A milled surface was not supposed worthy of consideration if a planed one could be had. Sterling merit, however, won the race, and the milling machine triumphed. But the matter set me thinking. Why such obstinate conservatism in a machine shop? Why relegate to oblivion any

labour-saving contrivance without a fair trial, simply on the ground that it is a novelty? I must not quote my authority, but I know as a fact that many of the suggested improvements in lathes and appliances discussed and approved in these columns by those specially qualified to judge of their value have been made for sale as suggested, only to lie in the shop unsold and utterly unnoticed.

I am not speaking of questionable stuff, much less of rubbish, but of apparatus well designed and of sterling merits. Of smaller appliances which certainly come under this category there are Noble's expanding mandrels and the J. K. P. chuck, the latter being now made to fit on a flange like the scroll chuck, so as to be readily fitted to any lathe. How many have been sold? Then there is the front slide-lathe, so hotly advocated that one would have expected it to meet with a large demand. It was duly made; but how many were called for? Who knows? Well, I do. I could quote a score of similar cases. Manufacturers could count hundreds to their sorrow. There appears from time to time to be a demand for some modification of an existing machine in order to adapt it for special purposes—*e.g.*, a milling appliance to a lathe. An enterprising manufacturer produces it—advertises it largely; but, behold, it is thrown back upon his hands to cumber the workshop, until possibly it is eventually broken up and any available parts are put to other uses.

We have now before us traversing bushes instead of traversing mandrels, the design of a trained engineer, of whose mechanical knowledge there is little room for question. The lathe is free from some defects connected with the ordinary traversing mandrel, besides having special merits of its own; but the traversing mandrel, which is "*in esse*," will keep out this, which is "*in posse*." The man in possession is an ugly customer always. Given a tool that will do its work well, it becomes a curious question how long it will take to introduce one which will confessedly do it better. One would have imagined that such an improved tool would find a ready sale, and in a very short time outstrip the older one; but experience proves that such is by no means the case. The labour-saving machines of America, of which we are slowly adopting a few, would never have seen the light of day except in the shops of the ingenious inventors, had the latter lived in England. There is indeed very little encouragement here given to inventors, and still less to the few enterprising manufacturers who consent to undertake the risk of introducing novel appliances. Our machine-made watches were written down and ridiculed. But look at the issue of the contest and the profits of the Waltham Watch Co. And who that saw the machines themselves at the Inventories in actual operation could hesitate one moment about the possibility of doing any work, however complicated, by machinery, and doing it thoroughly well. Yet mechanical conservatism would probably induce any English watchmaker to stick to hand work, even if he saw his trade steadily declining and customers going over to the enemy, rather than adopt the new tools and follow the unwelcome lead.

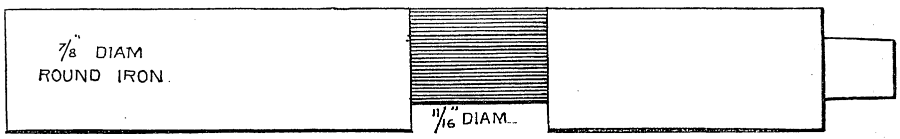
I often wonder what will be the fate of the screwing lathe of Niblett, which I am awaiting his pleasure to introduce. Having one, and being able to speak from practical experience, I can vouch for its merits. Its special advantages over the traversing mandrel are in fact many, its price will be low, and it will be applicable to ordinary lathes; but will it sell? and if not, why not? I had the pleasure of reviewing some time ago a new slide-rest of W. S. Brown. It was a good tool, specially adapted for cutting screws on an ordinary lathe by gearing the main screw with the mandrel or overhead. It was of practical use for all usual work requiring a slide-rest, and was applied to such purposes in the inventor's workshop. I do not feel at liberty to say how many found purchasers, but not enough to encourage invention. I believe the maker has retired from the lathe making business, but I hope the rest in question is not extinct, as I think if it persists in its endeavour to be seen it will yet find a satisfactory future. If not it will have many companions in its compulsory retirement—a goodly society in the main, although it may include some questionable characters. Sometimes I know there is a resuscitation of rejected candidates, and new lamps give place to old ones. But what is the real secret of these rejected addresses? Why are inventions so unconscionably snubbed? It seems to me that pills alone are exempt from this otherwise universal dilemma. Invent a pill and advertise it sufficiently and advisedly and, though its composition is unknown, it will sell abundantly, however worthless, and realise a hundred per cent. profit, and bring many fees to undertakers. In a general way, the survival of the fittest is a very satisfactory arrangement; but what a precious long time it takes to discover the fittest, and when found to introduce it at a profit! Of course, it is a question which is the fittest, and it is matter of experiment, as was the case when I tried at a vegetarian dining-room "fried sole of beetroot," which on trial I did not by any means prefer to fried sole of fish; but then experiment may, and does, prove that such and such novelty is superior to it older rival, and yet it does not find purchasers. Is a mechanical invention like a new book, a hit or a failure, irrespective of it real merit? Yet I feel that I could sell 10,000 copies of "Lilian, a Detective Story," before I could sell 100 of a new drill-stock, although the first would be humbug from beginning to end, and the latter from end to end a really good and serviceable article. I saw the other day the tail of a lathe carrier tied by a bit of string to the pin of the driver chuck. In that very shop were carriers of improved construction and Clements' driver-chuck, yet I suppose that conservative workman will continue to prefer his bit of string. I allow that his work was excellent—I never wish to see better. **O. J. L.**

LATHE WORK.

[26328.]—USING a chisel (with scraping action) to true up some worn roller-skate wheels a few days ago, I found that every now and then a series of ridges, like waves, formed across the wheel's circumference, which it was a deal of trouble to get rid of. The lathe and chuck ran true, and my hand appeared to be steady, so the only reason for this result I could give was that, perhaps, some portions of the wheels were harder than others, and that when the chisel got blunt (as it soon did), only the softer parts were cut. Can any of our friends give me a hint, as I want to do some more? **B. H.**

BENCH HOOK.

[26329.]—NOTICING the American bench hook, I thought it would be of some benefit to some of "ours" to show one that has been used for more than 20 years in a mill in Rochdale. The above is a sketch.



It is simply a piece of round iron turned to ⅞in. diam., and then thrown out of centre and swept to 11/16in. diam. The breadth of sweep depends on breadth of hook, as it has to hold it by being turned round by a box key.

To fix this simple appliance they have only to bore a hole in bench in line with mortise-slot for hook, and then have a box key to raise and lower it just to height. **Mill.**

AUTOMATIC ACTION.

[26330.]—"ANTI-VAC.'S" letter (p. 16). In reference to a statement of mine *re* the above, what I meant by "automatic" was something acting of itself, and not in the charge, nor under the control, of anybody. Signals only act automatically when the wire working them breaks; and brakes only when the connections are severed or damaged, and not when applied in the ordinary manner by the driver or guard. **Libra.**

COPYING DRAWINGS ON A REDUCED (OR ENLARGED) SCALE.

[26331.]—THE following method of copying a drawing on a scale $\frac{b}{a}$ times that of the original, although open to objection in some cases, may be of occasional use to those who do not possess proportional compasses. I have seen no notice of it in books, but the principle on which it is founded is too simple to allow me to suppose there is anything quite new in the process.

Suppose A B to be a line of fixed length, equal to ten units of the measure used in the construction of the figure, and A P, B P lines meeting in P, the lengths of which vary, but bear a constant ratio to each other, A P being equal to $\frac{a}{b}$. B P. The point P will lie on a curve which, in connection with the fixed points A and B, will furnish the draughtsman with the length P B of a line in the new drawing corresponding to the length A P measured from a line in the model.

We have now to determine the curve which is the *locus* of P.

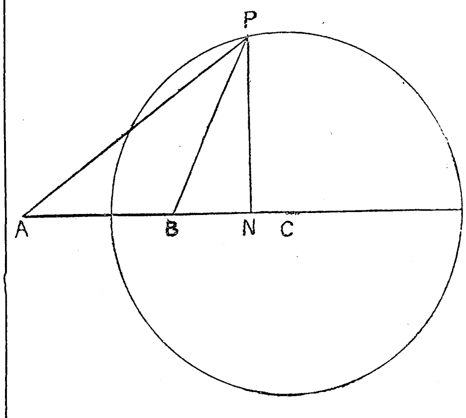
From P draw P N perpendicular to A B (or A B produced), and take B for the origin of co-ordinates. Let B N = x and N P = y.

Then— $$A\,P^2 = \frac{a^2}{b^2} . B\,P^2$$

or $$y^2 + (x + 10)^2 = \frac{a^2}{b^2}(y^2 + x^2).$$

Hence—
$$y^2 + x^2 - \frac{20\,b^2}{a^2 - b^2}x = \frac{100\,b^2}{a^2 - b^2}. \qquad (1)$$

This is the equation to a circle. To determine the position of the centre and the length of the radius, put $y = o$ in equation (1), and find the roots of the resulting quadratic.



Half the sum of these roots gives us B C, the distance from B to the centre C, and half their difference is the radius. B C = $\frac{10\,b^2}{a^2 - b^2}$, and the radius = $\frac{10\,a\,b}{a^2 - b^2}$.

For most ordinary values of a and b, a circle with the position of the points A and B can readily be constructed on a sufficiently large scale to serve for most of the measurements required in copying a drawing. It ought to be on cardboard, and have the points A and B protected by horn centres from the holing of compasses. In most cases, however, it will be found necessary to have a second circle on a smaller scale than that of the first, but which may be derived from the first by the simplest geometry. This will serve for the very short measurements. When the ratio exceeds 2, more than two circles may be required, in order to comprise all the measurements contained in a drawing; and the method becomes less and less satisfactory the greater the difference is between a and b.

The following are the lengths of B C, and of the radius corresponding to several values of the ratio, commencing with the ratio $\frac{\sqrt{3}}{\sqrt{2}}$, which is that used in isometric projection.

Ratio.	Length of B C.	Radius.
$\frac{\sqrt{3}}{\sqrt{2}}$	20·00	24·55
$\frac{3}{2}$	8·00	12·00
$\frac{7}{4}$	4·85	8·48
2	3·33	6·67
$\frac{9}{4}$	2·46	5·54
$\frac{5}{2}$	1·90	4·76

Charing, Kent. **John R. Campbell.**

Pearl Life Assurance Company.—The twenty-second annual general meeting of this company records a year of unexampled increase in the company's business. In taking a retrospect of the income for the past five years it will be found that it has in that time more than doubled—the income from premiums in 1881 being £91,458 13s. 10d., while it is now £195,737 13s. 11½d. 453,898 policies were issued during the past twelve months, representing a new annual premium income of £169,631 14s. 5d. The total income for the past financial year amounted to £199,985 5s. 4½d., and exceeded that of the previous year by £35,878 4s. 3d.

TO get an absolutely clear solution of shellac has long been a desideratum. The *National Druggist* says it may be prepared by first making an alcoholic solution of shellac in the usual way; a little benzole is then added, and the mixture well shaken. In the course of from twenty-four to forty-eight hours the fluid will have separated into two distinct layers, an upper alcoholic stratum perfectly clear, and of a dark red colour, and under it a turbid mixture containing the impurities. The clear solution may be decanted or drawn off.

REPLIES TO QUERIES.

*** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[59842.]—**Mathematical Probabilities.**—To "ALIOTH AND "R. E. F."—No doubt you are right in the way you look at the subject, but I think I am also right in the way I look at it—i.e., if you throw two dice for an indefinite number of times, 4 and 5 will turn up on an average once in every 18 throws. This must be so, else what becomes of the other 17 combinations. If "a dice be thrown repeatedly," the ace will turn up, on an average, once in six throws. You are, I presume, considering it in this way: Commencing to throw, it is even betting that 3 and 5 are thrown in the first 12 throws; and then, when they are thrown, you start again with the same conditions. To prove my view, I ask the following question. What is the probable number of times 3 and 5 will turn up in 900 throws?—LIBRA.

[59842.]—**Mathematical Probabilities.**—I shall be much obliged to "E. L. G." if he will explain what he means by the opening sentence of his last letter (p. 69). He says that the method given by me is "a needlessly operose way of getting Napierian logs. from common ones. Dividing each common tabular log. by ·434 would give two or three figures of the Napier log." But as this is exactly what I have done, I am at a loss to understand how my method is "needlessly operose." As "Alioth" addressed his queries to me, "E. L. G." had no right to intrude himself unless he had something new to say; but he has only solved one of "Alioth's" queries by guesswork, and he has not given any method by which the table he requires may be calculated. Therefore he has to content himself with trying to pick holes in my method; but as he clearly does not understand this part of the subject, his objections do not count for much. I may tell "Alioth" that my method is accurate enough when it is required to know between which two throws the required probability falls.—R. E. F.

[59926.]—**A Wonderful Lamp and Battery. (U.Q.)**—This query was answered at p. 464, Vol. XLIII., letter 26026, by Prof. F. R. Cheshire.—S. BOTTONE.

[59943.]—**Int. B.Sc. Lond. (U.Q.)**—Information as to Lumbricus Helix and Disternia, especially as regards their dissection, is difficult to get in a connected form, and I know of no book that covers the ground. The mussel is now left out of the syllabus. I do not think that the questions in biology are obtainable apart from the Calendar.—B. B.

[60037.]—**Mounting Sections for the Microscope.**—The query has already been answered twice, but as the following method has yielded very good results in my hands, "Ruse" may, perhaps, not object to a third reply. The slide is painted with a thin layer of a mixture of collodion and oil of cloves, in the proportion of one to four. On this the sections are arranged. The slide is then placed in the drying oven to melt the paraffin and evaporate the oil of cloves. If it be desired to mount the sections in balsam, the melted paraffin is washed away with turpentine, and the cover-glass with the balsam at once applied. But if the preparation is to be put up in glycerine, the slide is washed first in turpentine, then in chloroform, then in alcohol, and then in water. The sections may then be mounted in glycerine, or may first be stained with logwood, carmine, or any other staining fluid. If, after staining, it is desired to mount the preparation in balsam, the slide can be treated in succession with alcohol to dehydrate, oil of bergamot, and balsam. Oil of cloves must not be used, as it dissolves the collodion cement (Schällibaum). This method is taken from Purser's "Manual of Histology" (Longmans, Green, and Co.). It is absolutely necessary to use some method of cementing the sections when a large number have to be mounted together, and even in the case of one section the method is often very useful, when that section consists of several distinct parts—a mesial section of a young triton, for instance.—PLAYFAIR.

[60055.]—**Houseboat.**—To "PONTOON."—With each of the two pontoons the dimensions I mentioned, and 2ft. 6in. wide at greatest beam, flat bottomed and wall-sided, but boat built in their outline fore and aft on the outer sides, and covered in airtight, and carrying a load of fifty stone, they would be submerged about 10½in. On second thoughts, I should give the boat 8ft. beam at centre, from outer edge of one pontoon to outer edge of the other. It will be much more convenient, and it is a very narrow channel that will not take an 8ft. beam. I should suggest carrying the deck as far as possible fore and aft; it will be much more comfortable, and you must not forget two strong crossbeams at each end, with ringbolts, for the tow rope.—E. CONRY.

[60186.]—**Mathematical.**—Neither the fourth, nor third, 6in. ball can move when the box is shut if its dimensions do not exceed 10·242641.—E. L. G.

[60186.]—**Mathematical.**—Mine *re* this last week is wrong. Not feeling satisfied, I got out the drawing-board, and find "E. L. G." is correct, as also my former reply. As "E. L. G." says, the cube will also hold four balls. To hold two balls 6in. diameter I make the size 9·4in.—T. C., Bristol.

[60190.]—**Leclanche for Quantity.**—I have tried a zinc plate 2¼in. wide, instead of the zinc rod; deflection on tangent galvanometer 35½° with the rod, with the plate the deflection was 39°. The resistance was therefore about 12 or 13 per cent. less with the plate.—G. BOWRON.

[60191.]—**Vaporiser.**—If "G. P. P." would say more definitely what it is he wishes to learn, he might possibly obtain an answer.—J. T. M.

[60197.]—**Take a Postage Stamp.**—A number of replies have appeared which mostly refer to post-cards, or stamped envelope and paper. I asserted, and do still, that machines for the supply of postage stamps pure and simple are not in use.—T. C., Bristol.

[60198.]—**Centrifugal Pumps.**—Centrifugal pumps, like others, will only lift the water 28ft.; but they can be made to force it up to heights proportioned to their speed.—A. M.

[60203.]—**Japanning Small Castings.**—If this querist will procure No. 860, he will find on p 36 a useful article on Japan and Japanning. A japanner's stove may take any form, but it is usually made of sheet metal, with closely-fitting door, and a chimney to carry off the vapours. So long as it is dust-proof it may be set in any convenient way, and heated either by gas or coal. The best way is to build a furnace in which the coal can be consumed, and the hot gases can be made to pass around the sides of the stove.—SAML. RAY.

[60209.]—**Colours.**—This querist might be referred to recent letters on "is violet a primary colour?" Much difference of opinion always exists as to what is violet and what purple, and doubtless there is great difference in the colour sensations produced in different eyes, as many persons have not altogether normal colour vision. The spectral violet has not been decomposed, I believe.—S. S. A.

[60219.]—**Cordage.**—There is no kind of cordage which is altogether unaffected by weather, but much may be done by coating it with a thin solution of tar, or if preferred, by carefully coating with boiled oil.—SAML. RAY.

[60220.]—**Flexible Paint.**—Good white lead mixed with boiled oil—no driers—will be found as flexible as anything; but the canvas must be previously damped, just as oilskins are. No paint will stand much rolling up round a broomstick without cracking.—SAML. RAY.

[60224.]—**Tables, &c.**—"Traverse Sailing" might find what he wants in Merrifield's "Nautical Astronomy," Sampson Low and Co.—E. G.

[60230.]—**Ebony.**—If "Wood Broker," who on p. 19 is "amazed and amused" at the replies to this query, will refer to the query itself, it is not unlikely that he will be "amazed" at the magnitude of the blunder he has made. Nevertheless, he is to be thanked for the information he gave, though it is not an answer to the query.—VIDEO.

[60231.]—**Plaster Casts.**—It is not easy to clean plaster casts; but it is perfectly easy to prevent them getting dirty. As soon as cast, or before they become soiled, soak in paraffin wax, and thereupon find a surface which can be readily cleaned from dust, &c.—NUN. DOR.

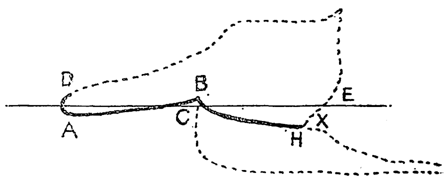
[60238.]—**Transfers.**—Stencils for the sand-blast can be made by soaking thick paper or card-board in boiled oil or copal varnish. A coat of glue will also effect the object.—NUN. DOR.

[60252.]—**Gravity.**—To "G. H. H."—I suspect that I have not been explicit enough. Of course, the earth behind the body will retard it, but not until it has passed the centre. What I should have said, therefore, is that the retardation does not commence until after the body has passed the centre.—RED LIGHT.

[60255.]—**Hydrostatic Pressure.**—In my reply to this (p. 91) it must be understood that the calculation is only applicable to the case of a beam the sectional area of which is small compared to the length, as in the present case, where, from the data given, the diameter will be found about 2in. Having a liking for this sort of problem, I calculated the value of x for a beam with circular section of any radius, but, as it is rather complicated, I do not send it. It is necessary to calculate the exact position of the centres of gravity for both portions of the beam, above and below water, and this requires the integral calculus; a beam of square section can, however, be worked out without the calculus. I can send a sketch of the working with the calculus if desired; it is very neat, like most calculus problems. The W in my reply should have been multiplied by 1·026 for salt water.—M.I.C.E., Bath.

[60268.]—**C. G. S. Units.**—To MR. WM. JOHN GREY, F.C.S.—There is nothing in your rejoinder for me to meet, as it consists practically of recrimination, and I am not fond of the "you're another" style of argument. I simply confirm what I have already said on the subject. Your corrections rest on your own unsupported assertion, for you have not condescended to give a single authority, or even to show how you work out your own statements. I may tell you, however, for whatever worth you may be disposed to attach to an unproved assertion of mine, that the part of the C.G.S. system that I described is, to my own knowledge, practised at this moment in more than one of the large engineering shops in Paris, where the work turned out is unexceptionable. I believe I can see that the cause of our difference of opinion lies in a slight misconception on your part of one of the factors of the C.G.S. system, which, if applied in one direction, produces only a slight variation, but applied in another (the present instance) makes a very serious difference. However, in any case, I do not choose to further prolong this absurd squabble, and if it will gratify you to have the last word you are welcome to it. I am at all times willing, and, indeed, anxious, to learn from any one who can give me correct information; and if a mistake (other than a mere printer's error) appears in anything I write, I shall always receive kindly any correction that is made in a kindly and courteous spirit; but I certainly do not feel inclined to so receive a flat contradiction, incorrect in substance, and rude in expression. When a man starts with the assumption that he is a scientific Pecksniff, and that, therefore, he being immaculate, all who differ from him must of necessity be wrong, it is useless to argue with him, and I must, therefore, decline further discussion with him. Moreover, your action in raking up and dragging into the argument, for the purpose of discrediting me, a reply of mine given long ago on a totally different subject, which you took no exception to at the time, but which you now incorrectly declare to be totally wrong, appears to me to be such a piece of puerile spite that I shall for the future decline all discussion with you upon any subject whatever.—E. CONRY.

[60294.]—**Action of Steam.**—There appears to be something wrong about your low-pressure card, as the initial pressure is greater than in the high-pressure exhaust pipe, from which it takes its steam. I have, therefore, sketched two imaginary diagrams and exaggerated the peculiarities which should theoretically be apparent.



As the l.p. piston is commencing its stroke when the h.p. piston has half finished its exhaust stroke, I have placed the l.p. diagram under the h.p. one in such a position that the end C is immediately under the centre B of the h.p. card. Two other points are to be noted: I have made the scale of the l.p. card the same as that of the h.p. card, and I have turned the l.p. card round so that its steam end is to the left instead of to the right, as in your example. Now let us trace the steam throughout its journey from the boiler to the condenser. The steam is admitted to the h.p. cylinder at E, is cut off, and expands to D. So far there is nothing in a compound engine different to a simple one. (In the figure all the parts of either diagram to which this remark applies are shown dotted. The parts shown in full—i.e., the line D A H—are affected by the special design, as will be seen). At D the exhaust port opens, but instead of exhausting into a condenser or into the open air, the steam has to pass into some form of receiver (such as the pipe between the cylinders), which already has some steam in it of about the pressure at which the steam in l.p. cylinder was cut off in the preceding stroke—i.e., the pressure shown at X. With this steam it mixes, and, of course, loses pressure in doing so very much, as brandy loses strength when mixed with brandy and water. The pressure, therefore, at once drops to A, and the temperature of the steam falls, and the walls of the h.p. cylinder are cooled down in consequence. The h.p. piston now begins its exhaust stroke, moving from A to B and forcing the steam into the receiver while so doing. The pressure ought to rise while

this goes on, as shown on the diagram, where the pressure at B is shown as above the atmospheric line. In consequence of the cooling effect of the sides of the h.p. cylinder (which were reduced in temperature during the exhaust, as noted above), so much steam is condensed that the line A B is generally nearly, or quite, horizontal, or may even slope the other way; however, this is a diagram intended to show what would happen if there were no consideration. At B the steam is admitted to the l.p. piston. As there is a "clearance space" between l.p. piston and slide-valve, which is filled with steam of a lower pressure, this has to mix with the fresh steam and lowers the pressure to C. The h.p. continues to exhaust and the l.p. to appropriate steam till the point H is reached. The steam now occupies a space equal to nearly the whole of the h.p. cylinder, the whole of the receiver, and nearly half the l.p. cylinders; as the same steam at B only occupied a space equal to half the h.p. cylinder and the whole of the receiver its pressure will evidently be reduced, as shown at H. Here the h.p. exhaust closes, and as the h.p. piston continues to move, although it is not in connection with the receiver, the steam is compressed to E in readiness to receive steam for another stroke. I should have said the end I have been considering is not in connection with the receiver, for at the moment that the exhaust from one end of the h.p. cylinder closes, that from the other end opens, and should produce a slight rise at X, where the l.p. steam is shut off; the rest of the course of the steam is the same as in any other engine. Observe that from B to H the diagrams are identical: this is not the case in practice, as there is always a loss from condensation. You will see that the pressure at C cannot be greater than at B, as in your sketch. P.S.—I have just received the copy of the ENGLISH MECHANIC for Sept. 24th, and I see that I have in my reply, which I sent yesterday, mistaken the bottom of the high-pressure diagram for the atmospheric line. My explanation will still hold good; but in my sketch the atmospheric line is higher than in yours.—GLATTON.

[60307.]—**Analysis of Silver Alloys.**—I am sorry that my answer to this query seems to have been rather unpalatable to "G. E."; but it is not my fault that persons cannot learn chemical manipulation from books. Much actual practice is necessary before the requisite dexterity is acquired. It is the same with other things: take rifle shooting, for example. There are plenty of manuals on the subject, written by first-rate men, giving full instructions; but if a recruit imagines that by reading the rules he can go on to the range and rival the splendid shooting of such a man as McVittie, he will find himself grievously disappointed: and similarly "G. E.," if you think that by reading "instructions" you will at once be able to do a delicate quantitative analysis, you will be disappointed also; but please do not blame me. If the Editor likes, I will send the instructions given by Fresenius; but I am not sanguine that they will help you materially.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60310.] — **Field Tubes and Tubulous Boilers.**—The American boiler you refer to is, I think, that known as the Herreshoff boiler. A long pipe was formed into a coil round the sides and over the top of a furnace; water was allowed to trickle into the upper end of the coil from a feed pump, and was drawn off as steam from the bottom of the coil. Sometimes the water had to traverse another coil outside the heating coils first, and in this case the pump fed the bottom of the outer coil, which was thus always full of water. The water was led from the top of the outer to the top of the inner coil, and was led off from the bottom of the inner coil as steam. A few coils were added at the crown of the boiler, through which the steam passed on its way to the engine, and in which it was superheated. I have known the steam-pipe to be at a black heat for some inches from the boiler. The efficiency of this boiler depends on the regularity of the feed, and it requires very constant attention. Too much water makes it prime, too little makes the steam nearly red-hot, and spoils the engines. The margin on either side of the right quantity of water is very small.—GLATTON.

[60310.]—**Field Tubes.**—I cannot speak from personal experience, but I know the manager of engine works in the North of England, who spoke to me on the subject some years ago, having had some fitted in a vertical boiler, and he expressed a very high opinion of them; and if my recollection does not lead me astray, I believe he constructed a vertical boiler for a stationary fire engine in which these tubes were used. Why these tubes are not more used I fail to comprehend. The circulation of water in the tube is so good that sudden expansion and contraction does not affect the tube like one rigidly fixed at both ends. I have always found the ordinary vertical tube boiler a source of annoyance. Horizontal tube ones are much better in every respect. When flame and hot gases pass through a vertical tube, the water has a tendency to separate from the tube, thus causing the tube to burn away; and not only that, but the rise and fall in temperature caused by opening and shutting the furnace doors causes the tube to expand and contract, thus making the ends of the tubes to leak. I will just place before the readers of this paper a curious fact. Now, from books on engineering, I have read one cause of boiler priming was from deficiency of steam space. Now, in the instance I quote, a tubular boiler to supply an engine of 250 H.P., worked at 90lb. on the square inch: it was a double end boiler with eight furnaces, four at each end. The glass water-gauge was, as near as I can recollect, from 18in. to 20in. long. Now, when worked with 3in. or 4in. in the glass, the boiler often primed, particularly when the fires were forced or on the safety valves lifting. We then worked with three-quarter glass with success, the boiler never priming. The conclusion I came to was that when working with only 3in. or 4in. in the glass, there was not a sufficient body of water to absorb the caloric efforts of the coal, thus causing it to prime.—INGENIERO.

[60311.]—**Slide-Rest.**— Finish with a broad spring-tool and plenty of soapy water. Every point on the edge of tool cuts a copy of the leading screw. If the tool is wide some of the points which would produce hollows will probably be in such a position as to cut off the tops of the threads left by their predecessors. Therefore, the wider the tool, so long as it does not chatter, the smoother the work.—GLATTON.

[60314.]—**Pollak's Battery.**—TO "R. E. F." OR MR. HABGOOD.—I shall be glad if you will kindly answer the following questions about this battery which requires so little attention. What thickness should the electrolytic deposit of copper be? Would it do for the carbon to rest on a copper plate instead of the deposit; and, instead of the upper portion of the carbon being agglomerated, to have an agglomerate cylinder resting on the carbon? Will the agglomerated portion last as long as the lower carbon, or does it become exhausted? ("R. E. F." does not mention the agglomerated portion in his description.) How is it that the current is so low as $\frac{1}{80}$ amp. when the "E. M. F." is given as 1·3 volt, and the resistance as 0·5 to 0·8 ohm? Would two cells give more power than one bichromate for driving small models; and could it be used ten hours daily for electro-deposition instead of a Daniell battery? I am sure a description of the modified form for electric lighting would be interesting to many beside myself.—H. H.

[60316.] — **Electric Time-Ball.** — You might arrange a swing-door so that the effect of its being opened by yourself or customers would be to wind up the ball, which would then be supported by a catch controlled by an electro-magnet. A very simple arrangement could be adopted to prevent overwinding.—GLATTON.

[60328.]—**Spirit Level.**—I do not know the usual way; but I think I should set about the job thus: Take a flat piece of board, and place it nearly level. Lay your level upon it, and fix the tube temporarily with two small pieces of putty. Mark the position of one end of the bubble with ink upon the tube. Reverse the level, and if the marked end of bubble has moved, mark it again, and raise one end of the board till the edge of bubble is half-way between the two marks. Rub out the marks, and put a fresh one, and try again until the bubble does not move when the level is reversed. Now press one or the other end of tube into the putty until the bubble is in the middle of tube, and mark both ends of bubble, and adjust board more carefully, until the bubble does not move on the level being reversed. Pour a little plaster of Paris over the ends of tube, and, when hard, test again, and mark the positions of the two ends of bubble with a diamond. Screw on the guard-plate, and the job is done.—GLATTON.

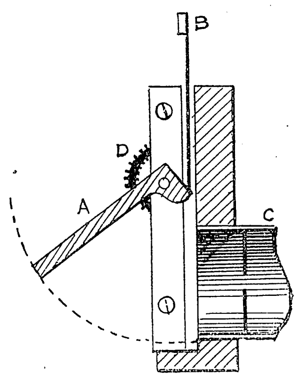
[60329.] — **Fire without Smoke.** — Will a spirit lamp or a Bunsen burner do, or one of Fletcher's gas-stoves?—GLATTON.

[60334.] — **Falling Bodies.** — The eastward distance travelled by a body falling from a height of any given latitude can be found by the same method as I gave on p. 45. For instance, let a body in lat. λ fall from a height of δ miles. A point on the surface has a radius of rotation of m miles, let us say; then the body, at a height of δ miles, will have a longer radius of rotation; but this will not be nearly so much as $m + \delta$ miles, but only $m + \delta$ cos. λ miles. In lat. 60° the radius would only be $\frac{1}{2}$ mile longer. The circles described by the two bodies in 24 hours will be $2\pi m$ and $2\pi (m + \delta \cdot \cos.\ \lambda)$ respectively, and the difference in length $2\pi\delta$, cos. λ. From this it follows that $S_1 = \frac{2\pi t \delta \cdot \cos.\ \lambda}{8640}$ where S_1 is the eastward motion in t seconds. If this is not sufficiently clear to "E. L. G.," I shall be happy to send a diagram. R. E. F.

[60335.] — **Turnbull Transmitter.** — Some years ago I was shown a sketch of a telephone almost identical with this, which represented one which a friend had fitted up. In it the position of the carbons was adjustable, and found by trial.—GLATTON.

[60336.]—**Keeping a Pony.**—Yes, I am in perfect earnest when I say "give the pony 1 to $1\frac{1}{2}$lb. of feeding three times a day, but quantity depends on the work it is doing." This, of course, does not include hay. My pony (14·1 hands high) gets that amount. It is only working, on an average, three days in a week, and its day's work is to run 15 or 23 miles, being in harness 3 to 5 hours. On its working days it gets 4 to $4\frac{1}{2}$lb. of feeding, and its non-working days $1\frac{1}{2}$ to 2lb., with as much hay as it can eat at all times, except when actually in harness. This costs, including hay, about 4s. to 5s. a week. My shopboy spends about two hours each day in cleaning pony and stable, and I give it a good cleaning myself before taking it out and after coming in, and to anyone who has an interest in the animal the work is as nothing. I can assure "Doctor Medicinæ" that in all the county side there is not a pony that has improved more than mine has during the last four months. It was a poor, lean thing when I got it four months ago, and it is anything but that now. If I thought that my pony required more feeding it would gladly get it, and as I am stabling beside a farm, and farmers are often visiting me, I am sure I would soon be told if I was starving my pony. When I say "beware of dealers" I don't mean don't buy of a dealer. Dealers must have good horses as well as any other person; but I hardly ever give a dealer more than half what he first asks for a beast, and I find that he would only offer me half what I gave him if I asked him to buy it back.—I. LOW, 2, Alexandra-terrace, Lenzie, N.B.

[60339.] — **Instantaneous Shutters.** — The sketch shows the principle of one now in the market.



The shutter A is opened by turning the milled head D. When full open, the projecting piece at its upper edge no longer supports the sliding shutter B, which consequently falls and covers the lens C. As shown in the figure, A has moved through about two-thirds of its travel, and the lens is rather more than half uncovered. The upper half is uncovered only during the remaining third of the travel of A, and is then promptly covered up by B. Thus the sky receives from one-third to one-fourth the exposure that the lower part of the picture does. Lancaster's shutter does much the same, but in a simpler way.—GLATTON.

[60354.]—**Box Filled with Spheres.**—A cube's edge is not blunter than an octahedron's, as I said hastily in p. 69; the former being rectangular, and the latter of 109° 28′. The cube, however, is the nearer to a sphere, for if both figures be inscribed in the same sphere, the cube is the bulkier, as 2 to $\sqrt{3}$. So, too, the dodecahedron excels its conjugate figure, the icosahedron. In all cases, the one with most corners (not most faces) excels.—E. L. G.

[60359.]—**Freezing Meat.**—At the Health Exhibition the machinery was shown in action. Powerful pumps compressed air, which in consequence became heated. After being reduced in temperature by water, it was allowed to expand in rooms in which meat was hung. In expanding, the air reabsorbed the quantity of heat which it gave out to the water while compressed, and as the meat was the only available source from which the air could extract the heat, it got colder and colder, and froze.—GLATTON.

[60368.] — **Exploding Spirit Lamp.**—The vapour of the spirit does not do much harm; the trouble is that air gets mixed with it, and produces an explosive mixture. I have had the same trouble, but have not been able to find a remedy. An accident is, I think, less likely to happen if the wicks fit tightly. I, too, thought there was no danger, till one day the greater part of the spirit followed the burner, and covered my head with

flaming liquid, which was not extinguished till I had been severely burnt. Better do as I did, and stop using such a dangerous concern. The price, by the bye, was nearer five than one shilling—it is a French affair, I believe.—GLATTON.

[60374.]—**Solder for Platinum.**—I have used common soft solder.—GLATTON.

[60375.]—**Lifting Power of Engine.**—ERRATUM.—In my answer to this number in "E.M." of 24th inst., for 46 read 36, twice.—E. CONRY.

[60378.]—**Beer-Raising Apparatus.**—I am much obliged to Mr. Paul Ward for noticing my query, and I have no doubt his idea would be very effective and simple, but not automatic. I have been told that there is an arrangement with two tanks, where one is the air reservoir and the other for water, with the valves so arranged that it works automatically, and with no chance of the water getting into the beer; the party who told me so could not describe how it worked, as he saw nothing outside the tank to regulate the water; so if any of your correspondents know anything of such an apparatus, or how it could be similarly done, a description would oblige.—VINO.

[60381.]—**L. B. and S. C. Locos.**—"Richmond—Portsmouth" has made a mistake in his answer to this query. The following is the correct information asked for:—Nos. 208 to 210 and 213 belong to the Richmond, and Nos. 212 and 214 to 219 to the Gladstone class. The Richmonds have 17½in. by 26in. cylinders. whilst the Gladstones have 18¼in. by 26in. cylinders; also larger boilers. The Grosvenor has 6ft. 9in. driving wheels; the others 6ft. 6in.; otherwise they are identically the same.—NORTH WESTERN.

[60382.]—**Equal Balance.**—The weight, by lowering the centre of gauge of the beam, makes the balance less sensitive, and therefore less accurate. If the knife-edges are not very nearly in a line, the scales are of little value. The middle one should be above the others.—GLATTON.

[60391.]—**Inspector.**—I am sorry I cannot advise you. In such an occupation experience tells beyond everything else.—GLATTON.

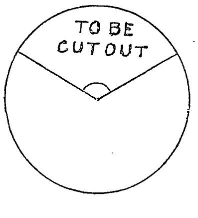
[60392.]—**Magic or Inexhaustible Ink-stand.**—I have heard that these contain a roll of blotting-paper, smeared with a paste of aniline black. What did you find inside yours?—GLATTON.

[60392.]—**Magic or Inexhaustible Ink-stand.**—Many years ago I used some of these, and on one occasion got one smashed by accident. I found it contained logwood chipped very small, and there were traces of some powder and a smell of an iron salt. I would suggest logwood chips—say, half a tumbler full—sulphate of iron, 1oz., powdered inkgall, 1 drachm, gum arabic, ½oz., as a likely mixture for the purpose.—GAMMA SIGMA.

[60395.]—**Water-Motor.**—The water may be unlimited, but it is necessary to know more of it before advising. Is it a river, a torrent, a waterfall, or water in a pipe? If the first or second, what is its speed? If the third, what is its height from the surface of one level to that of the other? If the fourth, what is its pressure and size of pipe, and how fast can it run out—i.e., how many gallons per minute?—GLATTON.

[60403.]—**Revolving Cylinder.**—Make a cylinder of suitable size, with a small hole at bottom, fill with silver sand, and place heavy weight on top; weight to be connected to drum by a cord.—GLATTON.

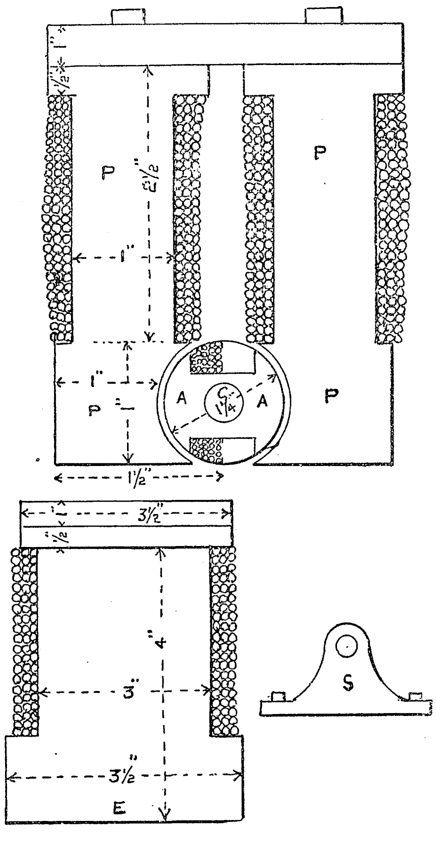
[60405.]—**Chimney Rain Guard.**—You must



cut your sheet of metal in the shape of a circle, and cut out part thus, angle of 120°.—R. S.

[60406.]—**Photographic Exposures.**—Let "N. Y." work with Platt's tables, published in "Beginner's Guide to Photography," Lejeune and Perken, 101, Hatten-garden. Price 1s.—O. O.

[60410.]—**Electro-Motor.**—I send sketch and dimensions, which you will understand if accustomed to dynamos and motors. If you do not know anything of their construction you had better get Mr. Bottone's book, "How to Build a Dynamo." The armature is the H pattern; commutator of two divisions; field-magnets (which may be cast in one piece with pole-pieces) wound with four layers No. 18 cotton-covered; armature with about seven layers No. 16 cotton-covered. If you get the field-magnet cores and pole-pieces cast in one, you will be able to wind the field-magnets in a lathe, and thus save much time and trouble. The crosspiece B is fastened to the heads of the



field-magnets by screws running into holes, drilled and tapped. S is a standard, two of which must be provided, and the pole-pieces must be cast or made with a lug each side, at E, for screwing down to a piece of board. The standards S have similar lugs.—E. CONRY.

[60413.]—**Steam Escape or Relief Valve.**—These are known as "reducing valves," and there are very many forms. Write to Bailey, of Manchester, for list, in which there are some figured.—GLATTON.

[60417.]—**Railway Fish Plates.**—Owing to the constant inspection (on most lines twice every day, except Sunday, and once on that day), nuts on fish-bolts seldom fall off, or allow the bolts to become very slack. Several methods of preventing the nuts turning have been devised (see Patent Specifications). Grover's patent spring washer is probably the simplest and best; they cost something under 3½d. for a joint with four bolts.—LIBRA.

[60418.]—**A Novelty.**—There is another such novelty as "Constant Reader" calls attention to at Plas Newydd, Llangollen, N. Wales. This charming and quaint house was once the home of the far-famed "Ladies of Llangollen." On one of the fine stained-glass windows is a fly, which defies the closest inspection, and has probably been the cause of many fruitless and unended arguments as to its position, in or on the glass. Probably the fly was painted by the same artist as the "Convent" fly, as it is certainly a rare novelty, and I doubt if there are many more such about the country. The fly at Plas Newydd puzzles the best eyesights as to whether it is alive or not.—W. STANLEY SMITH.

[60421.]—**Carriages — Railway Mystery.**—I notice that your correspondent, "Kentish Town," in his reply to this query, p. 94, says that it is impossible for a pistol to fall or ride upon a carriage step; but I think he had not the facts before him as I had when I gave evidence upon the subject. The carriage was one of the Midland 60ft. twelve-wheeled bogies, No. 643, and weighs about 23 tons. Practical experiments proved that it is possible for a pistol to fall from a window and lodge upon the high, continuous footboard. The footboard was rough, and the handle of the pistol was also made rough, and I am convinced that these long carriages ride so steadily (and especially the centre compartments) that, once upon the step, there would be nothing to shake the pistol off. It was found about 2ft. on the London side of the door, or just where it might be expected to fall when the train was in motion. This fact appears to me to show that it did fall from the window, as any murderer who placed a pistol on a step would, of course, put it just under the window; he would hardly stop to think about the laws of falling bodies or motion, or to calculate that the train would move forward during the time the pistol was falling. In further support of my opinion that a pistol would ride upon a step-board, I may say that, on the 28th April, 1885, the Scotch express came from London to Leicester without stopping with a number of brake-blocks, tools, and bolts upon the step of a carriage, these having been left on by mistake.—CLEMENT E. STRETTON, Consulting Engineer, Amalgamated Society of Railway Servants, 40, Saxe-Coburg-street, Leicester, Sept. 25.

[60430.]—**Gravity Daniell Battery.**—Mr. Bottone's reply to "Rho" is hard to reconcile with my own actual experiences obtained from the cell which he recently advised me about (query 60116). Large bubbles of gas will collect under horizontal zinc plate without using any acid, though as a fact a solution of comml. sulphate of copper is very decidedly acid of itself (per test paper). Working electrician, A.S.T.E., told me while watching a cell that the bubbles were of air imprisoned in crystals; but similar bubbles from my own cell exploded when brought to surface under lighted match. Does "C. D. R." hold that a copper-sulphate molecule can dissolve partnership without a zinc-sulphate molecule being formed to make up for it? And if not, whence the gain in free acid which "should be drawn off with a syringe and pure water added"? I doubt if the most careful amalgamation will protect a zinc plate in open circuit after copper has settled on it.—WEALD.

[60434.]—**Crank Movement.**—There is no dead point, because the centre of gravity is always outside the centre of motion whenever the power of wheel and piston are balanced, that is also why it becomes reversible in a simple way. I shift the centre of gravity to the other side of centre of motion. The only complications are a small amount of sliding or rolling motion which keeps continually shifting to balance distance and power, or equal weights on piston and wheel through the whole length of stroke. Would a ball roll down the diagonal of a square quicker than the mean time of same weight on crank? The former is the speed I attain. If "T. C., Bristol," or any other of your able correspondents will tell me the difference they will oblige.—SCOTTY.

[60442.]—**Thimble Battery.**—I shall be happy to write to him if he will send his address, but I do not publish the particulars of my batteries.—CHARLES PENRUDDOCKE, Compton Park, Salisbury.

[60446.]—**Bisulphide of Carbon.**—One fluid ounce = 1·728 cubic inch ∴ five fluid ounces = 8·64 cubic inches. A cubic inch of water weighs 252·5 grains, and as the specific gravity of CS_2 is 1·27, one cubic inch of it will weigh 321 grains, and 8·64 cubic inches = 5 fluid ounces will weigh 2,773 grains. The equation for the combustion of CS_2 is

$$\underset{76}{CS_2} + \underset{96}{3O_2} = \underset{44}{CO_2} + \underset{128}{2SO_2} \quad 172$$

so we have

$$76 : 128 :: 2773 : x$$

from which x = 4,670 grains SO_2 produced. 44·4 cubic inches of SO_2 weigh 32 grains, from which we easily get the volume of 4,670 grains—viz., 6,479 cubic inches = 3·75 cubic feet nearly. The combustion would also produce half this volume of CO_2. I do not know what the querist means by his second query; in what sense does he use the word "saturate"?—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60447.]—**Dynamo.**—To MR. BOTTONE.—The dimensions given are those of the iron ring *unwound*, not with the wire on. The distance between each section will be about ¼in.—S. BOTTONE.

[60448.]—**Legal.**—(1) A married woman cannot claim exemption from Income-tax in the circumstances mentioned by "The Bard." The joint income of husband and wife are held to be only one income. (2) A wife's private property is not liable for any unpaid debts of her husband's at his decease; but the real question here comes to be what is the wife's private property—this depends to a certain extent on whether the marriage took place before or after 1st January, 1883. Get the Married Women's Property Act, 1882, and study it.—B.SC. (Solicitor), Plymouth.

[60448.]—**Married Women.**—(1) The Income-tax authorities persist in assessing jointly the separate income of husband and wife, whom they still treat as one. If, therefore, the two incomes combined do not allow of a claim for exemption or abatement being successfully made, no such claim can be supported as regards each separate income; and so, in this case, the wife cannot claim exemption alone. I believe this rule to be illegal, at all events, in face of the Married Women's Property Act, 1882; but, there it is: and it was lately stated in the Commons that it would not be altered.

(2) The wife's separate estate is not liable for the debts of her deceased husband; of course, provided that it really is her separate property.—FRED. WETHERFIELD, Solicitor.

[60451.]—**Pocket Accumulator.**—You can make one out of the wood of an ordinary cigar box, but mahogany or oak would do better. Soak the wood for a few minutes in melted paraffin wax, made very hot (after having cut the pieces to required shape and bored all necessary holes), and put them together by dovetailing, or very thin brass screws. The right size of the latter is not kept at most ironmongers. You would have to write to Nettlefolds, or some other manufacturers for them; they would be ½in., and as thin as possible. Dimensions of box may be 6in. by 3½in. by 1in. outside. It must have a cover with holes for the connections of plates to come through. To get a good light, you would almost to a certainty require two cells, as I do not think there is any carbon filament lamp made which will light properly with only two volts. I tried to get such a one about twelve months ago, but found the best then obtainable to require nearly three volts, though sold as a two-volt lamp by one of the greatest electrical corporations in this country. Much improvement, however, may have been made since then. For plates, two strips of lead sheet about $\frac{1}{24}$in. or less in thickness, one of which should be completely sewn up in best thin flannel. Box should be lined with hot pitch, or melted indiarubber, but if it is well made, several coats of paraffin wax will do. Lid must be sealed on with pitch or indiarubber, and have filling aperture, closed by wooden plug. You would find two cells the size of the above much more satisfactory than one box divided into two cells, and it would be well for you to buy or make out of guttapercha tissue a small indiarubber bag to hold the cell, in case of a drop or two escaping. Very neat and safe little cells can be made by cutting the tops off two medicine bottles, of such a size as to fit one within the other, leaving sufficient space for the plates, which if of plain lead must be "formed." See back numbers. I sent in a sketch of an electromotor last week in reply to a query, but as it contained a diagram repuiring a woodcut, it was not in time; you will see it next number.—E. CONRY.

[60451.]—**Pocket Accumulator.**—An accumulator to light a lamp of 4 c.p. would not go in an ordinary sized pocket because you would require 4 cells, and if the plates are made too small the charge put into them would scarcely last a few seconds. The following is how I made my battery, which, when charged, lit a 4-volt lamp. Make a guttapercha vessel 3½in. by 5in. by 1in., and divide it into two cells by a strip 4⅞in. by ⅞in. Now cut four plates, each 4½in. by 1¼in., having an ear to each, from $\frac{1}{16}$in. sheet lead; punch as many holes in each plate as you can to within ⅜in. from the ear or top end. Fill up the holes, and also well smear the plates, with a thick paste of red lead and sulphuric acid. Now cut out a piece from some hard wood, 3½in. long, 1in. wide, and ⅛in. thick; pierce it with four slits large enough to allow the ears of the plates to come through (two to each cell), and also, where convenient, two holes should be made and fitted with glass tubes for the purpose of filling the cells. As soon as the red lead has become hard, place the four plates in their positions, and solder the ear of one plate to the ear piece of the next cell. This will leave one free end from each cell; to these a wire or terminal should be soldered. You can now cement on the top, and cover all over except the glass tubes with a composition of 1 of melted pitch and 2 of guttapercha. Having filled the cells three-quarters full with dilute sulphuric acid, connect the wires on a battery or small dynamo, charge, discharge, and reverse every three hours, and let the last charge remain in all night. Do this till you find your accumulator will ring a bell with fifteen minutes charging for about ten. Then only charge one way, and mark the ends in some way so as to know where to connect one next time for charging. This battery, when completed, will light a 3 or 4 volt lamp well during intervals for about two hours. My battery, which is exactly similar to the above, was formed by a 10-cell Daniell telegraph battery, and took a little more than a fortnight. Never charge your accumulator until within an hour or so of its being wanted for use, as it will run down a little by short-circuiting owing to the dampness of the inside. To show how long the charge will remain in such a small battery, I charged my accumulator last Monday evening and let it alone till Friday morning, when it contained sufficient energy to light a lamp for about 30 seconds. I forgot to say that before putting the plates in the cells for good, a piece of indiarubber should be placed between the plates as well as a piece on the two outsides, and held by a piece of asbestos fibre, not indiarubber rings, as they rot and fall to pieces in time. This prevents the plates from touching each other, as well as keeps them from shaking from side to side.—Y. E. E., Walworth.

[60452.]—**Loco. Question.**—The engine with the high boiler is considered to run easier than one with a low boiler, because it makes better use of the springs on which it is carried.—NOMEN.

[60452.]—**Loco. Question.**—The steadiness of a loco. is more marked when the position of her boiler is kept as low as practicable for the cranks to clear. An engine with her boiler placed high above the frame is more susceptible to oscillate laterally through the swerving motion of the frame, and especially is this more apparent at high speeds when traversing curves, crossing points, and other variable inequalities of the road.—W. R., B.A.

[60452.]—**Loco. Question.**—There was an article in last week's *Engineer* stating that the higher the engine the smoother it runs; but I think where the boiler overhangs the rails, it must make the engine run very rough. For example, the Dreadnought on the N. W., and the 2352 class of goods engines on the G. W., where 7ft. driving wheels are used, the boiler must be made to go between the wheels, thus preventing the boiler overhanging the rails.—NORTH WESTERN.

[60452.]—**Loco. Question.**—The greater the height of a locomotive boiler above the rails, the higher is the centre of gravity, and therefore the engine will run smoother. The centre of gravity may be taken as the point from which a pendulum is swung. Let this point be the apex of a triangle, and the gauge of the rails its base; the length of the pendulum is a line drawn from the apex perpendicular to the base. When the pendulum swings past the sides of the triangle, the engine will overturn. To demonstrate this, fix three nails in a wall at heights of 5ft. 6in., 6ft. 6in., and 8ft. Mark off the base properly underneath each, and make a pendulum. Swing the same pendulum on the nail, lengthening the rod each time, so that the bob is on the base line, and it will be seen that the longest pendulum has the slowest and steadiest motion.—O. W.

[60453.]—**North British Engines.**—The following are dimensions of above, viz.:—Diameter of driving and trailing wheels, 7ft.; bogie, 3ft. 6in. Cylinders, 18in. by 26in. Boiler, 10ft. 3½in. by 4ft. 4in. Firebox: length, 5ft. 7½in.; breadth, 4ft. 1in. Diameter of tubes, 1⅝in.; length, 10ft. 7⅝in. Heating Surface: firebox, 119 sq. ft.; tubes, 983 sq. ft.; total, 1,102 sq. ft. Grate area, 27 sq. ft. Weight of engine and tender, 72 tons 15cwt. Capacity of tender: coal, 5 tons; water, 2,550gals.—NORTH WESTERN.

[60454.]—**Wind-Motor for Electric Lighting.**—Such a wind-motor as you describe must be a clever thing, and if of any reasonable size and of sufficiently simple construction to avoid getting out of repair often, would, I should think, be a valuable invention, as there are many places in this country where the wind power, during 18 hours out of the 24, is strong enough to charge accumulators sufficiently to make them light lamps enough for any ordinary dwelling-house for the remaining six hours. Do not you forego a lot of possible power, however, if "the machinery driven by the motor runs at one uniform speed, however much the motor may vary in speed"? Do I understand you rightly that all increase in wind power after a certain point makes no difference to the speed of the dynamo, or do you utilise the wind increase for a separately-exciting dynamo while keeping the speed of the charging dynamo constant?—E. CONRY.

[60457.]—**Winding Gramme Armature.**—An illustrated article on winding Gramme armature appeared in the *Electrical Review* for August 6th, 1886. The *Review* is published at 22, Paternoster-row.—G. BOWRON.

[60457.]—**Winding Gramme Armature.**—TO MR. BOTTONE.—You will find directions for winding Gramme armature at pp. 47 and 94, Vol. XLIII. of the "E. M." Referring to the means of avoiding self-induction, this is impossible to obviate entirely; but it may be diminished very much by laying on only one layer of wire over the core of the armature. This necessitates a large and massive armature.—S. BOTTONE.

[60457.]—**Winding Gramme Armature.**—If the form of your armature as regards fastening on to the spindle admits it, have a 4ft. length of strong board screwed down to a carpenter's bench or fixed table at right angles to it, at a convenient height, and fasten the armature core down by two strips or blocks of wood connected by loose bolts and nuts through the ends, one block passing through the core and the other under the board, and both tightened up by the bolts. This will hold the core firm. You can then screw together or cut out two pieces of wood like tuning forks, with just space enough to take the core between the legs, and having long screws through the ends to similarly tighten them up, and by this means fix them on the core so as to inclose between their sides just the exact space you intend to allow for one coil. You can then wind the coil in the ordinary way, fastening the inner end to the blocks so as to keep a few inches of it free, winding in layers, as closely and evenly as possible, taking where necessary the strand over the previous turns of the layer inside the core, so as by making up for the difference of space between inside and outside to get the maximum number of coils into the outside layer and keeping the wire always as tight as you can pull without snapping the strand. With anything over No. 16, you can pull as hard as you like. A convenient way is to wind off as much wire as will just about make one coil on a strip of narrow board like a fishing-line; it is thus easy to pass it through the core. Of course, the core must first be properly covered with tape or other similar substance, and see there are no sharp edges or corners or jags on it. The above applies more particularly to laminated armatures built up on rods, as most of them are now, and joined to the spindle by brass caps or radiated castings fastening by nuts on to the ends of the rods, but may be useful for other sorts. There is no difficulty in bringing the ends together at the finish.—E. CONRY.

[60459.]—**Crane Chain.**—The old query of impact in a different form. The chain offers an elastic resistance, which depends on sectional area of chain as well as form of link, and even number of links. If the chain gave 1in. under the strain, it would be equivalent to a dead load of $25 \times 9 = 225$ tons, and very little short of the probable breaking strain.—T. C., Bristol.

[60462.]—**Testing Lightning Conductors.**—Tests of lightning conductors are made to find the resistance of the conductor and of the earth connection. The earth resistance can be ascertained by making connection with the bottom of the rod. The resistance of the rod can be found by fixing a wire to the top.—G. BOWRON.

[60462.]—**Testing Lightning Conductors.**—TO MR. BOTTONE.—Calculate height of tip of conductor from ground, measure off twice this length in No. 16 covered copper wire; connect one end of this wire to galvanometer, and the other end to one terminal of battery, the other terminal being connected to other binding screw of galvanometer. Note the deflection produced. Next cut wire in half; attach one end to tip of conductor so as to make good electrical contact; lead the other end of wire to the ground. Clean the ground end of lightning rod, connect one terminal of battery to this, the other terminal being attached to one binding screw of the galvanometer, while the wire led from tip is connected to the other. Deflection will take place if the conductor is unbroken, and if the conductor is fairly sound the deflection will be considerably greater than it was when the double length of wire was used. To know whether the conductor, though unbroken, has got thin at any point, it would be necessary to measure the resistance with bridge and coils, calculating the resistance which the rod should have if perfect, and comparing the trial with the calculated result.—S. BOTTONE.

[60463.]—**Lantern Slides.**—The greenish tint is certainly not due to the wet collodion process; it may be albumen, but more like pyro-developed gelatine.—S. BOTTONE.

[60463.]—**Lantern Slides.**—The green colour mentioned by "B." is caused by the toning of the collodion transparency; it will not answer with dry plates, nor is it needed, as good tone can now be obtained on dry plates equal to that on collodion. I should be glad to send "B." samples for him to see.—A. PUMPHREY.

[60465.]—**Sewing Machine.**—Querist does not say whose machine, but, if it is Singer's, I have been troubled the same way, and find it is mostly caused by needle not descending low enough, and so is cut by edge of shuttle. Remedy is obvious. It may also be caused by rough eye in needle, by bad winding of spool in shuttle, or by too great tension. See that needle is central in hole of needle-plate, and buy a book of instructions, price 1d.—T. C., Bristol.

[60468.]—**Action of Steam.**—I notice engine has cranks at right angles, and the exhaust pipe of h.p. cylinder is therefore the receiver, and acts as such. Following the course of one stroke, steam is admitted at 50lb., and probably cut off at half-stroke; the steam therefore expands and falls to $(17 + 4) = 21$lb. at A D. This is now exhausted, but steam already in receiver prevents a perfectly free exhaust, and this, with friction of passages, gives a back-pressure of 4lb. at A, which is raised to 7lb. at B, owing to the valve in l.p. cylinder not being open yet. This valve is now opened, and the steam, having to fill a larger space, falls to 2½lb. at E; but this is not noticed to so great an extent at B, owing to rapid movement of h.p. piston; it is, however, noticeable by slope of exhaust line in diagram. The valve of h.p. cylinder is now closed, and the steam in cylinder is compressed, and rises to 17lb. at C, and continues to do so until opening of port for steam, at which time it should nearly equal the boiler pressure. I think your difficulty is that you expect to see, say,

20lb. at E, but you must remember that receiver has to be refilled as well as valve-chest of l.p. cylinder, and this reduced the pressure to perhaps 5lb., which is further reduced on opening of l.p. valve.—T. C., Bristol.

[60469.]—**Hygrometric.**—If V is the volume in cubic inches of some air under a pressure, H, and temperature t, E its hygometric state, F the tension of water vapour at the given temperature, and α the co-efficient of expansion for gases, then the weight in grains is

$$= \frac{0{\cdot}31\ V\ (H - \frac{3}{8}\ F\ E)}{(1 + \alpha\ t) \times 760}$$

If the air be saturated, then E = 1. What does "Postulata" mean by a "rule for the correction of the barometric height of millimètres and centigrade scale"? I would have worked out an example for him, but he does not give the pressure.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60476.]—**Dynamo.**—To MR. BOTTONE.—Bring the two ends of the wire on the fields out so as to connect one to each brush; and take off the current for the outer circuit from these same brushes also. This is called "shunt wound." You should be able to light six twenties of 48 ohms resistance; 2,000 revolutions is rather high. I should think 1,500 would be ample; but trial alone can decide.—S. BOTTONE.

[60479.]—**Engineering Formulæ.**—In formula No. 1—

$$D = \sqrt{\frac{8500 \times H}{\sqrt{P} \times R \times S}}.\quad P = \frac{8500^2 \times H^2}{D^4 \times R^2 \times S^2}$$

$$R = \frac{8500 \times H}{D^2 \times \sqrt{P} \times S}.\quad S = \frac{8500 \times H}{D^2 \times \sqrt{P} \times R}$$

In formula No. 2—

$$A = \frac{C \times H \times 4}{(P - 16) \times 7 \times R \times S}$$

$$P = \frac{(C \times H \times 4) - (112 \times A \times R \times S)}{7 \times A \times R \times S}$$

$$R = \frac{C \times H \times 4}{(P - 16) \times 7 \times A \times S}$$

$$S = \frac{(C \times H \times 4)}{(P - 16) \times 7 \times A \times R}.$$

—RED LIGHT.

[60479.]—**Engineering Formulæ.**—

$$1.\text{—}H = \frac{D^2 . \sqrt{P} . R . S}{8500}$$

$$\text{From 1}\begin{cases} D = \sqrt{\dfrac{8500\ H}{\sqrt{P} . R . S}} \\ P = \left(\dfrac{8500\ H}{D^2 . R . S}\right)^2 \\ S = \dfrac{8500\ H}{D^2 . \sqrt{P} . R} \end{cases}$$

$$2.\text{—}H = \frac{14 . A . R . S\ (P - 16)}{8 . C}$$

$$\text{From 2}\begin{cases} A = \dfrac{8 . C . H}{14 . R . S\ (P - 16)} \\ P = \dfrac{8 . C . H}{14 . R . S . A} + 16 \\ R = \dfrac{8 . C . H}{14 . A . S\ (P - 16)} \\ S = \dfrac{8 . C . H}{14 . A . R\ (P - 16)} \end{cases}$$

—T. C., Bristol.

[60479.]—**Engineering Formulæ.**—(1):—

$$H = \frac{D^2 \times \sqrt{P} \times R \times S}{8500} \ \ldots\ldots\ldots\ldots (a)$$

$$D = \sqrt{\frac{8500 \times H}{\sqrt{P} \times R \times S}} \ \ldots\ldots\ldots\ldots (b)$$

$$P = \left(\frac{8500 \times H}{D^2 \times R \times S}\right)^2 \ \ldots\ldots\ldots\ldots (c)$$

$$R = \frac{8500 \times H}{D^2 \times \sqrt{P} \times S} \ \ldots\ldots\ldots\ldots (d)$$

$$S = \frac{8500 \times H}{D^2 \times \sqrt{P} \times R} \ \ldots\ldots\ldots\ldots (e)$$

(2):—

$$H = \frac{2 \times A \times (P - 16) \times 7 \times R \times S}{C \times 8} \ \ldots (a)$$

$$A = \frac{C \times 8 \times H}{2 \times (P - 16) \times 7 \times R \times S}. \ (b)$$

$$P = \frac{C \times 8 \times H}{2 \times A \times 7 \times R \times S} + 16 \ \ldots (c)$$

$$R = \frac{C \times 8 \times H}{2 \times A + (P - 16) \times 7 \times S}. \ (d)$$

$$S = \frac{C \times 8 \times H}{2 \times A \times (P - 16) \times 7 \times R}. \ (e)$$

I suppose this is what "Engineering, Manchester," requires.—YORICK.

[60479.]—**Engineering Formulæ.**—

(1)
$$D = \sqrt{\left(\frac{8500\ H}{\sqrt{P} . R . S}\right)}$$

$$P = \left(\frac{8500\ H}{D^2 . R . S}\right)^2$$

$$R = \frac{8500\ H}{D^2 . \sqrt{P} . S}$$

$$S = \frac{8500\ H}{D^2 . \sqrt{P} . R}$$

(2)
$$A = \frac{4\ C . H}{7\ (P - 16)\ R . S}$$

$$P = \frac{(224\ A . R . S) + 8\ C . H}{14\ A . R . S}$$

$$R = \frac{8\ C . H}{14\ A . (P - 16)\ S}$$

$$S = \frac{8\ C . H}{14\ A . (P - 16)\ R}$$

—R. E. F.

[60479.]—**Engineering Formulæ.** — Wanted D, P, R, and S:—

$$(1)\ H = \frac{D^2 \times \sqrt{P} \times R \times S}{8500}$$

Multiplying both sides by 8,500, and transposing $D^2 \times \sqrt{P} \times R \times S = 8{,}500\ H.$

$$D^2 = \frac{8{,}500\ H}{\sqrt{P} \times R \times S}$$

Dividing both sides by $(\sqrt{P} \times R \times S)$.

$$\therefore D = \sqrt{\frac{8{,}500\ H}{\sqrt{P} \times R \times S}}$$

Taking square root of both sides.

$$\sqrt{P} = \frac{8{,}500\ H}{D^2 \times R \times S}$$

Similarly, dividing both sides by $(D^2 \times R \times S)$.

$$\therefore P = \left(\frac{8.500\ H}{D^2 \times R \times S}\right)^2$$

Squaring both sides.

R and S can be found in the same way. These forms are the nearest values you can get for D and P, and similarly for the others, without substituting numerical values for the letters. If you do this, of course you can multiply out, and work each expression down to a single numerical quantity.

$$(2)\ H = \frac{2 \times A \times (P - 16) \times 7 \times R \times S}{C \times 8}$$

Wanted A, P, R, and S.

$$2 \times A \times (P - 16) \times 7 \times R \times S = 8\ H\ C$$

Multiplying both sides by C × 8, and transposing.

$$A\ [(P - 16) \times 7 \times R \times S] = 4\ H\ C$$

Dividing both sides by 2, and re-arranging.

$$A = \frac{4\ H\ C}{(P - 16) \times 7 \times R \times S}$$

Dividing both sides by co-efficient of A.

$$(P - 16) = \frac{4\ H\ C}{7\ A\ R\ S}$$

Similarly.

$$P = \left(\frac{4\ H\ C}{7\ A\ R\ S}\right) + 16$$

Adding 16 to both sides.

R and S may be similarly found.—E. CONRY.

[60479.] — **Engineering Formulæ.** — The querist should put his eqns. 1 and 2 in this form—

$$(1)\ \ 8500\ H = D^2\ R\ S\ \sqrt{P}$$
$$(2)\ \ 4\ C\ H = 7\ A\ R\ S\ (P - 16)$$

Then from the first he has—

$$D = \sqrt{\frac{8500\ H}{R\ S\ \sqrt{P}}};\quad P = \frac{(8500)^2\ H^2}{D^4\ R^2\ S^2}$$

$$R = \frac{8500\ H}{D^2\ S\ \sqrt{P}};\quad S = \frac{8500\ H}{D^2\ R\ \sqrt{P}}$$

And from the second—

$$A = \frac{4\ C\ H}{7\ R\ S\ (P - 16)};\quad R = \frac{4\ C\ H}{7\ A\ S\ (P - 16)}$$

$$S = \frac{4\ C\ H}{7\ A\ R\ (P - 16)};\quad P = \frac{4\ C\ H}{7\ A\ R\ S} + 16.$$

—NO SIG.

[60480.]—**Conic Sections.**—This is a similar query to the above, only in a literal form—

$$e = \frac{2\ a - e . D\ A'}{2\ a + D\ A'}$$

from which—

$$2\ a\ e + e . D\ A' = 2\ a - e . D\ A'$$

or—

$$2\ a = 2\ a\ e + 2\ e . D\ A'$$

striking out the numerical coefficient of each—

$$a = a\ e + e . D\ A'$$

or, in another form—

$$a = e\ (a + D\ A').$$

—NO SIG.

[60480.]—**Conic Sections.**—If the querist is not able to solve this very simple fractional equation, I would advise him to give up the study of conics until he has a wider knowledge of algebra. Multiplying each side of the equation by $2\,a + D\,A'$ (whereby its value is not altered), we get $2\,a\,e + e . D\,A' = 2\,a - e . D\,A'$; transposing, $-2\,a = -2\,a\,e - 2\,e . D\,A$; changing signs and dividing by 2, $a = a\,e + e . D\,A'$.—R. E. F.

[60480.]—**Conic Sections.**—

$$e = \frac{2a - e . D\ A'}{2a + D\ A'}$$

To find $a = ae + e . D\,A'$.

$$2a - e . D\ A' = e\ (2a + D\ A')$$

Multiplying both sides by denominator, and transposing.

$$= 2ae + e . D\ A'$$

Multiplying out

$$2a = 2ae + e . D\ A' + e . D\ A,$$

adding $e D\,A'$ to each side.

$$a = ae + e . D\ A',$$

collecting and dividing by 2.

—E. CONRY.

[60480.]—**Conic Sections.**—First multiply the equation by $2\,a + D\,A'$, thus—

$$2\,a\,e + e . D\,A' = 2\,a - e . D\,A'$$
$$\therefore\ 2\,a\,e + 2\,e . D\,A' = 2\,a.$$

Dividing this by 2, we get $a = a\,e + e . D\,A'$—RED LIGHT.

[60481.]—**Polarised Light.**—Whether good artificial tourmalines are in the market or not I would not like to say. If they are, the scientific societies who work in the interest of the public should cause it to be known. The high prices "E. W." mentions are forbidding to badly-paid science teachers, who would have to spend half their salaries to procure only a few of the optical instruments necessary for demonstration. I may mention that I get fairly good tourmalines from Paris at a fourth the price he mentions, and still think them unnecessarily dear, though, being scarce minerals, one must not grumble.—A. CAPLATZI.

[60482.]—**Feeble Sum—Carbon in Steel.**—I have taken the liberty of altering the title to one that seems to me more suitable. An error in weight of ·004grm. in the case of the 5 per cent. steel and of ·002 in that of the 1 per cent. steel would make a difference of ·01 per cent. of C. From this the requisite accuracy of the balance may be judged.—B. B.

[60483.]—**Electro-Motor.**—To MR. BOTTONE.—If you will kindly refer to p. 570, Vol. XLI., of the "E. M." you will find both description and illustration of a motor with Siemens' armature, 4in. by 1½in., which works with three bichromate cells; if one gallon capacity, will give ⅙ horse-power easily.—S. BOTTONE.

[60484.]—**Twilight.**—"Laura" has confounded 18° of angular measure with degrees of geographical longitude—quite another thing. The lines on earth dividing day from twilight, and twilight from night, are two parallel circles, about 1,250 statute miles apart, everywhere and always. Twilight begins or ends when the sun is 108° from your zenith; so that a spherical triangle whose points are at the pole, zenith, and sun will give you the time. The shortest possible twilight is near 70 minutes; and that only at the Equator the day of an equinox. At other times it is longer, even at the Equator—at the solstices above 80 minutes, even there.—E. L. G.

[60485.]—**Waterproofing Double Textures.**—"Waterproof" must not bring the two coated surfaces together till all the solvents are evaporated; they will then require only the slightest pressure to make them adhere to each other.—N. PUMPHREY.

[60487.]—**Dynamo.**—To MR. BOTTONE.—If the lamps are coupled up in parallel so as to bring the resistance down to 1/12th of that of a single lamp, the dynamo would light them easily; but if the lamps were arranged in series so that the resistance became twelve times as great, or 300 ohms, then 300 volts would be needed. The shocking sensation will depend whether the current is continuous or broken: if the latter, 20 or 30 volts can be distinctly felt, if the former 400 volts are supportable by some people without any serious inconvenience.—S. BOTTONE.

[60487.]—**Dynamo.**—A dynamo giving 25 volts, 12 ampères, would light 12 of the lamps in parallel. A dynamo giving 300 volts, 12 ampères, would light 144 lamps in 12 parallel sets, each set having 12 lamps in series. As each dynamo gives twelve times the number of ampères required for one lamp, 12 lamps must be put in parallel. As the second dynamo gives twelve times the number of volts required for one lamp, therefore 12 lamps must be put in series. Again, volts × ampères given by dynamo divided by the volts × ampères required by one lamp gives the number of lamps the dynamo will light.—G. BOWRON.

[60488.] — **Medical Battery.**—I have seen Leclanché cells made with a porous diaphragm of

blotting-paper instead of the porous pot, so should certainly think canvas would do. The chief thing to be guarded against would be the bag sinking to one side or other and resting against the zinc, as this would probably result in a short circuit; but you can guard against this by fastening the top of the bag to the top of the jar by some cross-stick arrangement, or wooden cap, or sealing compound. The difference in price of the peroxide means simply difference in quality; the cheaper the price, the more adulteration there is in it. I should suggest a middle course as to price. For pure needle-peroxide, 8d. to 1s. would not be too much. The cheapest sort will do for a time; it is only a question of how long it lasts.—E. CONRY.

[60489.]—**Electric Lighting.**— TO S. BOTTONE.—If you were to work steadily for a week, without stopping to take meals, you might run your four 10c.p. lamps for an hour on Sunday evenings; and I think no one would grudge you the enjoyment that the lights would afford you.—S. BOTTONE.

[60492.]—**Mechanical.**—Find the least common multiple of the two numbers of teeth, and divide this by the number of teeth in each wheel, the quotients will be the number of turns each wheel will make to bring the same two teeth together. Thus, in the case given, l.c.m. of 44 and 28 is 308; and 308 divided by 44 and 28 gives 7 as the number of turns made by the wheels and 11 by the pinion. —PURDUE.

[60492.]—**Mechanical.**—Find the greatest common number that will divide the number of teeth in each wheel. This is called the greatest common measure. Divide either wheel by this number, and it will give you the number of turns the other wheel must make before the same teeth again come in contact. Thus, in wheels of 28 and 44 teeth the greatest number that will divide both is 4, and dividing 28 by 4 gives 7 turns for the large wheel and 11 turns for the small wheel. If there is no whole number that will divide them, the turns will be inversely as their number of teeth. Thus, wheels 29 to 35 teeth, the smaller wheel must revolve 35 times, and the larger 29 times.—T. C., Bristol.

[60492.]—**Mechanical.**—Find the "greatest common measure" of the two numbers. Then divide the number of teeth in the larger wheel by this G.C.M., the quotient gives the number of revolutions, or turns, the smaller wheel makes to bring the same two teeth together. Thus, wheels of 44 and 28 teeth—

G.C.M.— 28)44(1
28
—
16)28(1
16
—
12)16(1
12
—
G.C.M. = 4 .... 4)12(3
12

$$\frac{44}{4} = 11 \text{ revolutions of smaller wheel}$$

$$\frac{28}{4} = 7 \text{ revolutions of larger wheel.}$$

Proof:—28 teeth × 11 revs. = 308 teeth passing the line of centres.

44 × 7 = 308 also.

—YORICK.

[60494.]—**L. and B. S. C. Locos.**—Silverdale belongs to the "D." class. Principal dimensions, viz.:—Driving and leading wheels, 5ft. 6in.; trailing, 4ft. 6in. Cylinders, 17in. by 24in. Chamberry to the "E." class; it is a six-coupled tank, with cylinders 17in. by 24in. All wheels 4ft. 6in. —NORTH WESTERN.

[60495.]—**Britannia Developer.**—Probably it is your dark room, or camera, which is at fault, and not the developer; actinic light getting in somewhere. However, try the pyro potash developer (a recipe for Beach's is given in last number), it does well with Britannia plates, as with all others.—B.SC., Plymouth.

[60495.]—**Britannia Developer.**—If you are a beginner, I think it is a mistake for you to begin with "Britannia" present make of plates, as I have heard a great deal that is highly unsatisfactory about them. They used to be first-class, but now have been cheapened, which seems to have been fatal. I always use "Ilford," which are the old make "Britannia," and are first-rate in every way. I have never heard anyone complain who uses these plates.—R. A. R. BENNETT.

[60495.]—**Britannia Developer.**—One of the following three causes is at work to produce your hazy pictures: 1st. Your plates have been exposed to diffused light. (To see if this is the case, give one to a good photographer, and see if they fog in his hands.) 2nd. Your dark room allows light to enter. Either the blind is too light in colour, or you are working with too strong a light. 3rd. Your measure and dishes are not clean; and perhaps your developing solution was made up carelessly as to weight, or got messed.—S. BOTTONE.

[60496.]—**Telephone Fixing.**—I have not had the pleasure of reading the paper by Mr. Preece to which you refer; but from what I know of telephones should certainly prefer a double line to a single line and earth return, for in the former case you get, unless other wires are very close, no more induction than that of the one wire on the other, which is not much; but with an earth return, you may get the click of the sounder from half a dozen different returns of various telegraph lines, each of which will faithfully repeat its messages on the diaphragms of your telephones, to the spoiling of their utility, while you may also have to contend with the continuous rumble of earth currents, and either of these impediments are, with an earth return, very difficult to get rid of. On the score of expense, however, the earth return is generally used.—E. CONRY.

[60497.]—**Acoustic Telephones.** — Ordinary electrical insulators will not do to convey these wires round corners; but the querist will find all the information that he requires on page 447, No. 1,041.—W. E. S.

[60497.]—**Acoustic Telephones.**—You have not got the conducting wire strained tight enough. Try and arrange so as to get the wire strained as tight as possible without the insulators, and then still further tighten it by pulling it on to the insulators with the hands.—E. CONRY.

[60503.]—**Photography.**—Dry plates at 1s. a dozen are not usually good; for 1s. 6d. you can get several first-rate makes, including Marion's "Ilford" and Fry's "German."—R. A. R. BENNETT.

[60503.]—**Photography.**—(1) For quick-acting portrait lenses the ratio of aperture to focus should only be 1 : 3; for ordinary, 1 : 4; diameter of a lens for cabinets and cartes should be about 3½in. (2). Instantaneous. (3) Depends more on the photographer than the plate; an experienced artist can produce first-class portraits with a good lens on cheap dry plates.—B.SC., Plymouth.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last, "B. B." has replied to 59943.

Charterhouse Science and Art School.—The winter session of this, one of the largest science and art schools in the United Kingdom, will commence to-morrow, under the presidency of the Rev. Henry Swann, M.A. During the late session about 850 students, mostly elementary teachers, availed themselves of the privileges afforded by this institution, and of that number upwards of 600 presented themselves for examination, and were successful in obtaining a number of 1st class certificates, and also a goodly number of honours' certificates, awarded by the Science and Art Department. Of the 13 national scholarships granted by the Government, three were carried off by London candidates, all of whom were students of this institution. Instruction of a practical character is given in most of the sciences at a nominal fee; whilst in art, at an equally low rate, students can be advanced in their studies. Those who have leisure can, at a moderate charge, attend the day classes in art; day classes will also be held to prepare candidates for matriculation (Lond.), the clerical, medical (including dental), legal and other examinations. Students who aim at becoming proficient in chemistry (organic and inorganic) have the opportunity of working in a well-fitted laboratory, capable of accommodating 60 students. Full particulars of the classes may be obtained from Mr. C. Smith, organising secretary, and we may mention that the institution is located within easy distance of communication to all parts of London.

QUERIES.

[60506.]—**L.T. and S.E. Side Tank Engines.**—Can anyone inform me what is the weight of the London, Tilbury, and Southend side tank engines, built by Sharp and Stewart, stationed, I believe, at Fenchurch-street station?—NOMEN.

[60507.]—**Electrical.** — I require to move a lever through an arc of ½in., against a pull of 3lb. What sized solenoid or electro-magnet shall I require with a small battery of, say, one cell? Perhaps some of your correspondents will kindly tell me the most economical proportions to use between size of battery and solenoid. I also require to fire a small alarm gun from the same battery. Will it be necessary to use a coil?—E. C. H.

[60508.]—**Aureolin.**— There is a fine yellow water-colour pigment, which goes by the name of "aureolin." Where can I find any account of its composition and preparation?—W. A. B.

[60509.]—**Gold in Quartz.**—Will one of your readers favour me with details of some simple method of discovering the presence of gold in quartz rock, and how quantitative results are best obtainable?—GLOBE.

[60510.]—**Mathematical.**— Will any reader kindly explain why the average value of the cosine of an angle which varies between 1 and 0 four times is equal to π (3 1-7)?—A. F.

[60511.]—**Boys' Marbles.**—How and where are these made? I mean, of course, stone ones, which "J. K. P." well calls "wonderful," the most spherical things seemingly in nature or art. It does not follow the fittest for his experiments (Reply 59854), as they specially need uniformity of size, more attainable by bullets cast in one mould. If he puts three marbles in contact on a plane mirror, and another plane over them, I doubt if he will often get the two planes very parallel.—E. L. G.

[60512.]—**Mathematical.** — Can anyone solve the following equation? $a = x^2 + y,\ b = x + y^2$. It is beyond me, a—YOUNG MECHANIC.

[60513.]—**Pianoforte Repairs.**—TO MR. DAVIES.—I have a horizontal grand, by Brinsmead, with spring and loop action. Some of the keys stick through damp, and some springs are broken. How can I get the keys out to ease them after I have removed the action from the piano? Should I take out the hammer rest and draw the key out from behind? If so, how am I to lift up all the hammers at once to get the rest in again?—APOLLO.

[60514.]—**Silvertown Firing Battery.**—Can anyone tell me the internal arrangements of the old pattern cell used for this purpose? It had a large zinc surface (so I am told), and the internal resistance was very small, no porous pot being used. How was the mixture of manganese and carbon kept together and away from the zinc? Any information will much oblige—M.M.I.SC.S.

[60515.] — **Vibrator.** — The arrangement of carbon electrodes, &c., in letter 26285 is not very clearly explained. Can, or rather will, "Vibrator" oblige myself and others by giving full details with measurements, &c., as a good transmitting telephone within the capabilities of an amateur to construct will, to use the ordinary quack medicine vendor's expression, "fill a long-felt want?—LINNÆUS.

[60516.]—**Railway Locomotive Returns.**—Will "G.," or any other correspondent, kindly give me the number of locomotives owned by the L.B. and S.C., L.C. and D., S.E., and all the Scotch companies ending June, 1886?—NORTH WESTERN.

[60517.]—**L.B. and S.C. Engines.**—Would some correspondent kindly give me the following information? I cannot refer to back numbers. Wanted, the numbers and names of all engines numbered above 400, and to what class they belong, with full dimensions and where stationed. Also full dimensions of the Gladstone, Richmond, and E classes; and boiler and firebox dimensions of the Westminster and Ferrier (also number of tubes, heating surface of tubes and firebox) classes. Are there any more engines like the Barcelona, which is slightly larger than the rest of the E class?—NORTH WESTERN.

[60518.]—**The Starry Heavens.**—In the Entrance Hall of the Ordnance Survey Office at Southampton, there is (or was formerly) a large map of the starry heavens, delineated in accordance with the sentence in Latin placed over the top: "Cœli Besse Tenus Liceat Convexa Tuera," "As far as two-thirds of heaven it is possible to see its space." I do not think that this is far from being the truth, but it has been disputed. Will any of our astronomical contributors to the "E. M." kindly show by diagram (or explain) how this is made to appear?—ONE NOT AN ASTRONOMER.

[60519.]—**Large Induction Coil.**—TO MR. S. R. BOTTONE.—Will you please say how much larger and what lengths of wire I should require to make an induction coil, say, twice the strength of the one you describe in No. 1121 of the "E. M."?—M. D.

[60520.]—**Kauri Gum Solvent.**—Will any correspondent kindly inform me what is used commercially for dissolving New Zealand Kauri gum? I know that chloroform and strong scents will do it, and gas tar will mix with it and melt it; but what is used for dissolving it in large quantities for making varnish? Any additional information as to details of process will much oblige—TEST.

[60521.]—**To Mr. Lancaster.** — Thanks for your reply. My aneroid is a pocket one, about 3in. in diam. It is compensated, and appears to be highly sensitive to atmospheric variations. Its outer circle can be rotated; but it is only divided for a very short part of its circumference. If one of its terminal lines is made coincident with the 30in. line of the dial, its other last line will coincide with 30·440. Its central line is numbered 0, and the scale on either side of this runs up to 10. I think its smallest subdivisions are 45ths of an inch. What is its use?—X.

[60522.]—**Evaporation.**—I shall be glad to know what is the average evaporation from an ordinary fresh-water pond, say, on a calm day at a temperature of 60° Fahr.?—SOL.

[60523.]—**To Mr. Striffler.**—I have read, with much

interest, your letter on page 395, Vol. XLIII., on the Daniell cell for electric lighting. I wish to light a room 22ft. by 16 by 12 high with incandescent lamps. Would you kindly tell me how many lamps, and of what power, and the number and size of cells I should require, the maximum time of continuous lighting being six hours? The room is used as an ordinary sitting room. I should like to use "Bernstein" lamps, as, I believe, they take very little power. You mention in your letter the copper plate is to be 50in. by 10. I presume, as the plate is corrugated, this so shortens the 50in. so as to make it go once round the cell. Would not a canvas bag do in the place of a porous pot?—NEMO.

[60524.]—**Hide and Feather Press for China.**—Which is the best hydraulic or other press for hand power, exercising a power of 100 to 150 tons, and turning out bales of about 4ft. by 1ft. 6in., weighing about 4cwt.? Presses requiring solid foundation inadmissible, simplicity and solidity indispensable.—NATIVE POWER.

[60525.]—**Bewitched Barometers.**—Now that our erudite and too-long absent friend, W. J. Lancaster, has returned to us, I shall esteem his consideration of the cause why my barometer has lately become unreliable. For more than half the past abnormally wet month of Aug., I found that as the mercury rose the rain came down, and when the mercury fell the rain ceased. Again, during the past few days of thick foggy weather, I have observed the same phenomena. I was an advocate of the uses and merits of barometers, and frequently told the farm workmen to consult the mercury indication, and be guided by its truthful revelation. Now I have to bear the labourers' free and uncomplimentary jokes. Thus, No. 1 comes on and says, "Master, how has your anney lied (aneroid) this morning." Soon appears No. 2: "Fine morning, sir; is the glass down?" the word "glass" said with an emphasis as though I am not a member of the Blue Ribbon army. Then No. 3 touches his hat (this man has been to Nebraska), "I reckon, boss, things are going up; look out for an anticyclone and a miniature carthquake." Then No. 4 feels confident to tell me to take my glass away to the optician who sold it to me, and get back my money. No. 5 remarks that I could foretell the weather better by a consideration of the changes of the moon; and, with sly irony, No. 6 insinuates that mine are "The kind of instruments used by the man who makes weather for the newspapers." Now I am sure Mr. Lancaster, who is himself often worried, though not as I am with rustic chaff, will sympathise with me and tell me why those erratic readings occur. Have recent cosmic influences produced them? Up to this my barometer behaviour was all I could desire, and now it seems as though some occult influence has bewitched it.—E. B. FENNESSY.

[60526.]—**Cable Winch.**—Could one of our kind readers give a rough sketch, with dimensions, of a winch as used by cable men for transferring telegraph cables from lighters to tanks of temporary cable ships, and vice-versa?—ANTIPODEAN.

[60527.]—**Medical Coils and Paralysis.**—Will Mr. Bottone, "W. S. W.," or any correspondent experienced with medical coils and batteries, kindly give me the following information required? (1) Is the medical coil described by Mr. Bottone in last week's "E. M." suitable for a case of paralysis in the legs, and, if so, how should it be applied? (2) What would be the difference in the effect between using the constant current from the primary coil and the constant current from a galvanic battery consisting of 50 or 60 small cells, but no coil? (3) Is there any difference between the secondary current from Mr. Bottone's coil and the current from a galvanic electric machine? I have been using a galvanic electric machine for some weeks in a case of paralysis in the legs, and have found much benefit from it; but the machine appears to have less effect now than at first, on both spine and legs, so think a coil might be desirable, if properly applied.—D. R.

[60528.]—**Photographic.**—Will any kind reader tell me how I may know when I have washed my negatives and prints enough? Some simple test for this purpose would be of very great use to me. I think there is one with bichloride of mercury, but am not sure.—BOW.

[60529.]—**Polishing Paste.**—Can any of your readers give me a recipe to make a good brass polishing and cleaning paste—one that will both polish and clean well? Do any of them know how the German paste is made?—POLISHING PASTE.

[60530.]—**Lenses—Grinding.**—TO MR. LANCASTER—Shall be very much obliged if you will give me information on above subject? I have ground a lens, but cannot get a good polish when looked at through a magnifying glass. I used the finest emery for polishing, and fastened window leather over the lead tool, which is attached to the face plate in the lathe, and is run at about 600 revs. per min. A can of water is fixed above the tool, and allows water to drop on to the glass, which is stuck to a piece of wood, and is held by the hand and slightly pressed against the concave tool.—J. H. WHEAT.

[60531.]—**Lamp for Boiler.**—Would some reader please tell me if I could get a lamp that would not smoke to heat a small boiler connected with a tank that holds about two gallons of water from 100 to 110 degrees? I have one with a burner without a chimney; but it smokes a great deal. Also would be obliged to hear something about the construction of boiler.—ONE IN A FIX.

[60532.]—**To Mr. Lancaster.**—I am desirous of using, if practicable, a magic lantern for the purpose of exhibiting, in my home circle, microscopic mounted objects. I do not want to enlarge them beyond a disc of, say, 4ft. or 5ft. diam., with the use of a paraffin lamp. I am informed that the intense heat of a magic lantern would melt the Canada balsam, and otherwise injure the objects themselves. No doubt this would be the case with a large and powerful apparatus; but I am anxious to know if such a small affair as I propose (effective for discs and not more than 5ft.) would do any harm? I have made an apparatus, similar to that described in No. 980 of the "E. M."; but the light is so feeble that a very small image can be got properly illuminated. No doubt Mr. Lancaster could easily tell me if I am asking for what cannot be accomplished, and, in any case, I shall be most thankful for his opinion and advice.—D. A.

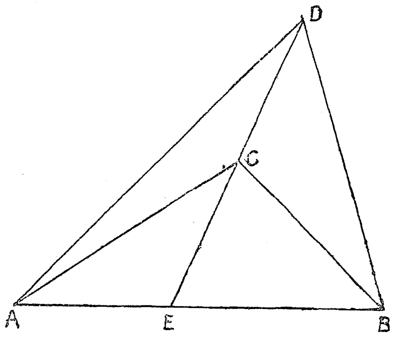
[60533.]—**Crystal Slides.**—Is there any book published on the preparation of chemical crystals for examination with the microscope, giving full and explicit directions for making the solutions and crystallising them upon the slide, &c.? I should be greatly obliged to any chemical reader who would inform me if any such publication exists, and price, &c., so as to enable me to enlarge my range of "crystal" slides.—D. A.

[60534.]—**Dynamo.**—Will some of our readers kindly tell me what to do? I am in trouble with my dynamo: it has a commutator at each end of the armature, one end being large and the other small. Now when in motion I can only get a spark on the brushes from the small commutator. It is a light machine, and it will not light one 20c.p. Swan as it is. Any information will oblige—ANXIOUS.

[60535.]—**To Mr. Bottone.**—Could you say whether a ½in. spark could be got from the coil you described last week without a condenser? If not, would you mind giving dimensions for making one?—F. SCHULTZ.

[60536.]—**Irish Locomotives.**—Can any of our readers give sketch with dimensions of a new locomotive on the Londonderry and Seaham Railway, the which is reported to be a model of engineering skill, and capable of drawing double the load of similar sized engines?—BRASS, JACKINTON.

[60537.]—**Problem.**—Given angles B A C, A B C



A C E, B C E, and A D B to find the other angles.—H. K.

[60538.]—**Formula for Train Speed and Brake.**—Wanted, arithmetical formula for finding time and distance required for a train at rest to attain various speeds on level and various gradients, both up and down. Also time and distance required to bring train to rest on level and various gradients, both up and down, by ordinary hand tender brake, steam brake on driving wheels, hand tender and van brake, and other combinations that can be used. Also by continuous brake.—GOODS FIREMAN.

[60539.]—**Valve Gear of Marine Engines.**—Would any reader inform me if cams have ever in any way been applied for working the steam valves on the marine engine? If so, say where, when, and also if there is a written description of the valve gear to be found anywhere; or, if it will not put the reader too much about, would he describe how the gear works?—J. O.

[60540.]—**Tricycle Matters.**—It is some years since these have been discussed at any length in the "E. M.," and the use of these machines has increased enormously; not only so, but quite recently some very important changes in the principles of construction have been introduced which merit some discussion. Of these, what is termed "automatic steering" and the use of much smaller "geared-up driving wheels" than of yore are especially worthy of consideration. Personally, I have tried neither—they did not commend themselves to my notions of what is good in mechanics; but the evidence I have from some who have tried them, who understand next to nothing of mechanics, but who are practised and skilful riders, and know very well whether they gain an advantage or not, assure me that they not only ride with less labour and cover more ground in a given time with the new than with the old type, no matter whether the roads are good or bad. I was also informed, only yesterday, by a clever constructor of these machines, that he was now actually adapting his patents for use with these geared-up machines, and intended abandoning the manufacture of those with the 50in. and 48in. wheels in favour of the 42in., not from any preconceived idea on the subject, but in consequence of actual experiments which had incontestably proved to him that advantage. The only explanation that he appeared able to suppose was that not only were the smaller wheels of less weight themselves than the larger ones, but their adoption enabled other parts of the machine to be made lighter, though just as stong. This seems to me paradoxical. I don't exactly see why the other parts can be made lighter and yet as strong, merely because the wheels are smaller, and, again, I can suppose that on smooth ground the reduction in weight may compensate for the smaller diameter of the driving wheels; but on rough ground theory seems to me to be all on the other side. I should much like to hear what experts have to say on this question.—GAMMA SIGMA.

[60541.]—**G.W. Trains.**—I should be much obliged to any reader who would answer the following: Does the G.W. Company run through trains between London and Manchester, viâ Oxford, Birmingham, Wellington, and Crewe, or viâ Shrewsbury and Chester, and, if so, what class of engines work them? Also, do they run through trains from London to Plymouth by the narrow gauge, and, if so, what class of engines work these trains?—Z.

[60542.]—**Photography.**—At what stage of development can citrate of silver be used, both in negative plates and printing paper positive? Can it be used with advantage instead of citric acid, relative costs out of the question? If so, please give formula that includes citrate of silver both in developing and printing.—YELLOW FINGERS.

[60543.]—**Steam Diggers.**—Can anyone give me some particulars of the steam diggers used for planting trees, &c., on the Saidaput model farm, Madras? I believe they are made in America; but there may be similar machines made in this country.—F. A. R.

[60544.]—**Microscopical.**—(1) I wish to draw on paper, by means of the camera lucida, a set of scales for the easy measurement of objects for each of the different objectives with the several eyepieces. I have been quite successful with the No. 1 eyepiece, but when I come to use No. 2 eyepiece I am completely floored, as I cannot even get the disc to appear on the paper. (2) How can I best modify the light, so as to read a micrograph slide with a low-power objective, say a 2in.? I can make it out, but not clearly, as the light seems to drown it?—G. E. H.

[60545.]—**Photo. Micrography.**—Given a good compound microscope, also a camera, could I, without much extra expense, enlarge objects and produce them on slides suitable for magic-lantern work?—G. E. H.

[60546.]—**Phantasmagoria.**—I have several oleographs, semi-transparent, about a foot square, and should like to exhibit enlarged reflections of them on a screen or mirror. I have a large magnifying lens. Will anyone kindly give me information?—T. J. MOORE.

[60547.]—**Letters on Glass.**—I want to paint some lettering, &c., on glass, to be silvered afterwards. I have done some, but the silvering process has blackened the colour, for want of a protective medium (to be used after painting). Will one of "ours" kindly tell me what to protect the colour with?—GLASS PAINTER.

[60548.]—**Copper Boiler.**—I have made a small vertical boiler of sheet copper (No. 20 gauge), the size being 14in. by 7½in., with two stays across the body and one from top to bottom. Will anyone kindly give me the following information (1) as to how many pounds pressure of steam per sq. in. will it stand to work with safety? (2) How many pounds per sq. in. will it require to drive horizontal engine, the cylinder being 2⅝in. stroke and 1½in. bore?—A COUNTRYMAN.

[60549.]—**Telegraph Connections.**—TO MR. CONRY.—I want the arrangement in duplicate, so as to ring from both ends in the ordinary manner.—E. M.

[60550.]—**Chemical.**—How can I reduce a mixture of cyanide of copper and potash oxide in solution to metallic copper and potassium cyanide?—T. MORRIS.

[60551.]—**Reed Organ.**—I purpose making a reed organ, on suction, to have one 16ft., two 8ft., and one 4ft. stops, the 4ft. preferably steel, with 2½ octaves of pedals coupled to manual. What size should pallet holes be for 3½ rows reeds? Would reservoir 16in. by 3ft. to fall 8in. be of sufficient capacity? How can I obtain Vox Humana without sharpening? Have plenty of tools, ordinary. What reeds must I use to get the nearest approach to a pipe organ, or would tube boards be best? I may add cost is some consideration.—G. D. G.

[60552.]—**Air Gun Trigger.**—Seeing an engraving of an air-gun trigger in the "E. M." the other week (Sept. 10th), by R. L. Readdie, I should like to ask him, on behalf of myself and others, if he will kindly give an illustration, with your kind permission, how the air passes from the air chamber into the barrel, seeing that the mechanism for firing is between air chamber and barrel? Does it come through the works direct, or through a separate tube? Also show form of valves, if possible. Also if ordinary brass gas tubing will do for air pump and barrel, and if the piston should be solid iron, or packed with hemp, like a garden syringe?—ONE WHO HAS TRIED AND FAILED.

[60553.]—**To Mr. Wimshurst.**—Having constructed a 17in. machine as per your instructions which appeared in these columns, I am desirous of gathering a little more information. Would you be kind enough to give particulars of construction of one of your 8-plate machines, size of bosses, length of stand, conductors, Leyden jars, brass balls, thickness of spindle, how many sectors on each plate? Will 21oz. window glass be strong enough for plates and the straight jars used by confectioners answer for Leyden jars?—EVENO OAKLAND.

[60554.]—**Charging Accumulators.**—Many thanks to Mr. E. Conry, and to the other gentlemen, who have so kindly taken notice of the above query. I have not as yet had time to carry their suggestions into effect, but hope to be able to do so shortly. The cells have, I believe, been short-circuited to a greater or less extent by sulphate of lead within the cells, and they have also leaked enough to keep the place on which they were standing wet. Mr. Conry is mistaken as to the resistance of my dynamo being only half an ohm. It is wound with about 6lb. No. 16 on field, and about 6oz. No. 20 on armature. This quantity of wire would give a resistance of a little over two ohms. For charging the cells in question, I have been in the habit of running the machine in series. Perhaps now that I have given quantity of wire, the correspondents who have noticed this will be able to form an approximate idea as to the capability of the dynamo, and be good enough to inform me if it is powerful enough to form the six cells.—IOTA.

[60555.]—**Sardines.**—Could any brother reader give me some particulars of the manufacture of these in tins? Are the fish boiled in the oil? What oil? What herbs are used to flavour with?—OLD SUB.

[60556.]—**Wimshurst Machine.**—Will Mr. W. be kind enough to give me number of sections for a machine with 16in. plates, and explain construction? Does each disc revolve in opposite direction? Can I get the pamphlet on its construction mentioned as in the press some time ago?—CARNFORTH.

[60557.]—**Honours Exam.**—Can Mr. Bottone, "Sigma," or some other gentleman of experience advise me how to prepare for the honors exam. in electricity of the Science and Art Department? What are the best means of study, and is there any special book?—CARNFORTH.

[60558.]—**Forging Engine Work.**—Will any of our readers who are practical forgemen describe the proper method of forging double cranks for small engine-shafts and similar work—say a 4in. crank out of a round bar of 1¾in. thickness? I find it difficult to prevent the diminished thickness just at the angle of the bend outside, and to get the angles up square and true. Also, which is the proper way to forge the two-eared ends of connecting-rods and valve-rods?—NERO.

[60559.]—**Liquid Compass.**—Will any correspondent kindly say what liquid is used for liquid compasses? Also, in what are the magnets inclosed to prevent rust? Any particulars respecting making will oblige—TADDY.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

BACK NUMBERS.

WE receive so many queries asking for directions how to make many instruments and appliances which have been fully described in back volumes, that we have compiled a list, which we shall insert in this column at intervals, of those most frequently sent, and as the numbers are still in stock, new subscribers should consult the list before sending their questions.

Bookbinding: No. 613.
Electric machines: Nos. 1,009, 1,025.
Electro-magnets: Nos. 772.
Lacquers: No. 866.
Pattern Making: Nos. 938, 941, 943, 945, 948, 950, 952, 954, 955, 956, 958, 959, 962, 963, 969, 974, 978, 986, 989, 993, 995, 998, 1,000, 1,001, 1,003, 1,004, 1,008, 1,009, 1,010.
Silver-plating: Nos. 1,009, 1,010.
Varnishes: Nos. 478, 619, 675, 723, 775.

The following are the initials, &c., of letters to hand up to Wednesday evening, Sept. 29, and unacknowledged elsewhere:—

S. GIBSON.—G. E. Davies.—T. R. Willis.—W. F. Stanley.—T. Dolan.—W. H. Numsen.—G. Birch and Co.—Lux.—A. J. Frost.—S. R. C.—Amateur.—Desideratum.—Billy.—Beginner.—A Vet. Surgeon.—Libra.—B.—C. B.—R. H. Gates.—A Countryman.—Geo. Wells.—Z. Y.—O. H. P. Scourfield.—H. Purse.—Glatton.—South-West.—H. A.—Snipe.—Force Pump.—Induction.—C. D. R.—G. H. L.—K. K. K.—Kappa.—Ingienero.—Ramases.—R. E. F.—W. H. Taylor.—H. Palmer.—Simplex.—J. H.—Jas. Jones.—Arthur Bowes.—A Socialist.

TO SOME VERY PROLIFIC CORRESPONDENTS. (It is absolutely impossible to find space for the shoals of letters that reach us on railway matters and locomotive details. We have given such correspondents considerable latitude lately, and now some want to discuss what details should be submitted for controversy as well as the subject itself! A similar reason compels us to close the correspondence on English versus Foreign Microscopes. Considerable and unnecessary heat has been introduced into it, and nearly all have wandered far beyond the point submitted for discussion.)—GALA. (Allow half an inch for each wire or note, and an inch all round for the frame; but an inch and a half is better; or you can cut the back out of the solid—say, 30in. at one side, tapering off to 15in. at top.)—W. W. (Do not understand what you mean by "loaded at ends with solder." Perhaps they are acetate of soda footwarmers, which contain that salt, and are immersed in hot-water simply—none being required inside, hence they are sealed up.)—ELECTRIC. (See the indices of recent volumes.)—RD. STEWART. (Try a whistle mouthpiece in the spout.)—T. F. FORDE. (We might fill our pages with examples of that kind without getting any nearer an explanation. See what has been said in back volumes, and in works on the subject.)—T. F. F. (The only way is to scarf the ends and cement with rubber solution; but broken tires are never safe, however well they may have been repaired.)—R. W. C. (Do you mean paper balloons or gas-tight affairs, which can be used over and over again?)—SUFFERER. (Ointment of galls is a useful preparation; but see No. 899, pp. 329, 338, and No. 900, p. 361. See also the indices under head Hæmorrhoids.)—R. J. T. (You will get an idea from No. 919, p. 211, and have only to add other magnets to reset the indicators. See also No. 904, p. 455, and the indices.)—VERY PUZZLING. (See No. 1028, p. 308—"Jumping Beans of Mexico." The action is supposed to be due to changes of temperatue.)—GRAVER. (The query was actually answered last week—see p. 93—and as to the tools, look in Nos. 935 and 734.)—MINERAL. (Dana's "System of Mineralogy," £2 2s. (Trübner), is a first-class work. We do not think any work has been published on the microscopical study; but you will find papers in back volumes, and in the *Journal* of the Royal Microscopical Society.)—A. R. F. K. (Is not the "explanation" supplied by the fact itself? The barometer is a measurer of the weight of the atmosphere, and if the column of mercury falls when the air is charged with aqueous vapour, does not that show that wet atmosphere is lighter than dry?)—TRINITY HALL. (There is a groove in the periphery of the piston, and the rings are sprung on, being cut through with a diagonal cut.)—N. W. SMITH. (Surely you can try which sort of socks suit you best. We presume you have tried cotton; if not satisfactory, try silk.)—ANXIOUS. (Answered last week.)—T. M. T. K. (Use a blue lacquer or varnish: that is the only method.)—A. J. G. (Solution of chloride of cobalt is perhaps the best; but see the indices.)—S. S. (We suppose you mean the machine which rolls the thread up instead of cutting it out. That was exhibited by J. H. Ladd and Co., 116, Queen Victoria-street, E.C. No. 1144 in the third edition of the catalogue.)—C. MATHER. (Coat with gold size and dust on the bronze powder. If that is not what you mean, see indices.)—BIOLOGICAL STUDENT. (If you cannot accept the statements of those who have already dissected such animals, you can easily obtain a supply of them from naturalists. An advertisement in the Wanted Column would no doubt bring you plenty of offers.)—F. C. S. (There is much information in the back volumes—see indices to Vols. XIV. and XV., for instance; but if you put specific questions, no doubt you would obtain replies.)—FIDES ET JUSTITIA. (Do you think that the processes of brewing can be described in a receipt? See the indices for much information, and procure one of the cheap handbooks.)—BEN SCROGGINS. (You can obtain a judicial separation, but until you do that you are liable.)—POULTRY. (About 103° Fahr. is the temperature required for hatching eggs.)—E. S. I. (The actual heat of a Bunsen burner depends on its size, as heat refers to quantity. The temperature is about 1,200° Fahr. With an ordinary mouth blowpipe you can possibly obtain a temperature of 2,000° Fahr.; but it is doubtful if you can yet 1,600° C. with anything less than a furnace and a blast.)—W. G. MORGAN. (You should say what you mean by "railway work"—what branch?)—JOSEPH BRYAN. (No doubt your opinion is correct; but what can be expected for the money?)—MINERAL. (Directions for cutting rock sections will be found in last volume, pp. 490, 512. See also No. 1056, p. 342, and the indices.)—W. H. S. (Procure the reprint of the articles by "Sable," which appeared about sixteen years ago, and now published by Mr. Hughes, of Mortimer-road, Kingsland-road, N. See p. 553, No. 908, and the indices, especially of Vol. XXXI., which contains an interesting discussion on transparencies, and an article by the Rev. W. H. Dallinger in No. 782.)—JOHN JACQUES. (A solution of common washing-soda is as simple and useful as anything, but much depends on the character of the water, and it is better in every way to purify that before putting it into the boiler. See No. 974, p. 261, No. 979, p. 374, and look through the indices for a number of suggested, and sometimes useful, methods of preventing incrustation.)—W. B. (We believe the dimensions have been given. Look through the indices.)—YOUNG MECHANIC. (Procure one of the handbooks issued by the agents advertising in these columns. The actual cost for the stamp on application is now only £1, and for a shilling or two more you can sufficiently protect each invention for nine months, as drawings are not required with the application. You can obtain the new Act for 1s. 1d. from the Queen's printers, and the Rules for 7d. 2. If, as we understand you, the glass is not to be engraved, you may possibly succeed by grinding up some of the finest lampblack in oil of lavender, and drawing the lines with a small brush. A good deal of practice will be needed if you have never done such work before.)—F. W. HARRISON. (The "Practical Guide to Photography," published by Marion and Co., Soho-square, W., will no doubt suit you.)—HOLLAND. (The coil referred to is purely experimental, and no one can say what result would follow your plan without actual trial. Silk-covered wire must be used. Better make one on the lines indicated in No. 1,092, p. 543, and look through the indices for much useful information.)—WM. JOHNSON. (You had better procure the salts ready prepared, if the directions given in No. 994 are not sufficient. Battery working is troublesome; but procure a catalogue from Elmore and Co., Charlotte-street, Blackfriars-road, London, S.E.)—G. (There is an illustration of an improved Æolian harp in No. 1048; but any sort of shallow box which is strong enough will do. The strings are carried over bridges at each end.) W. S., Rochdale. (See pp. 424, 514, 535, last volume; but if the instrument is a good one, better let some one who understands it do the regulating. They are described in most works on Physics—Ganot's, for instance.)—NOMEN. (No. See the descriptions of the Siemens' gas and coke stove in Nos. 817, 819. Gas stoves have special advantages, and if you wish to learn what has been done in that way, procure a catalogue from Mr. Fletcher, of Warrington.)—DARK. (We do not know. Apply direct to him at Bowdon, Cheshire.)—W. E. S. (Why not procure the patent specification. There is not much in that part, as the gear simply slackens the driving strap and allows the wheel to run free.)—LANCASHIRE YOW-YOW. (You supply the answer when you say you seem to lose all confidence in yourself. Don't lose it—that is all.)—G. N. (See indices for Muscæ volitantes. If it is very serious, better consult a medical man; but probably if you do not think anything about it, you will not notice it.)—X. Y. Z., London. (Simply want of the lubricant synovia. Probably cold. Rub in a little sweet oil or liniment where the cracking is felt.)—F. A. R. (See indices. If the surface is worn off, dye must be applied, and the glaze be put on with white of egg beaten to a froth.)—PATERFAMILIAS. (No special dimensions. A praxinoscope is better (see No. 732) as slits are dispensed with, and the picture slips revolve round a pillar formed of mirrors.)—M. A. B. (The ends of the secondary are connected to the dischargers.)—LOCO. (If you warm them gently that will soften them; but you must remember that indiarubber is not everlasting when exposed to air.)—C. N. H. (We do not know where you can obtain the machine; but the offices of the company were, until recently, at 58, Coleman-street, London, E.C. No doubt you will see the advertisement in the daily papers.)—FRANCOIS. (Isinglass is made from the "sounds" of sturgeon, gelatine from bones, cuttings of skins, &c.—in fact, anything which contains it, as when it cannot be cleared and purified, it does for glue. No book; see back volumes.)—H. (You give no address; but if in London, attend the classes of the Finsbury Technical College, pass well up, and any electrical engineer will be glad to have you as an apprentice. Not very good condition at present, but is going to be better.)—C. W. (You can get them readily enough through the post. When you ask, Will something else do? one is tempted to reply, "Try," for you do not suppose that everything has been experimented with. 2. If you mean the blown glass, yes; cast won't do.)—DARWEN (Answered last week.)

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XI., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

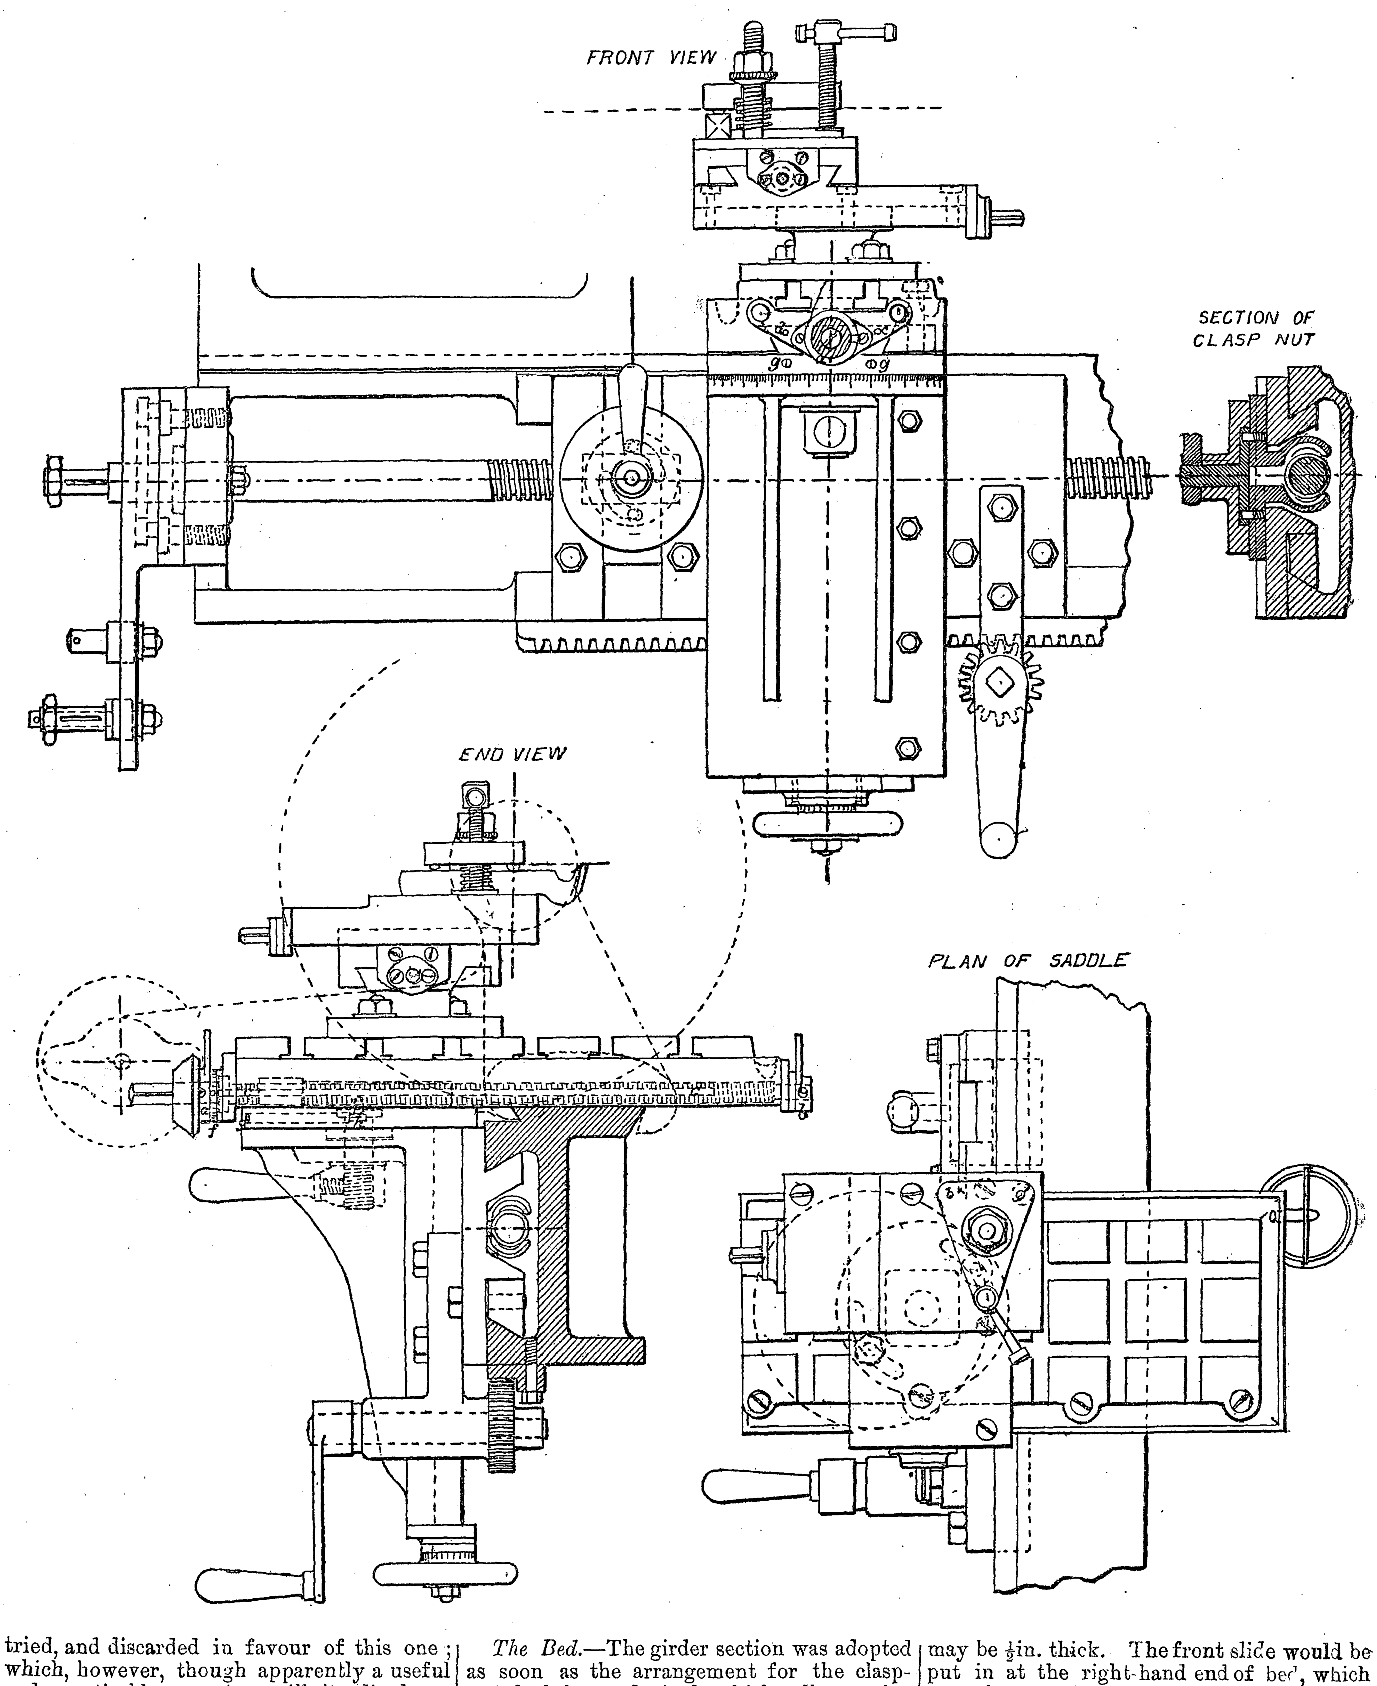
FRIDAY, OCTOBER 8, 1886.

SADDLE WITH FRONT AND VERTICAL SLIDES.—II.

THE arrangement about to be described has been under consideration for some time, and several alternative plans have been tried, and discarded in favour of this one; which, however, though apparently a useful and practicable one, has still its disadvantages.

The section of bed adopted is practically identical with that propounded by Mr. Carre about two years ago, just as the mandrel with traversing bushes is due to a suggestion of "Vulcan," another correspondent. The idea of passing the mandrel stud through the star-guide is due to Mr. Massa, an American amateur, and it has been carried out by him. In fact, every suggestion by whatever correspondent which seemed likely to be of service has been weighed, and the whole design, as it now appears, is in some degree the child of the several writers on "Lathe Matters" in this paper.

The Bed.—The girder section was adopted as soon as the arrangement for the clasp-nut had been devised, which allows of a shallow opening in front between the top and bottom web. The form of the top of the bed is preferred because, whilst the heads have a broad base to stand upon, their alignment does not depend upon tenons which might come to fit loosely, but upon the front top V, up to which they are drawn. In the drawing of the fixed headstock one of two small screws is shown in the base of the headstock, which screws are intended to draw it up into contact with the front edge before the holding-down bolt is fixed; this bolt is omitted in the elevation and plan, and is shown dotted in the end view. The webs at the back would occur about every 9in. and may be ½in. thick. The front slide would be put in at the right-hand end of bed, which must be planed right out clear, there being only a removable bracket-arm to support the end of the lead-screw. The method adopted



for securing this and the other screws employed to move the slides is somewhat unusual; it will be clearly seen by the dotted lines to the left of the front view. These screws are all held by one end only, by means of a kind of gland piece, which contains the large collar and resists endlong motion. On the left hand of the bed there is a strong flange, which is bored and surfaced square; the lead-screw is threaded through from the left till the collar goes up; over the end of the screw goes the gland-piece, the face of which is filed or turned away till the recess is just deep enough to contain the collar (which process must be repeated if any wear takes place), and the gland-piece is secured by two stong cheese-headed screws; next comes the wheel-plate, which contains the circular T-slot. These wheel-plates might have been 1in. longer; they are made so that the studs can be slipped in at the end, and the sides are strengthened that they may not spread when the stud nuts are fixed by the spanner. The reason for fitting the slide-screws in this way is that when a washer and lock-nuts are employed it frequently happens that the screws will move harder at one part of the revolution, proving that the washer and face against which it works are not true, and that a slight amount of endlong motion of the screw takes place at each revolution. Now if this be so it must be evident that it is quite useless to expect a good result when screwcutting even were the lead-screw never so true. In this arrangement the endlong motion is not taken up by lock nuts at all, but by a large turned collar sunk in a turned recess in the gland-piece. The same plan was adopted for securing the traversing screw, since it is intended to use this in connection with the mandrel by means of the upper wheel-plate, for traversing (flat or conical), for giving feed when milling, and for screw-cutting by turning it parallel with the bed; in fact, one might be very well satisfied to have no lead-screw in the bed, since by the long traverse slide screw-cutting 8in. long can be accomplished.

The front slide is 13in. long, which should give a good bearing to resist wear; the gib is placed at the bottom, though the reasons for having it at the top appear to be about as strong. It is evidently of the greatest importance to prevent any spreading of the upper and lower front flanges of the bed, for this reason the webs at the back of the bed were added, and the flanges of the clasp-nut have been placed in front of the front slide instead of inside it, in order to save space, and so bring the front slide closer to the central web of the bed. The front view shows in dotted lines an oblong hole in the front slide, through which the clasp nut is passed till the guide-plate of each half drops into a shallow vertical groove planed in the front. This may be seen in the section as well as in the plan. The guide-plates come flush with the surface of the $\frac{1}{8}$in. circular facing, then the spirally slotted plate is slipped over the pins which control the halves of the nut, and over this goes the recessed cover-plate.

In the vertical slide, as in the others, the usual arrangements are reversed, and it is the larger, or female slide, which moves. This arrangement is stronger, and more convenient in many ways, but it has its disadvantages. The proportions of the vertical slide are not shown in section, since it, with its screw and gib, is arranged exactly like the horizontal or traversing slide, seen just above in the front view; it is strongly webbed up to the top plate, 6in. diam., on which turns the traverse slide to any angle on the graduated circle, and it is clamped by the handle seen underneath. The male vertical slide is 6in. long, and the moving part can rise 4in. The vertical slide is slid on from the top, and the screw, with its hand-wheel, yoke, and gland-piece, fixed afterwards by two screws similar to those seen in front of the traverse slide in the front view.

On the top of the vertical slide is the male part of the traverse slide, with its 6in. flange underneath; it is 5in. long, and its front edge is within $1\frac{1}{2}$in. of being under the lathe-centres, so that work being milled is always overhung to that extent, but never more. The main part of the traverse slide next claims attention. The top of this slide forms a most convenient milling-bed or table for fixing work; the screw is perfectly covered and protected, as is the screw of every slide in the lathe, and there is a gutter all round to catch turnings, soapsuds, oil, or what not, and a little can should be hung on a spout, as seen in plan, to receive the drip. In sliding or screw-cutting with the lead-screw in action, the vertical slide would be down, and the presssure of turning would not come on the vertical slide or on its screw, nor on the bottom V of the front slide, but on the broad top of the lathe-bed, thus obviating the only important objection which has been raised to the use of the front-slide—*i.e.*, that the smaller bearing surface would, in time, wear hollow. Returning to the circular movement under the traverse-slide, it will be seen that it can be instantaneously released by the handle beneath, when the long traverse slide can be swung round parallel with the bed, and then the whole front slide, and all upon it, can be racked away past the poppet-head. Another advantage is that, as already mentioned, the long traverse slide (which may be longer if desired) can thus be utilised for cutting spirals, cones, and parallel work (whether screwing or sliding) up to 8in. long, all this being done very conveniently by connecting the long traverse screw with the mandrel by means of the upper wheel plate, the sliding shaft within it, and the Hooke joints. Also by means of a pair of small bevel wheels, one of which is shown in the end view, fixed upon the end of the screw, which wheels, however, would only be required when the traverse slide lay across the bed, and not when it was turned round parallel with it, or nearly so.

Passing on to remark upon the slide-rest fixed upon the top of the traverse-slide, the two screw-bolts securing it have T heads, which lie in the two longitudinal slots; thus, when the nuts are slackened the whole of this part can be drawn or slid off towards the workman to leave the milling bed clear. The slide-rest consists of *two* slides at right angles, for several reasons. First, because it allows the back-stay to be mounted on the back end of the traverse slide or milling bed; because the second screw will help to save the traverse screw from wear; because the upper traverse screw would give the feed in screw-cutting, whilst the lower main screw could be used for quick withdrawing; and, lastly, because when screw-cutting with the traverse slide set parallel with the bed, the two slides above would be needed to adjust the tool-point.

The Willis tool-holder is arranged so that no spanner or tommy is required to fix the tool.

One more device requires explanation: in turning, and still more in milling, it is desirable, if not essential, to have stops of some kind fitted to the main slide; the usual form of stops cannot well be applied to these reversed slides, but the much better form known as the circular stop is suitable. The difference between them is that, whereas the ordinary form of stop arrests the motion of the slide when it meets the end of an adjustable screw, the circular stop arrests the revolution of the screw which moves the slide, thus avoiding all strain to the parts, and stopping the movement with still greater precision. Mounted upon the boss of the bevel wheel at one end of the traverse-screw, and upon its point at the other end, will be seen two rings or bosses *a*, *b*; these carry short arms, and can be fixed by small pinching screws so as to revolve with the long screw. Through the male or fixed part of the traverse slide, and on each side of it, are bored two long holes through which pass two steel rods $\frac{1}{4}$in. diameter, which fit rather tightly, and yet can be pushed in or out by the fingers; one of these bars or rods is marked *c c* in the end view, and *c* in the front view, and it comes through the yoke in *front*, and is seen projecting $\frac{1}{8}$in. in the end view; the other rod seen dotted in the front view comes through *backwards*, and it stops the revolution of the main screw by means of the arm of *b* when the slide is drawn back far enough, whilst the rod *c c* arrests the motion in the other direction when the slide is moved forwards far enough for the rod *c c* to project through the front yoke and so catch the arm of ring *a*. By pushing the rods in or out the movement can be confined to any number of turns of the main screw, and by adjusting the position of the rings on the screw before fixing them, any part of a revolution can be obtained. A micrometer collar is seen at *f* on the boss of the bevel wheel (it should have been shown wider); the screw being of ten pitch, it might be divided into ten, and would then measure 1-100th of an inch. It can be turned round on the boss and fixed again, and thus the measurement can start from the *o* mark. There is also a simple device for fixing the rods *c c* and *d*: two other holes at *g g* are bored in the flange just under and parallel with rods. In these fit two short rods having their ends for $\frac{1}{4}$in. turned slightly eccentric; short holes are bored from the top of the slide through the holes for the long rod down to the 2nd holes, and in these vertical holes are two bits of rod about $\frac{1}{8}$in. long standing on the eccentric ends of the lower rods and reaching up to the underside of the long ones (dotted at *h*). When the lower rods, *g g*, are turned by a screw-driver, the short $\frac{1}{8}$in. bits will be raised, and the long upper rods pinched and held firmly.

A word, in conclusion, about the uses of the whole arrangement. The front slide allows the whole saddle, rest and all, to be slid out of the way when hand-turning is to be done, without even moving the poppet; this is not a great advantage, since the slide-rest is so easily removed from off the traverse slide, and the hand-rest might very conveniently take its place, being fixed with its sole on the milling-bed instead of on the lathe-bed. The vertical slide allows of work being firmly fixed and fed up to milling cutters carried on the mandrel; also a strong driller can be fixed on the milling bed and adjusted, or fed up or down for slot drilling or milling work fixed on the face-plate; this same driller would carry the wheel-cutters if it were fixed vertically, or they might be carried in a wheel-cutting frame adjusted to height by the vertical slide. For instance, an engine cylinder having been bored out by a slide-rest tool on the face-plate, the slide-rest would be removed, and the long slide being turned parallel with the bed, the strong driller carrying a milling-cutter would be mounted upon it; the cylinder would then be fixed so that the valve-face and flange of chest were vertical, and the driller, by means of the vertical slide, would face the flanges, the valve-face, and cut out the steam ports true with the bore, and all at one chucking. The vertical slide converts the lathe into a very efficient milling machine, and almost doubles its powers. The only wonder is that we have done without it for so long, or been contented with unsteady attachments.

REVIEWS.

Photo-Engraving on Zinc and Copper in Line and Half-tone, and Photo-Lithography. By W. T. Wilkinson. London: England Bros.; Otley: W. T. Wilkinson.

The art of photo-engraving has been practised for many years with more or less success, but latterly it has made considerable strides, for surface blocks suitable for printing in the ordinary press with type have been produced in half-tone, excellent examples of which may be seen occasionally in the *Building News.* Mere line work is, in fact, looked upon as beneath the artist workman, and the aim of all inventors is to produce a surface in zinc or other metal from which a picture can be printed having all the gradations of tone seen in a first-class photograph. The little book issued by Mr. Wilkinson, though it contains less than 120 pages, is a practical manual, and will be found extremely useful by anyone desiring to take up the art of producing blocks for printing direct, as it were, from nature, without a touch from the graver. We have from time to time given ample directions for producing process blocks, as they are called, so long as the drawing is confined to lines; but the methods of making a zinc surface yield desirable pictures in half-tone when printed with type in a newspaper are very much trade secrets, which, to judge by some of the results, are scarcely worth five minutes' endeavour to discover. Nevertheless, sufficient has been already accomplished to indicate the possibilities of the future, and Mr. Wilkinson says in his Chapter VI., "we now come to the most important chapter of this book—viz., the production of photo-type blocks, or the means whereby the half-tone of a photograph is levelled up, so as to print in a typographic press." Briefly stated, this is accomplished in the ordinary processes by interposing a screen before the sensitive plate, so as to produce a negative with a definite grain. It is here where the skill of the practised worker and the genius of the inventor are required, for it is very easy to have too much grain, and yet grain is essential to the production of the picture. Mr. Wilkinson's practical directions will be very useful to the experimenter, not only in producing the photograph on the zinc plate, but in the subsequent manipulations, which require great care and skill. The photograph having been obtained on the zinc, the image is rolled up carefully with ink, and the plate having been warmed, is cooled, and then coated with thick gum, which must be dried by fanning, or in some other method which will prevent the gum cracking. The plate is then washed under the tap so as to remove the gum from the ink, but not from the surface of the plate, which is then inked up again; that is, to a certain extent, the crucial operation in the whole series of processes. The rolling-up with ink being accomplished, touching up is done by an artist workman, and the plate is then ready for the first acid bath, which is a rocking tray containing a weak solution of nitric acid. The operations of washing, gumming, rolling with ink, &c., are repeated several times, until the etching of the zinc has proceeded far enough, and the plate is ready for testing. It will be seen that there is plenty of opportunity for the introduction of skill and "brains," and as much remains to be achieved, with a certainty of ample reward when it is accomplished, Mr. Wilkinson's little work may be found very useful by many. The second part deals with photo-lithography in line and in half-tone, and here again it is in the latter branch that improvement is required. An appendix which occupies more than one-third of the book contains a number of general hints and extracts from technical serials; but the practical directions given by Mr. Wilkinson will be sufficient for the worker who understands how to "try, try, try again." In a new edition it will be advisable to give specimens of the work produced by the different processes.

Short Lectures to Electrical Artisans. By J. A. Fleming, M.A., D.Sc. London: E. and F. N. Spon.

This volume differs from all the text-books which treat of electricity and magnetism, and for that reason, probably, will be welcomed by the large class who, already acquainted with the workshop rules and details, will be glad to learn something of the principles on which they are based. The work consists of nine lectures, which were delivered at the request of Mr. R. E. B. Crompton to the pupils and workmen associated with his firm, in order that they might comprehend the why and the wherefore of the practices of the shop. We think Prof. Fleming has done well to publish these lectures; for while they will interest the student who knows nothing about the subject, the workman who is acquainted with the practical details of electrical engineering will find in them just the information that he often requires. They are freely illustrated with diagrams which, as a rule, relate to apparatus actually in use, and consequently better comprehended by those engaged in the construction of machines or in arranging the circuits. An index renders the subjects easy of reference, and completes a very useful work.

Money-making Men; or, How to Grow Rich. By J. Ewing Ritchie. London: Brain and Co.

Full of anecdotes of men who have grown rich by their perseverance and industry, as well as by their luck, as Mr. Ritchie would put it, this work should find many interested readers, especially amongst the young. The first two chapters, comprising some 60 pages, are entitled "In the City," and "Across the Atlantic," and contain brief sketches of the careers of many well-remembered names of millionaires, including the most illustrious—George Peabody—whose portrait is selected as a frontispiece. Charles Bianconi, the Irish carman, has a chapter to himself, as has "George Moore, citizen and philanthropist"; there is a curious autobiography of a vegetarian, and a chapter on "A Fortune Made by Teetotalism"; "Money-making Publishers" is a heading many literary men would expect to see. In "Money-making Men in the Provinces" we have a brief note of Benjamin Attwood, who used to leave £1,000 notes at hospitals and ask merely for an acknowledgement in the *Times;* a short account of the career of Arkwright, a more lengthy one of Fairbairn, and Dickens's account of how Salt took up alpaca wool. Mr. Ritchie gives us some account of men who have made money in an "eccentric" fashion, and has produced a very readable book which may be placed in the hands of the young for their advantage and that of others.

Practical Guide to Photography. By Marion and Co. London: Marion and Co.

This is a new edition, revised and enlarged, of a guide to photography which has deservedly obtained a wide popularity, for in the twenty-six chapters of which it consists the reader will find full practical directions for pursuing the art of picture-making by the aid of the camera, and also the theory on which the processes are based. The optical branch of the subject is fully explained with the aid of engravings, so that the beginner can at least choose his apparatus with some definite knowledge, although he may find it difficult to make up his mind, his desires being constrained by the state of his pocket. The work is freely illustrated, and may be confidently recommended to all who desire to learn the art of photography.

Beginner's Guide to Photography. By A Fellow of the Chemical Society. London: Lejeune and Perken.

This is an elementary work, which, as its title implies, is adapted to the wants of beginners. It is not unlikely that many of those who purchase it and study it thoroughly will not require the aid of more expensive manuals, for it contains all that is really necessary to know, and it will assist the beginner in selecting the apparatus. The chapter on Exposure, by Mr. A. S. Platts, will be found serviceable by beginners, as it contains useful tables and simple directions, which, with a little practice, will enable the amateur to successfully master the difficult matter of exposure.

Circular Work in Carpentry and Joinery. By George Collings. London: Crosby Lockwood and Co.

Many carpenters and joiners who are masters of their trade while it is confined to what is known as straight work often find themselves puzzled when engaged in shaping pieces of wood which involve single or double curves. A man may go through an apprenticeship, and even pass several years as a journeyman, without meeting with a job in curved work which calls for the exercise of more than rule of thumb; but, nevertheless, the skilled workman will not consider himself master of his trade unless he knows how by rule to set out any possible piece that may be demanded. The accurate execution of curved work invariably demands the aid of geometry for finding the different moulds, and many young carpenters and joiners in this country and the colonies will thank Mr. Collings for this book, in which all kinds of circular and curved work are clearly set out with the aid of diagrams. The book is one of the excellent series which bears the name of Weale, and, almost as a matter of course, is as cheap as it is useful.

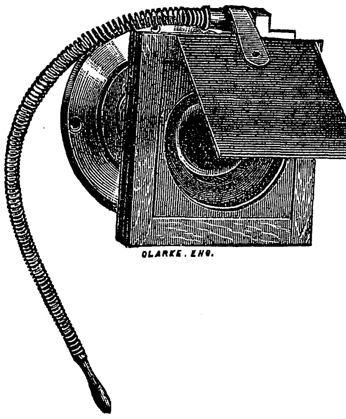
We have also received *The Engineman's Pocket Companion*, by Michael Reynolds (London: Crosby Lockwood and Co.), a work which contains a great deal of useful information for enginemen in charge of the different types.——*Burton's Modern Photography* (London: Piper and Carter) is a sixth and enlarged edition of a well-known work, in which the various processes are described with the most recent improvements.——*The Techno.-Chemical Receipt Book* (London: Sampson Low, Marston, Searle, and Rivington) is a collection of several thousand receipts, edited chiefly from German sources, with additions, by W. T. Brannt and W. H. Wahl. The volume contains nearly 500 pages of closely-printed matter, illustrated by 78 engravings, and will certainly be found useful by everybody.——*Analysis Tables for Chemical Students*, by R. L. Taylor (London: Sampson Low and Co.), and *Exercises on Mensuration*, by T. W. K. Start (London: Sampson Low and Co.), are low-priced little books for the use of junior students.——*Model Dwelling Houses*, by Sir James Gowans, is a little work which contains a description of the model tenement erected in the grounds of the Edinburgh Exhibition. —— *Designing Wrought and Cast-iron Structures*, by Henry Adams, M.Inst.C.E., &c. (London: 60, Queen Victoria-street) is Part II., containing notes, calculations, stress diagrams, and working drawings for a lattice-girder bridge between two warehouses, and gives just the information that the young draughtsman or engineer requires, because all the details of a practical piece of work are clearly set out.——*Walks in Epping Forest*, edited by Percy Lindley (London: 123—125, Fleet-street) is a new edition of this excellent little guide to the Forest, with some remarks on what

has been done since it came under the control of the Conservators.

We have also to acknowledge *Arc and Glow Lamps*, by JULIUS MAIER, Ph.D. (London: Whittaker and Co.); *The Life and Labours of John Mercer, F.R.S.*, by E. A. PARNELL (London: Longmans); and *Modern Steam Engines*, by JOSHUA ROSE (London: Sampson Low and Co.)—works which from their importance will receive a longer notice than we can give them here.

THE LEICESTER EXPOSING FLAP AND SHADE.

THE principal novelty introduced in this instrument, which is made by Messrs. T. S. and W. Taylor, Slate-street Works, Leicester, is the flexible shaft by which the flap is moved, and which possesses the following merits:—Its flexibility relieves the camera of direct movement from the operator's hand; it bears the stoppage and return of the flap, and prevents the "kick" which occurs with rapid shutters of the same class, through the stoppage being borne by the camera; it reduces all jerks and irregularities in the motion of the operator's wrist to a regular flowing motion of the flap.



A catch is arranged to keep it closed, until opened in the proper way by the shaft; it will be seen that the instrument may be used in any position, and that the flap forms a sky or side shade, under control of the operator; a sharp motion of the wrist gives an effective exposure of one-twelfth of a second, and anything from and above that amount may be easily obtained. One-twelfth of a second is as short an exposure as can be given with ordinary subjects, plates, and lenses; shorter times are only given under special circumstances. The instruments are to be obtained through all dealers. The size for an 8in. by 5in. lens occupies a space 3½in. by 3in. by ½in.

THE TOBACCO-GROWING EXPERIMENTS.

SUCH results as have been made known in connection with the experimental trials of tobacco-growing in the fields seem to show that so far as weight is concerned the experiments have been a success; but the more important points have still to be settled—whether the leaves can be properly cured, and what they will sell for when put upon the market, the latter depending entirely on the quality. More than a century ago tobacco was extensively grown in Yorkshire and other parts of this country, and it is still cultivated in Sweden, where, as an instance, it has been grown for fifty consecutive years on a few acres of land near Stockholm. There is, then, nothing in mere height of latitude to prevent the raising of crops of tobacco in this country—the question is, Will they be more profitable than other produce? We mentioned on page 3 the principal experimental plots; but for several reasons, that of the Messrs. Carter, at Plaistow, in Kent, is the most interesting. The first and most important reason is that the land on which the tobacco was grown is decidedly poor in quality—in fact, the only recommendation the plot has is that it is sheltered. But the object of all experimenters is not to prove that the plant will thrive on good land, but that it can be cultivated with success on a great variety of soils, and even on some which would scarcely carry a crop of anything else. The soil at Plaistow is a black sandy loam, which gets too much moisture at times, and for the experimental trials was dressed with farmyard manure and an alkaline compost. The young plants, in seventeen varieties, were set out on June 16 a yard apart, on the top of ridges, so that there would be just 4,840 plants to the acre. When set out, the plants had a height of about 3in., and careful measurements were made at intervals of the growth of the different varieties up to Sept. 18, when the crop was cut. The height of the plants at the end of the twelfth week ranged from 30in. to 46in., and the weight of green wilted plants from ¾lb. to 2lb. The gross weight of the crop from 3,846 plants was 5,163lb., or about 2¾ tons per acre, the weights being taken after the stems and leaves had been left for twenty-four hours on the field. Measurements of the leaves were made of all varieties, the dimensions ranging from the 20in. by 10½in. of the Havana to the 31½ in. by 16½in. of the Connecticut, figures which will give some idea of the appearance of plants of Nicotiana Tabacum, and N. macrophylla. As might be expected, some varieties ripen off before others, and it may be are too delicate for the climate; but it may also be found advantageous to grow them for that very reason, especially if it should turn out that their rich golden leaves are equal in quality to any tobacco grown. The varieties cultivated at Plaistow are divided broadly into two sorts—those, like Kentucky (one of the delicate varieties), having semi-erect pale green leaves, and those having pendent foliage like Big Frederick, a variety noted for leaves more "leathery" than the Kentucky type. A number of species of Nicotiana have been cultivated in this country simply as foliage plants, and it is not unlikely that if the business is taken up in earnest as a commercial crop, that varieties more suitable to the climate may be raised by the skill of the hybridist. It should be noticed that in Messrs. Carter's case the date of planting out is considered to be late, while the season has not been at all favourable. It is also not unlikely that it will be found more advantageous to have larger plants when the time arrives for setting out in the open ground, especially as it will cost little, if anything, more, as the seedlings must, it seems, be raised in heat, except in the more favoured parts of the country. The curing of the leaves is by far the more important part of tobacco growing, and it is mainly on the outcome of that branch of the experiment that the interest centres; for although tobacco is a crop requiring a good deal of care and attention, and therefore involving considerable expense, there is reason to believe that if the curing of the leaves can be carried out so as to obtain fine-flavoured tobaccos, the cultivation of N. Tabacum will pay.

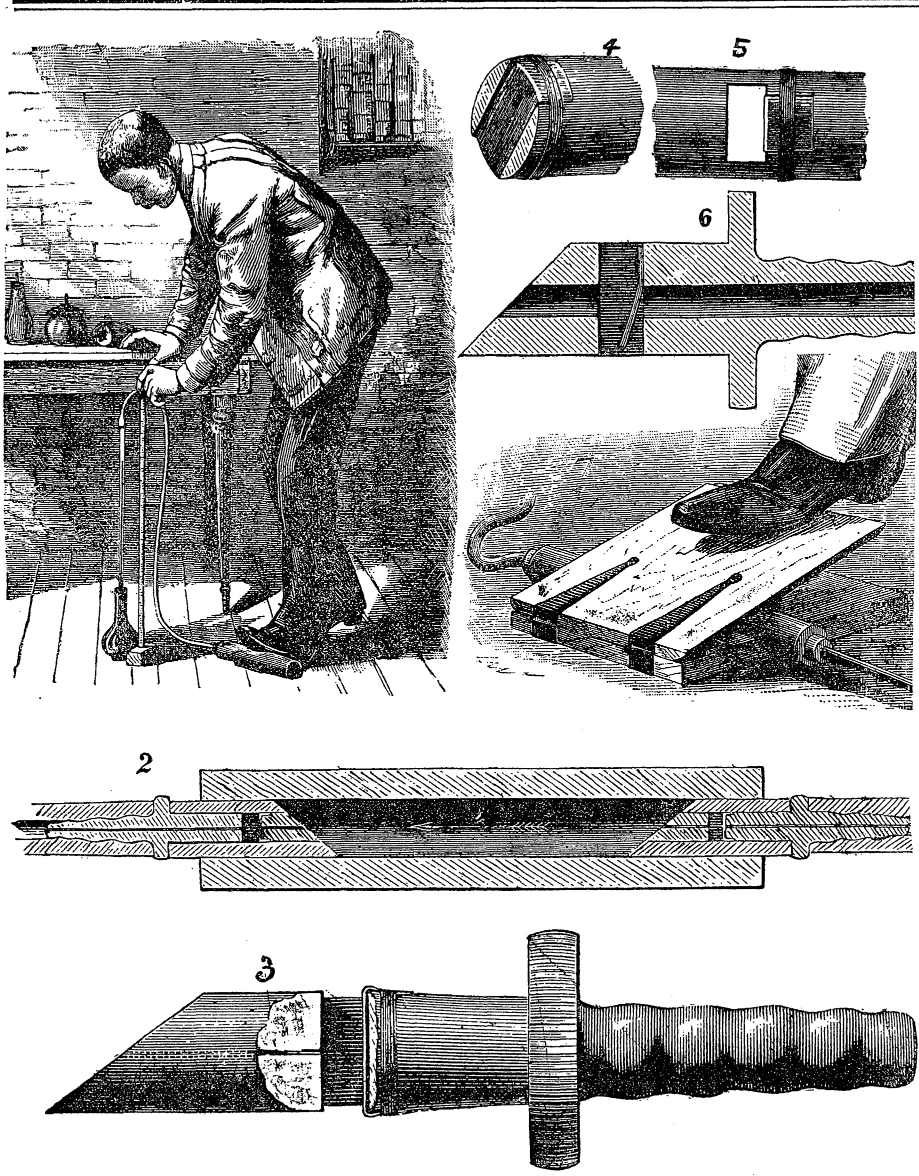
HOW LONG TO SLEEP.

IT is manifestly impossible to lay down any universally applicable rule as to the number of hours which it is desirable to sleep. Probably no two persons require precisely the same amount of slumber, and it is scarcely likely that any person needs the same length of sleep on all occasions. Even the most monotonous lives involve the expenditure of varying quantities of energy, and make differing demands on the stores of nerve and muscle power on several days. We do not, of course, mean to imply that sleep is *the* season of recuperation. That is unlikely in view of the ascertained facts in relation to tissue-feeding and physiological change; but it is nevertheless true in practice that prolonged or exceptionally severe exertion, whether of brain or muscle, requires a correspondingly lengthy or deep repose. Speaking broadly, sleep is the state in which the fires are, so to say, damped down, and the machinery has opportunity for cooling. The bow is, as it were, unstrung, and may recover its elasticity during the recurring periods of slumber. The great point is to secure what Bichât characterised as general sleep made up of particular sleeps. The whole body should be rested—so far as any avoidable demand on its energy is concerned—during sleep. The Irishman, who explained that a short sleep did for him because when he slept he "paid attintion to 't," uttered a truth in his witticism. If sleep be thorough, then a short spell will do more good than a much longer duration of sleep that is incomplete and imperfect, both in its nature and in its effects. We cannot discuss the physiology of sleep in this place; but two or three propositions, based on experience and observation, may be briefly set down by way of suggestion worth thinking out for special application in individual cases. Sleep is a distinctly natural function, and, therefore, both as regards its induction and management, ought to be performed in conformity with natural laws. That it is a state which should recur periodically is evident from the rotation of day and night, and approximately we ought to go to sleep when the natural light fails and wake with the sunrise. It will, therefore, be evident that Nature meant us to sleep longer in the winter than in the summer, for the sufficiently plain reason that the maintenance of animal heat during the cold season necessarily requires a larger consumption of energy than is expended on this vital purpose in the warm season. It has been alleged that the organism takes in and stores just as much oxygen during sleep as it has expended during the waking hours, and when the reserves are replenished wakes; but this is only a half-truth, in so far as it is a truth at all. What happens is rather a rest from the rapid movements of waking life, during which the slower activities of function have time to overtake the faster ones. Recuperation by nutrition is a more tardy process than consumption by work and heat production, and if the hare were not to sleep the tortoise would be left hopelessly behind. It is essential to health that the tortoise should not lag far in the rear, and sleep must be just as long as will enable the laggard nutritive processes to overtake the impetuous destructive processes. Practically, therefore, a man should sleep until he is refreshed. The mistake many persons make is in attempting to govern what must be a matter of instinct by volitional control. When we are weary we ought to sleep, and when we wake we should get up. There are no more vicious habits than adopting measures to "keep awake" or employing artifices, or, still worse, resorting to drugs and other devices to induce or prolong sleep. Dozing is the very demoralisation of the sleep function, and from this pernicious habit arises much of the so-called sleeplessness—more accurately wakefulness—from which multitudes suffer. That day is not the time for sleep is evident upon the face of the fact that Nature has provided the night, wherein no man can or ought to work. Instead of trying to lay down arbitrary rules as to the length of sleep, it would be wiser in a common-sense and physiological way to say, Work while it is day; sleep when you are weary, which will be at night if the day has been spent in honest and energetic labour. When you wake, rise; and if the day's work has been sufficiently well done, the time of waking will not be earlier than sunrise. The difficulties about sleep and sleeplessness—apart from dreams—are almost uniformly fruits of a perverse refusal to comply with the laws of nature. Take, for example, the case of a man who cannot sleep at night, or rather who, having fallen asleep, wakes. If he is what is called strong-minded, he thinks, or perhaps reads, and falls asleep again. This being repeated lays the foundation of a habit of waking in the night and thinking or reading to induce sleep. Before long the thinking or reading fails to induce sleep, and habitual sleeplessness occurs, for which remedies are sought and mischief is done. If the wakeful man would only rouse himself on waking, and get up and do a full day's work, of any sort, and not dose during the day, when next the night came round his sixteen or twenty hours of wakefulness would be rewarded by a sleep of nine or ten hours in length; and one or two of these manful struggles against a perverted tendency to abnormal habit would rectify the error and avert the calamity. The cure for sleeplessness must be natural, because sleep in a state of natural rhythmical function. You cannot tamper with the striking movement of a clock without injuring it, and you cannot tamper with orderly recurrence of sleep without impairing the very constitution of things on which the orderly performance of the function depends.—*Lancet.*

AN INEXPENSIVE AIR-PUMP.*

A BRASS air-pump gleaming with polished and lacquered surfaces, mounted on the conventional mahogany base, and furnished with accessories for convenient experimentation, is desirable and useful, beside being ornamental; but how many of those interested in the study of pneumatics have free access to such a machine, or, indeed, any other apparatus which will enable them to investigate practically and individually the interesting phenomena of the air and gases? It may be safely said that the number is comparatively small. The engraving illustrates an

* By GEORGE M. HOPKINS, in the *Scientific American.*



2, Longitudinal section of simple air pump; 3, valve casing partly in section; 4, transverse section showing valve in perspective; 5, plan view of valve.

efficient air-pump for both exhaustion and compression, which may be made from materials costing one dollar and fifty cents, and with the expenditure of not more than two or three hours' labour. With this pump, the entire range of ordinary vacuum and plenum experiments may readily be performed by the aid of a few well-known and inexpensive articles, such as lamp chimneys, fish globes, a tumbler or so, and pieces of sheet rubber, bladders, &c. Fig. 1 illustrates the manner of using the lamp. Figs. 2 to 5 inclusive are sectional views of the pump and valves. Fig. 6 shows a form of valve for the compression pump, and Fig. 7 shows the application of a foot pedal to the pump.

The materials required are as follows:—A piece of so-called pure rubber tubing $1\frac{3}{4}$in. external diameter, 1in. internal diameter, and 9in. long; a piece of pure rubber tubing 1in. external diameter, $\frac{5}{8}$in. internal diameter, and 5in. long; a piece of heavy pure rubber tubing $\frac{5}{8}$in. external diameter, and 4ft. long; two wooden valve casings (shown in Fig. 2); a strip of the best oil silk, $\frac{3}{8}$in. wide and 8in. or 10in. long, and some stout thread.

The piece of 1in. rubber tube is cut diagonally at an angle of about 30°, so as to divide it into two similar pieces. The wooden valve casing is pierced longitudinally with a $\frac{1}{16}$in. hole and transversely with a hole $\frac{1}{2}$in. square and thoroughly shellacked or soaked in melted paraffin to render it impervious to air. The longitudinal hole is cleared out, and the walls of the square transverse holes are smoothed. One of the walls of the square hole into which the $\frac{1}{16}$ hole enters forms one valve seat, and the other forms the other valve seat. The valves each consist of two thicknesses of the oiled silk strip stretched loosely over the valve seat, and secured by the thread wound around the wooden valve casing. It will, of course, be understood that when the valve casings are placed in the 1in. rubber tubing, and the 1in. tubes are placed in the ends of the larger tube, as shown in Fig. 2, the valves must both be capable of opening in the same direction, so that the air may pass through the pump, as indicated by the arrow, entering by one valve and escaping by the other.

The pieces of rubber tube inclose the valve casings, so that each valve has a little air-tight chamber of its own to work in. The bevelled ends of the rubber tube are arranged as shown in the engraving, and the inner ends of the wooden valve casings are bevelled to correspond, so that when the large rubber tube is placed on the floor and pressed by the foot there will be very little air space left in the pump. The 4ft. rubber tube is attached to one end of the pump for vacuum experiments, and to the opposite end for plenum experiments. To avoid any possibility of the sticking of the valves, the valve seats are rubbed over with a very soft lead pencil, thus imparting to them a slight coating of plumbago, to which the oiled silk will not adhere. As an elastic rubber pump barrel of the kind described requires considerable pressure of the foot to insure the successful operation of the pump, it is advisable to construct a treadle like that shown in Fig. 7. It consists of two short boards hinged together, the lower one having a shallow groove for the reception of the middle part of the pump. The edges of the upper board are bevelled at about the same angle as the ends of $1\frac{1}{4}$in. rubber tube. The width of the hinged boards should be somewhat less than the length of the chamber in the pump. A mark is made on the side of the larger tube at one end to indicate the top, the proper position for the pump being that shown in Fig. 2.

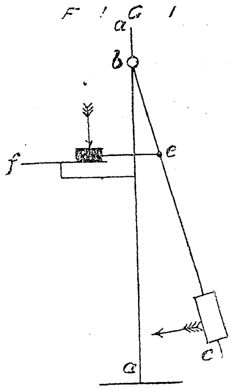
The pressure of the foot on the side of the pump barrel expels the air through the discharge valve, and when the barrel is released, its own elasticity causes it to expand, and while regaining its normal shape it draws the air from any vessel communicating with the suction valve.

A vacuum sufficient for most of the ordinary experimental work may be produced by means of this pump in a short time. A gauge may be improvised by attaching the suction pipe to a piece of barometer tube about 30in. long, and dipping the end of the tube in mercury, using a yard measure as a scale, as shown in Fig. 1. The pump will be found to compare favourably with piston pumps. When it is desired to construct a pump of this kind for compressing air or for a low vacuum, the elastic tube forming the pump barrel may be larger and thinner, and the hole through the wooden valve casing may be made larger, as shown in Fig. 6, and the oiled silk valve may be replaced by a simple rubber flap valve, held in place by a single tack.

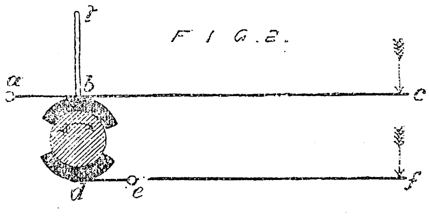
RECENT RESEARCHES ON FRICTION AND THE ACTION OF LUBRICANTS.*

By PROF. HELE-SHAW.

THE engineer has to deal with friction from two opposite points of view. On the one hand he has to employ the useful, and on the other to obviate the prejudicial resistances to which it gives rise. It would, perhaps, be difficult to say which is the more important problem of the two; but, taken together, they form a subject which is second in importance to no other. The nature and laws of friction have been the subject of scientific investigation since the end of the 17th century, when Amontons published his researches; but it is to Coulomb that we owe the first definite statement of the laws of sliding and rolling friction, the general truth of which was established by the experiments of General Morin, between the years of



1830 and 1834. These laws, which are remarkably simple and convenient of application, and which it has been the practice of various writers to state as universally true, have thus not unnaturally been employed until quite recently by practical men, as near approximations to the truth, for all cases and under all circumstances. The above experiments, although very numerous, were, however, made under a limited range of conditions, Morin himself never asserting that the truth of the laws established by them held beyond this range. The extensive investigation which has taken place during the last ten years, not only in connection



with the friction of solid bodies, but concerning that of fluids, has made evident the existence of much more complex laws of friction. We are still far from having arrived at any state of finality in our knowledge as to the nature of friction, and, in truth, such is the vast range of the subject that it is no easy matter to obtain a general grasp of the whole, which will be found to include all the most important questions in what we know as physical science. The literature of the entire subject is not yet published in any one book, and, with the exception of a few treatises on separate portions, is only to be found in the form of papers and articles in scientific periodicals and journals. It is not to be expected that even an abstract of it can be given within the brief limits of a paper like the present one, the object of which is to bring before the members of this society some of the results of recent experimental work which most directly concerns engineers, omitting all reference to the friction of liquids (acting otherwise than as lubri-

* A paper read before the Liverpool Engineering Society

cants), and also to the friction or viscosity of gases.

The laws of the friction of solid bodies enunciated by Coulomb are expressed thus:—

For sliding or lower pairing:

Resistance of friction $= F = \mu R$.

For lower or higher pairing:

Resistance of friction $= F = \mu \frac{R}{r}$

Where R = the pressure between the surfaces in contact.

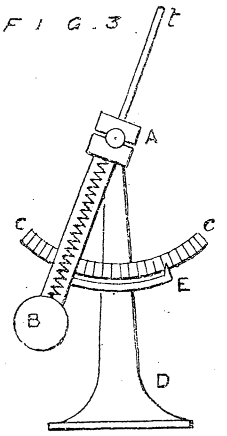
r = radius of the rolling body.

μ = a quantity, called the co-efficient of friction, depending on the nature of the surfaces in contact.

These laws leave nothing to be desired in point of simplicity; but this simplicity is attained by the sacrifice of exact truth, even when the surfaces are dry. When lubricants are used, Morin found these laws to approximately hold for a limited range of conditions; but when the range is extended so as to embrace modern conditions of working they utterly fail, and must be replaced by others of quite a different form. Thus the influences of change of velocity and change of temperature, of which the law takes no account, and of which the resistance of friction is supposed therefore to be independent, are in reality very important factors, while the statement that for any given material the resistance varies directly as the pressure—that is, $\frac{F}{R} = \mu =$ a constant—is, as will be seen, quite erroneous. It is not easy to consider the effects of frictional resistance due to these four conditions at once, and thus they will be dealt with separately in the following order:—

1. The effect of the nature of substances in contact.
2. The variation of effect with variation of pressure.
3. The effect of change of relative velocity of the surfaces.
4. The effect of change of temperature.

FIG. 3.



This separate mode of treatment, which, although convenient, cannot, from the difficulty of dissociating the effect of the various conditions, be in any case rigidly adhered to, will only be applied to the case of sliding or lower pairing. Afterwards the nature of rolling friction, or the friction of higher pairing, will be briefly considered.

I. *The effect of the nature of materials in contact.*—This part of the subject, which may be said to be the most important of all questions, was long ago sufficiently examined for dry surfaces under ordinary conditions by Morin, and the results are well known; but for the important conditions to which the dry surfaces of brake block are subject, Morin's results are quite inapplicable. Captain Galton, in his experiments on the effect of railway brakes (*Proc. Inst. Mechanical Engineers*, April, 1879, p. 174), found the co-efficient of friction was affected both by the material in the brake blocks and by the state of the weather. On dry rails the co-efficient of friction was generally above ·2; but in some cases it was as much as ·25, and sometimes even higher. On wet or greasy rails on which no sand was used it had an average value, for 300 experiments, of ·18, but in one case was only ·15. With sand on wet rails it was always above ·2; but when sand was used at starting, and was therefore not carried off by the wind of the rotating wheels, it was as much as ·35 and even ·4. For lubricated surfaces and lubricants there have been great recent advances in our knowledge. Surfaces may be lubricated with either solid or fluid lubricants. The chief solid lubricants are graphite or black lead, asbestos, and soapstone. Of these graphite is the most important, and though it has been employed for the purpose in question for more than 200 years, it is only of late that its proper mode of preparation has been understood, and its use consequently much extended. It must be free from grit, and in order to attain this end it is floated in water, and treated with a bath of dilute sulphuric acid. The particles of iron and spar are thus removed, and the remaining impurities can be washed out. Asbestos, which has become an article of great importance, as packing for steam engines, is a mineral substance found most plentifully in Savoy and Corsica. It has a fibrous texture which undergoes little alteration by heat, and though known to have been woven by the ancients into cloth, its extensive and quite modern application, when used as packing, has resulted, to a great extent, from its lubricating qualities. Asbestos, it is true, is almost invariably employed in conjunction with some fluid lubricant; but its nature is such as to considerably reduce the friction. Soapstone, which is a silicate of magnesia and alumina, is now prepared somewhat in the same manner as graphite, being used sometimes as a powder, but more generally mixed with a rather larger quantity of oil or grease. In the preparation, choice, and examination of fluid lubricants great progress has been made. With regard to the first two matters, little can here be said; but it may be remarked that the special qualities of the three main classes of oils—viz., animal, vegetable, and mineral—are now understood, their special adaptation to particular purposes known, and the advantage to be derived from their mixture realised. An undoubted authority on the subject says: "Bearing in mind the natural and almost ineradicable tendency of animal oils to develop acid, and of vegetable oils by absorption of oxygen to gum and clog bearings, and to induce spontaneous combustion; bearing in mind that mineral oils can now be obtained in every respect as safe as the finest animal oils, and that the admixture of mineral oil with animal or vegetable oil neutralises the acidity in the one case, and the acidity and oxidising tendency in the other, I am of opinion that the safest, most efficient, and most economical lubricants for all manner of bearings are to be produced by judicious mixtures of animal or vegetable with good mineral oils." The examination or testing to which oils are subjected are of three kinds—chemical, physical, and mechanical. There are, of course, the time-honoured tests by the senses of touch, taste, and smell; but of these, though valuable to the experts, nothing need be said. The chemical tests are chiefly for the purpose of detecting adulteration and measuring acidity and actions upon metals. Various chemists, amongst whom are Calvert, Cailletet, Chateau, Wallace, Waltz, and others, have investigated the subject of the reactions of various oils, and an abstract of the principal results has been given by Prof. Thurston. It may be necessary to ascertain what an oil or lubricant actually is; but it is much more frequently required to know whether it is pure or not, and the work of the above-mentioned chemists and others has resulted, not only in a knowledge of facts, such, for instance, as that chlorine turns animal oils brown and vegetable oils white, but also in certain systematic methods of test. The first step is to place the lubricant in one or other of certain defined classes, next, by other tests, to place it in its proper sub-divisions, and finally to analyse it with a view to the determination of its constituent parts. It must be remembered that by far the greater proportion of lubricating oils are ostensibly mixtures; vendors of such oils holding (as, for instance, Mr. Veitch Wilson, in the paragraph previously quoted) that such mixtures produce the best results. Thus chemical tests, though sometimes employed for examining the actions of lubricants on metals, chiefly tell what the lubricant *is*, and are of little practical importance compared with physical and mechanical tests, which tell what the lubricant *does*. The chief physical tests are the determination of (1) density, (2) the effect of heat, (3) the gumming and drying properties of a lubricant. 1. The density or specific gravity of an oil is sometimes an important matter, as there is a considerable difference between various oils; but the determination is easily affected by ordinary methods. 2. The effect of heat on the nature of a lubricant must not be confounded with the effect of rise of temperature on frictional resistance. The application of heat is important rather in connection with mineral oils which vaporise, and compounds into which mineral oils largely enter, than with animal and vegetable oils which thicken and decompose. There are two points for consideration in connection with the former class of oils, one being the amount of evaporation taking place at temperatures not exceeding the boiling point of water, the other the actual point at which the ignition of the vapour given off takes place. Mr. Wilson in his paper states that, though many oils, considered good, lost 5 per cent., and one or two samples 10 per cent., in a 10-hours' test at 212° F., yet, on the other hand, many oils lost nothing at all. The second point is, however, much more important, and there are strong reasons for attributing several recent conflagrations and consequent destruction of mills to the ignition of the lubricants used in them. The "fire test" thus becomes an important one. There are several pieces of apparatus for the purpose, the principle of them all being simply to heat the oil until the vapour given off ignites on the application of a light, the temperature of ignition, or "flash point," being observed by means of a thermometer. The neatest instrument for the purpose is that of Bailey, in which the oil is heated in a copper vessel about three-quarters full, the vapour from which, issuing laterally, comes in contact with the flame of the heating lamp or Bunsen burner. This is a more satisfactory arrangement than the application at intervals of a light to the orifice. There are many oils which flash at 180° F., some at 150° F.; but an oil should never be used for lubricating purposes which flashes at a point below 250° F., some of the best mineral oils vapouring at 600° F. 3. The gumming and drying properties of oils may be simply tested by allowing samples to flow down an inclined plane, when the nature of the oil becomes manifest; sometimes, if a bad specimen, after an hour or two, and sometimes after a day or so, the best oils remaining liquid, and continuing to flow down even after several days. This is the mode in which the Swiss watch oils are tested. Mr. Bailey has contrived, for this purpose, a convenient arrangement, consisting of a box filled with water, and, having an inclined sheet-glass top, the water is kept at 200° F., and the behaviour of a given small quantity of oil placed on the surface of the glass is noted. There are other modes of physical tests, but not of sufficient practical importance to demand consideration.

(*To be continued.*)

THE NEW APOCHROMATIC MICRO-OBJECTIVES AND COMPENSATING OCULARS OF CARL ZEISS IN JENA.*

Dr. Carl Zeiss has had the kindness to send me four of his new apochromatic objectives, and three of his new compensating eyepieces for inspection, and as a short notice of only one of these objectives has to my knowledge appeared in this country—viz., in the *Journal* of the R. M. S., Vol. VI., part 2, fol. 375-6, I trust that the following remarks, culled chiefly from Dr. Abbe's pamphlet, "Ueber Verbesserungen des Mikroskopes mit Hilfe neuer Arten optischen Glases" (on improvements in the microscope by the aid of new kinds of optical glasses), may be acceptable to the members of our society.

Professor Dr. Ernest Abbe, who is "the first living authority on microscopical optics," and to whom we are indebted not only for the greatest recent improvements in the construction of micro-objectives, but also for the theory of the formation of microscopical images by diffraction spectra, and for lucid mathematical expressions of the relation of aperture, resolving power, focal depth, &c., &c., finding that the aperture of micro-objectives had been pushed to almost its theoretical limit, and foreseeing no adequate advantages in trying to increase the aperture with the means hitherto at our command, directed his attention to further improvements by an entirely different method.

In conjunction with Dr. Carl Zeiss, the eminent optician of Jena, and with the assistance of Dr. Schott, Dr. Abbe began in 1881 to make experiments with the view of producing new kinds of optical glasses.

The relation of the optical properties to the chemical compositions of various kinds of experimentally produced glasses was first established by spectroscopical researches, and finally such glasses were produced as possessed the properties most desired. In this way, and by combining a far larger number of elements than formerly, especially by means of phosphoric and boric acids, besides silicic acid, two new and much desired results have been attained—viz:

(1) The production of crown and flint glass in which the dispersion for the different regions of the spectrum shows approximately the same ratio, and which, therefore, in achromatic combinations permits of the almost complete elimination of the secondary spectrum.

(2) The increase of the number of optical media in such a way that with the same mean refractive index the dispersion, or with the same dispersion the refractive index, may be varied within considerable limits, especially so that high values of the refractive index can be obtained, not as hitherto only in combination with flint glass of high dispersion, but also with lower dispersive indices as in crown glass.

These new kinds of optical glasses are produced in the Glastechnisches Laboratorium, in Jena, which has been supported in the most liberal manner by the Prussian Ministry of Public Instruction, and they are now being supplied to the trade.

Mr. Carl Zeiss, who constructs all his lenses on strictly scientific principles, and according to the

* Read by Adolf Schulze before the Natural History Society of Glasgow, Tuesday, 28th September, 1886.

formulas of Professor Abbe, is the first optician who has produced micro-objectives of these new glasses, and he has thus been able to correct two important defects which up to now could not be overcome with the means at the disposal of opticians and which offered insurmountable obstacles to the further improvements in lenses. In consequence, namely, of the great disproportion of the dispersion of the various colours of the spectrum, a property inherent in crown and flint glass, our best so-called achromatic lenses have up to now been corrected for only two colours of the spectrum, and the hitherto unavoidable remnant of unachromatism, the so-called secondary spectrum, was always more or less perceptible. With the crown and flint glass used by opticians it was equally impossible to correct the spherical aberration for more than one colour. All objectives, although fairly well corrected for the middle of the spectrum, showed, nevertheless, a spherical under-correction for the red and a spherical over-correction for the blue and violet rays, which imperfection appeared as a more or less great inequality of the achromatic correction between the central portion and the peripheral zones of the objectives.

These defects caused an imperfect combination of the image-forming rays, and as a result objectives, especially those of large apertures, did not allow the employment of high magnifying oculars, because those deficiencies of spherical and achromatic corrections became more apparent with them than with the lower magnifying ones.

The practical advantages of Abbe's new objectives made by Carl Zeiss from the new optical glasses are the following:—

(1) The full value of the large apertures of objectives becomes now only apparent, because owing to their perfect corrections, the images formed by the new dry and water immersion objectives are scarcely distinguishable from those formed respectively by the water and homogeneous immersion objectives of perceptibly larger numerical aperture hitherto constructed.

(2) The largest magnifications for a certain aperture can be obtained by high eyepiecing and by objectives of relatively long foci, thus obviating the necessity for objectives of extreme short focal lengths.

(3) By the correction of the secondary spectrum and the perfect spherical correction of these new lenses, the visual and actinic foci coincide, rendering them especially suitable for photo-micrography.

(4) The increased spherical and achromatic corrections of these objectives produce a larger concentration of light in the images projected by them.

Dr. Abbe calls these new lenses *Apochromatics* or *Apochromatic Objectives*, owing to their superior spherical and achromatic corrections, which represent an achromatism of a higher order than hitherto attained.

These apochromatic objectives require special eyepieces in order to utilise their capabilities to the fullest extent, and Dr. Zeiss has constructed suitable eyepieces, and designates them *Compensating Oculars*.

In objectives of short focal length or in high powers the front lens is generally a single crown glass lens, which is, therefore, unachromatic, the result being coloured outlines of the image in the marginal zone, as the lens is only well corrected for its central portion. The front lenses of the high-power apochromatic objectives are evidently also single ones, and the so-called compensation oculars have been constructed with a view to correct this residue of peripheral aberration, and to balance or compensate the chromatic differences of magnification, as the picture produced by the blue and violet rays is larger than that produced by red and yellow rays. In order, therefore, to make the compensation oculars available not only for the high objectives but also for the lower ones, the latter had to be so constructed that the difference of the chromatic magnifications of the marginal zone should be practically the same as in the former. These compensation oculars differ from the ordinary Huyghenian and other eyepieces in this respect, that their eyelenses of even the strongest have relatively long foci, so that they can be used with almost as much comfort as the lower power oculars. The camera lucida can also be used with any of them save the highest, which magnifies 27 diam., and has 10mm. focal length. These are great recommendations, and the wonder is that opticians have not long since constructed high magnifying eyepieces with large eyelenses of such focal lengths that comfort is insured thereby and undue straining of the eyes avoided.

Instead of naming the different eyepieces A B C, &c., or 1 2 3, &c., as other opticians do, Mr. Zeiss designates the compensating oculars by their magnifying power; thus the eyepieces No. 1, 2, 4, 8, 12, 18, 27 magnify the image produced by the objective 1, 2, 4, 8, 12, 18, 27 times respectively. Both the magnifying power or number and the focal length are engraved on each eyepiece, so that when the magnifying power of an objective at the end of a tube 160mm. or 250mm. long is known, one can at once find the magnifying power of the microscope by multiplying the initial magnification of the objective by the number of the ocular with which it is combined.

The compensating eyepieces are divided into three classes—viz:

(1) *Search oculars* of great focal length. The one No. 1 constructed for the short or Continental tube does not magnify the initial magnification of the objective at all, and the two No. 2 magnify, both on the Continental and on the English tubes respectively, the image produced by the objective two diam. These objectives, as their name indicates, are intended to enable the observer to find rapidly an object in the field without employing another low-power objective, and perhaps a cumbersome nosepiece, which is so prejudicial to the centricity of the optical system and to the fine adjustment of the microscope. A great saving of time, labour, and annoyance can thus be effected by these low-power eyepieces, especially when using immersion lenses.

(2) *The ordinary working oculars*, magnifying respectively 4, 8, 12, 18, and 27 diam.; their focal lengths vary from 45 to 10mm. for the Continental stand, and from 67 to 10mm. on the English 10in. tube.

(3) *Oculars for projection*, magnifying 2 and 4 diam. for a tube of 160mm., and 3 and 6 diam. for a tube of 250mm. or 10in. long respectively. These oculars have two diaphragms each, to reduce the effective apertures of the high-power lenses should such be desirable.

They are constructed for photo-micrography and for the lantern microscope, and yield an evenly illuminated flat field and a well-defined image at any screen distance. They can also be used advantageously with the ordinary achromatic micro-objectives.

The mountings of these oculars are so arranged that the lower foci of all those belonging to one series are lying in the same plane, so that when interchanging them no new focussing of the objective is required, the optical tube length remaining the same.

I subjoin tables of Mr. Carl Zeiss' new apochromatic objectives showing their numerical apertures, equivalent focal lengths in millimètres, and their magnifications at 250mm. It will be seen from them that the whole series for both Continental and English tubes together consists of only 11 lenses, and that 3 dry, 1 water immersion, and 1 (or 2) homogeneous immersion lens, in all 5 apochromatic objectives, would constitute a complete series, and in conjunction with the new compensating eyepieces would do all the work for which hitherto often from one to two dozen objectives were required.

The homogeneous immersion lenses are constructed without screw-collars, and they require to be used with thickened cedar-wood oil, having a refractive index of 1·5128. In spite of their large apertures, they will work through covers of about $\frac{1}{100}$in. thickness.

The lenses kindly submitted to me for inspection are the following:—

	mm.		focus.		mm. aper.
Apochromatic objective	16	about	$\frac{4}{5}$in.	and	0·30
,, ,,	4	,,	$\frac{1}{7}$in.	,,	0·95
,, water immersion ,,	2·5	,,	$\frac{1}{10}$in.	,,	1·25
,, homog. ,, ,,	2	,,	$\frac{1}{12}$in.	,,	1·40

and they are undoubtedly the finest objectives which I have ever seen, leaving far behind in their performances many lenses which I have hitherto considered as almost unsurpassed. The pictures produced by these new lenses are remarkably achromatic and bright, and owing to the exquisite definition of these objectives structural details on surface markings come out with wonderful sharpness and distinctness. I am especially pleased with the lens of 4mm. focus and the homogeneous immersion lens of 2mm., which latter, owing to its enormous aperture and brilliant definition, resolves test objects, considered difficult, with the greatest ease. The facility with which high magnifications may be obtained without loss of definition, and without discomfort to the eyes from using high eyepieces, is most agreeable. I have no hesitation in saying that these apochromatic objectives are destined to supersede the present achromatic objectives, and that as Mr. Carl Zeiss offers his new optical glasses to the trade, and, with his usual liberality, places no restrictions, by patents or otherwise, on the making of these lenses, other opticians will soon enter into wholesome competition with him, with the result that apochromatic objectives will shortly be supplied by all good makers. Meanwhile, the high prices of the apochromatics are standing in the way of their general adoption, the lower powers costing almost double the price that our best English opticians charge for theirs, whilst the prices of homogeneous immersion lenses are, considering their great aperture, probably the same as those of our first English makers. Meanwhile, many microscopists, especially students, have to content themselves with a microscope stand and objectives of 1in. and a $\frac{1}{4}$in. focus, costing altogether not more than one of the new apochromatic 1in. objectives, and a good working instrument can be had nowadays at a very small cost. In conclusion, I express the hope that other optical apparatus besides the microscope will derive important benefits from the invention of these new optical glasses.

Tables referred to in this paper:—

APOCHROMATIC OBJECTIVES.

	Num. apert.	mm.	
Dry system.	*0·30	24·0	screen distances.
,,	0·30	16·0	,,
,,	*0·60	12·0	,,
,,	0·60	8·0	,,
,,	*0·95	6·0	,,
,,	0·95	4·0	,,
Water immersion	1·25	2·5	,,
Homog. ,,	1·30	3·0	,,
,,	1·30	2·0	,,
,,	1·40	3·0	,,
,,	1·40	2·0	,,

* These are manufactured only for the English tube.

Table of the magnifications of the apochromatic objectives and compensation oculars for 250mm. screen distance:—

Screen distance of the objective.	Search oculars.		Working oculars.				
	1	2	4	8	12	18	27
24·0		21	42	83	125	187	281
16·0	15·5	31	62	125	187	281	
12·0		42	83	167	250	375	562
8·0	31	62	125	250	375	562	
6·0		83	167	333	500	750	1125
4·0	62	125	250	500	750	1125	
3·0	83	167	333	667	1000	1500	
2·5	100	200	400	800	1200	1800	
2·0	125	250	500	1000	1500	2250	

A number of test objects, such as Amphipleura pellucida (half a dozen valves in one field showing all their crossmarkings most distinctly resolved) Navicula rhomboides, Surirella gemma, Pleurosigma angulatum, Heliopelta, Podura scales, &c., were exhibited under the new apochromatic lenses at the close of the meeting, and as a proof of the photographic excellence of these objectives, negatives of photo-micrographs of most of the above-mentioned, including Amphipleura pellucida, all taken by ordinary lamp light, were placed upon the table.

SOME LATHE WRINKLES.*

EVER since lathes have been used, there have been cases when the largest available lathe was too small for the work to be done upon it.

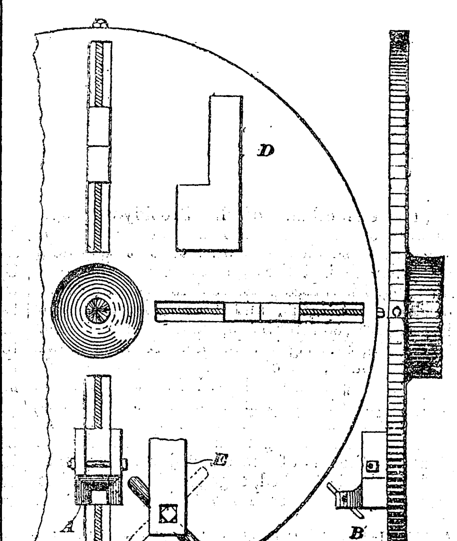


Fig. 1

Rigging up seems to be one of the principal parts of the jobbing machinist, and the more jigs and kinks available, the better off he is. The examples given below are from the production of O. C.

* By JAMES F. HOBART, in the *American Machinist*.

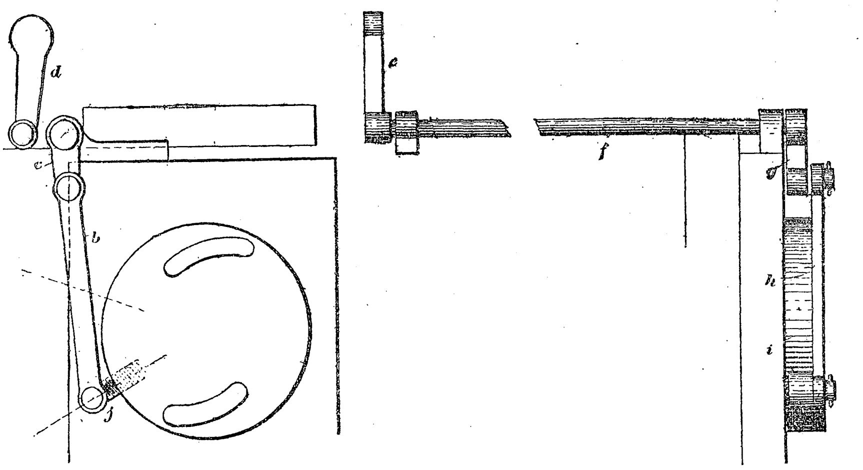

Fig. 2

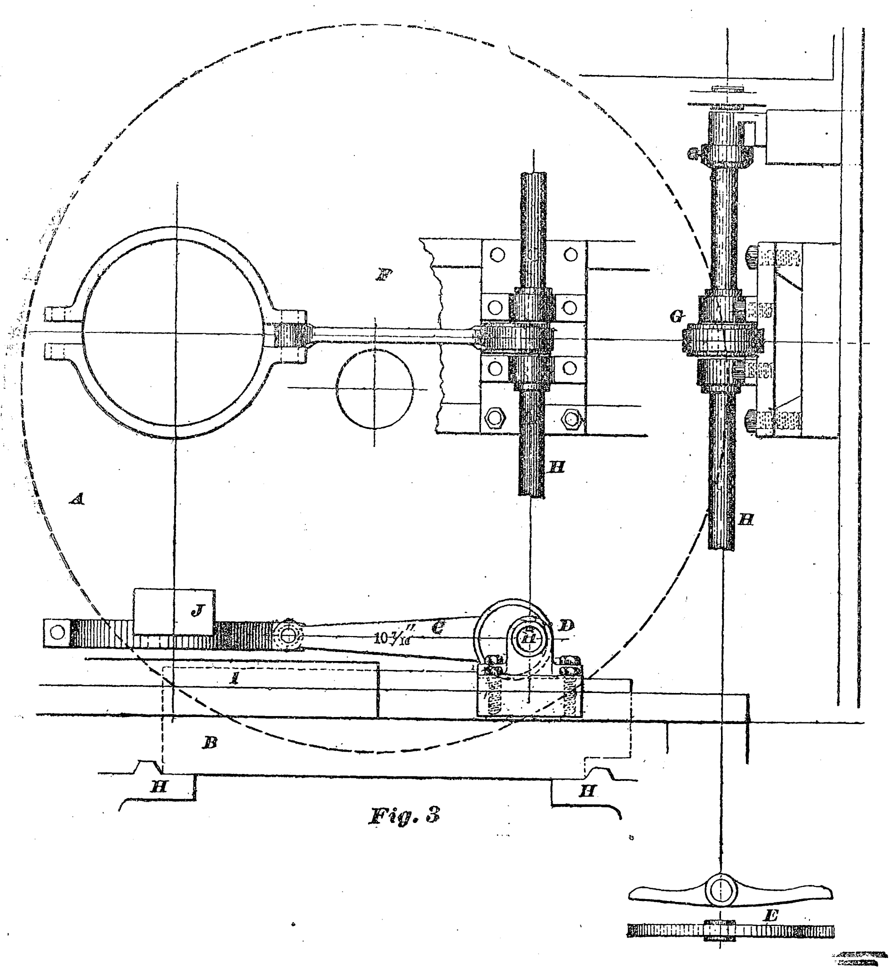

Fig. 3

Crane, master mechanic of the Brooklyn Bridge. Some of them are well known; the method of application is so clearly shown that it may help others when their lathes get too small for their work. Fig. 1 is a face-plate tool for turning work placed upon the lathe, and bolted thereto. For facing columns, counter boring, and facing cylinders and like jobs, this rig is valuable. At D is shown one of the four jaws of the independent chuck, which has a $\frac{5}{8}$in. hole drilled in it as shown. The rig shown at A and B is bolted to the jaw D, and the end of the rig is drilled for tools and a set screw as shown on a larger scale at E. At C a star is placed on the end of the chuck-jaw screw, and a pin F, in the lathe bed, engages the star and revolves one point at each revolution of the face plate.

A 32in. lathe in this shop has the nut-locking mechanism at the back side of the lathe, and to operate the nut, the lathe man must either lie down upon and reach across the lathe bed, or travel around it to the other side. To help this matter, the screw eye *j*, Fig 2, was tapped into the nut cam, and the rod *f* placed besides the cross slide on the rest is connected by crank *c* and rod *b* to bolt *j*. The crank *d*, as shown at *e*, serves to operate the nut from the front of the lathe, and proves a convenient time saver. Sometimes the rod *f* is in the way when work is being done close to the tail stock. In this case the rod may be quickly detached, and removed altogether.

Fig. 3 shows a rig for turning an eccentric shape in the lathe, or for turning but one side of a body. The tool nut J is disconnected from the cross-feed screw, and connected with the cam P by the lever C, the whole sliding easily upon the slotted rod H, which carries the clip E. This clip engages two pins upon face plate A, causing the rod H to make one part of a revolution, and moving the tool to and from the work. The cut shows so plainly the construction of this device, that further description is unnecessary.

An old drill press which had become so worn that $\frac{1}{8}$in. of lost motion presented itself in spindle connections, was "cured" by means of a forked lever attached to a loose collar just below the tight collar. This lever was weighted by means of a wire cable carried over two sheaves. The weight was just sufficient to overbalance the weight of spindle, allowing a hole with a $\frac{1}{10}$in. drill to be drilled through a piece of iron without the risk of the drills dropping suddenly through and breaking off.

PRACTICAL SUGGESTIONS ON BOOKBINDING.

AT the meeting of the Library Association of the United Kingdom, Mr. J. W. Zaehnsdorf read a paper entitled "Practical Suggestions on Bookbinding," in which he remarked that there was no doubt the strength of a bound book was like every other built-up fabric, and that was in the foundation; for if th foundation was good, the finished building would be firm, and he took it that the foundation of a bound book was in the binding. He passed over the pressing or rolling, because pressing only gave the book a better or firmer feel, and it had nothing to do with the strength. If they examined a book bound, say, 200 years ago, they would find the whole of the binder's craft in the sewing, thread being used made of hemp or flax. Each sheet was sewn round the bands, of which there were never less than four, in many cases six, eight, or many more. They would find even the head band worked round a cord which gave further strength to hold all together. If a book was now sewn with bad thread or three bad cords, it was considered to be very well done; and if the book fell to pieces in a short time it was nothing more than the bookbinder expected, and he got the book back to rebind for his benefit. Arnett, in the introduction to his "Art of Bookbinding," quoted one of the statutes and rules of 1750 about sewing: "That the master binders do sew all their books with thread and real bands, and that in case of infringement for each volume the sum of £30 be paid." (Cheers.) The importance of good sewing was not lost sight of by the binders of that date as it was by those of to-day. He would admit that the old paper was of a very different quality to that now used; but in times gone by the paper-maker manufactured a paper that enabled the binder to make the back of his book as firm as a wooden board, the paper being so fine and pliable that it laid down and gave little or no strain to the back. Binders did not get such paper to work upon now, for often it was so thick that it was impossible to get it to lie down flat under any treatment except that of "guarding." His first suggestion was that the books should be sewn with the best thread, for when bad thread was employed the book had to be re-bound. His second was that the books should be "sewn all along," if that were possible—that was to say, that each sheet should have a thread to itself. His third suggestion was that the books should be sewn flexible or on raised boards, if the value of the book warranted the spending of the extra sum. His fourth was that good boards should be used. He would further suggest a cloth joint for all books. The importance of good leather should not be overlooked. They must not be misled by some of the imitations now so often used. There was no leather which wore so well as morocco, but green should be avoided. He would not advise them to have anything to do with russia leather, as this had deteriorated. Within the last year or two pigskin had been manufactured expressly for binding, and this ran morocco very close, and perhaps for hard wear would prove to beat it. He suggested that all books in libraries should be tipped at the corners with vellum, and should be covered with cloth. Mr. Zaehnsdorf exhibited a sample of hemp-thread which ought to be used in sewing books, and also showed a fireproof box invented by himself for valuable books.

USEFUL AND SCIENTIFIC NOTES.

Allen's Gumming Machine.—A useful little gumming machine has been recently patented in this country by Mr. Allen, of the Allen Machine Company, Halifax. It is made in various sizes, but the most generally useful has a length of $8\frac{1}{2}$in., breadth $4\frac{1}{2}$in., height $4\frac{1}{2}$in., and a weight of $7\frac{1}{2}$lb., so that it is readily portable, while its chief merit is its cleanliness. The base of the machine forms the gum-well, through which the gumming cylinder revolves, being driven by a little crank handle which can be turned only in the proper direction. Toothed gear imparts motion to the feeding cylinder, which is covered in parts with rubber, and it is impossible for any gum to get on to the wrong side of the label. The amount of gum can be regulated from the thinnest film to the thickest coat desired, by a similar arrangement to that adopted for supplying ink to printing machines. One end of the feeding roller projects beyond the bearing, so that a machine which will gum labels $4\frac{1}{2}$in. wide may also be used for gumming edges. For speed, cleanliness, effectiveness, and economy of gum this machine leaves nothing to be desired. We understand it can be seen at Messrs. New and Co., 15, Devonshire Chambers, Bishopsgate-street, E.C. As there are few wearing parts, the machine will last a very long time, and rarely if ever need repairs.

MR. THOMAS ANDREWS has carried out a long series of tests on pieces of iron and steel submerged at the mouth of rivers, where the fresh water began to mix with the salt water of the ocean. The tests have proved that under these circumstances the corrosion is from 15 to 50 per cent. greater than when the article is submerged in pure ocean water. This increased action is attributed by Mr. Andrews to a galvanic action that is brought into play by the difference of potential caused by the mixture of the waters.

SCIENTIFIC NEWS.

BY the death of Mr. James Kennedy, who was born in Edinburgh in 1797, another link connecting the present with the past history of the locomotive is snapped. Mr. Kennedy, as manager to George Stephenson, made the plans for the first three locomotives employed on the Stockton and Darlington line; but he subsequently became a partner in the firm of Bury, Curtis, and Kennedy, designing amongst other locomotives the Dreadnought, which obtained some celebrity on the opening of the Manchester and Liverpool railway. Mr. Kennedy was the first to use the cranked-axle and horizontal cylinders, the Liverpool being the earliest example, and also the first case of a broken cranked-axle. Mr. Kennedy was afterwards engaged in iron shipbuilding and in the construction of marine engines, and was the first to use pressures so high as 60lb. in marine boilers. In 1860 Mr. Kennedy was elected President of the Institution of Mechanical Engineers.

The death is announced of Rear-Admiral Bedford Pim; an Arctic voyager who played an important part in the rescue of the crew of the *Investigator*, which, under Capt. McClure, had been ice-bound for three years. Lieut. Pim was under Capt. Kellett in the famous *Resolute*, and after an arduous sledge journey of twenty-eight days, reached the *Investigator* and rescued the crew. The deceased Admiral was only in his sixty-first year.

The death of Mr. William Muir, who for more than half a century has been engineer superintendent of the fleet of steamers owned and managed by Messrs. G. and J. Burns, removes from the world a man whose life was intimately connected with the growth of the marine engine. As an apprentice he saw the engines built for the *Dumbarton Castle* in 1814; he superintended the construction and equipment of those famous West Highland steamers so well known to tourists, and as a fitting crown to a remarkable career, he was responsible for the enormous engines of the *Umbria* and *Etruria*, the latest representatives of the Cunard line, every steamer in which was fitted with engines under the superintendence of Mr. Muir, who died recently in his native city, Glasgow, at the age of 81 years.

From Dun Echt Circular No. 125 we learn that Prof. Krueger has distributed a telegram announcing the discovery of a comet by Mr. W. H. Finlay, chief assistant at the Cape Observatory, on Sept. 26. The comet is described as circular, 1′ in diameter, not brighter than an 11th mag. star with some condensation, but no tail. The position was G.M.T. Sept 26, 8h. 0m. 49s.; R.A. 17h. 2m. 1·9s.; S. Dec. 26° 4′ 6″. Daily motion plus 2m. 20s., 4′ south.

The Rev. T. E. Espin, observer to the Liverpool Astronomical Society, says in Circular No. 10:—

A star was observed by Prof. Vogel and Dr. Müller on the night of Feb. 24, 1880, "Spectrum III. *a*, farbe röthlich gelb; geschätzt 9·2m.; fehlt bei Argelander." This star was looked for with the $17\frac{1}{4}$ equatoreal on the nights of Sept. 14 and Sept. 30, but not found. There is no star above 11·5 now in this place; it will probably turn out to be an interesting variable. The star's place for 1885 is R.A. IV. 21m. 25s.; N. Dec. 15° 50·7′; it lies 0m. 35s. *p.*, 0° 8′ N. of θ_1 Tauri.

A new observatory is being erected near the town of La Plata, under the direction of M. Beuf, an ex-officer of the French navy. The instrumental equipment will include a telescope of 31in. aperture, an "équatorial coudé" of 17in., a meridian instrument of 8·6in., a photographic apparatus of the same dimensions as that employed by MM. Henry at Paris, and a Thollon spectroscope with objective of 9·8in. aperture. M. Beuf will at first devote his principal attention to the carrying out of a geodetic survey of the province, including the measurement of an extensive meridian arc in the plains of Chaco and Patagonia.

The International Geodetic Conference will assemble in Berlin on the 20th inst. The chief business is a consideration of the best method of executing the resolutions arrived at in Rome and Washington respecting the actual measurement of a degree on the earth's surface, and in reference to a scientific survey of the European continent. The adoption of Greenwich as the prime meridian is to be insisted upon; but the introduction of international normal time will be postponed.

The Cryptogamic and Botanical meeting of the Essex Field Club will be held on the 15th and 16th inst., the headquarters being at Buckhurst Hill.

The annual report of the Secretary for Mines and Water Supply to the Minister of Mines for Victoria has been received, as has also the report on Mineral Statistics. These are useful works, for mining is carried on with a high degree of perfection in Australia. The Report on mines and water supply contains a number of sheets of drawings of parts of machines, &c., and a large sheet showing the plant of the Port Philip Co.'s Crushing Works, Clunes.

The University of Durham is about to try a novel scheme of University Extension. As in similar schemes, the lectures will be delivered in the evening; but unlike any other extension scheme, this provides that the lectures shall be the same, and be delivered by the same lecturers, as those given to students resident in Durham. Students having attended these evening lectures, and having passed an examination, may then obtain the degree of B.A., or the License in Theology, by one year's residence in Durham. Before being admitted to attend evening lectures, students are required to pass a preliminary examination equivalent to the matriculation. The experiment will first be tried in Sunderland.

A gas locomotive has been tried for several months in Melbourne, Victoria, on the street railways. The gas is carried in four copper containers, 16in. in diameter by 6ft. long, and is compressed to 150lb. on the sq. in. The contents represent about 280 cubic feet of gas at normal pressure, which is found sufficient for a run of fifteen miles. The locomotive weighs about $4\frac{1}{2}$ tons, and the carriage 35cwt.

The congress of the Amalgamated Society of Railway Servants was opened at the town hall, Brighton, on the 5th, when in the absence of the president, Mr. C. E. Stretton occupied the chair, and delivered the address, as well as a lecture in the evening. On the 6th inst. the meeting resumed at 2 p.m. at the Brighton railway station, where the examination and practical trials of the train fitted with the Westinghouse brake were carried out under the direction of Mr. Stretton.

The Baldwin Locomotive Works have nearly completed four Honigman locomotives, which are to be used on the Minneapolis, Lyndale, and Minnetonka railway. The boiler or furnace in these engines is charged with acetate of soda or caustic soda, as explained in No. 962, p. 598.

Herr Paul von Ritter some time back gave £15,000 to the Jena University, for the furtherance of scientific investigation on the basis of Darwin's theory. It has been decided to use half the interest of that sum in maintaining a "Ritter professorship of Philogeny," and the other half is to be expended in grants for scientific travel. Dr. Arnold Lang, formerly assistant to Prof. Haeckel, will be the first occupant of the chair.

At the meeting of the San Francisco Microscopical Society on Sept. 8th, the Secretary, Mr. A. H. Breckenfeld, exhibited specimens of "jasperised" wood from the petrified forest at Chalcedony Park, Arizona Territory. This material, by reason of its extreme hardness and great beauty, is beginning to be extensively used in the manufacture of jewellery and for various ornamental purposes. Under the microscope, the woody fibre, with its characteristic markings, is seen to be perfectly preserved. In fact, it is in many cases possible to determine not only the genus but even the species, by a microscopical examination. Some exceedingly minute "jumping seeds" from Calaveras county, California, each probably containing an insect larva, were shown by the President, and referred to Dr. Bates for further examination.

Dr. Junker, the African traveller as to whose fate considerable anxiety had been felt, has reached Msalala, on the southern shore of Lake Victoria Nyanza, in safety.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

THE LIVERPOOL ASTRONOMICAL SOCIETY — THE EXTENSION OF ASTRONOMICAL RESEARCH—STELLAR PHOTOGRAPHY AT HARVARD COLLEGE OBSERVATORY—PANCRATIC EYEPIECE—TWILIGHT—TIME—VISIBLE AREA OF THE HEAVENS—BAROMETER.

[26332.]—IT must gratify all who have the interests of amateur observational astronomy at heart to learn of the very marked recent success of the Liverpool Astronomical Society, for the membership of which, I am credibly informed, there are at present upwards of 60 new candidates. Following as this does so closely upon the resumption of office by those to whom the Society owes its origin, and under whose fostering care and judicious management it so rapidly developed during the early part of its career, it surely offers a tacit rebuke to the well-meaning gentlemen who temporarily supplanted them, and were so anxious to eliminate the cosmopolitan element from the Society, to circumscribe its sphere of usefulness, and to convert it into a small and strictly local association. Their success in this respect must of necessity have ruined it; in fact, it is a most instructive fact that, as I am told, scarcely six out of the 60 candidates at present up belong to Liverpool itself; and that of the overwhelming majority 35 are from various other parts of the United Kingdom, and no less than 22 from South America. Nor are the new members likely to be disappointed in their anticipation of the advantages to be derived from their connection with the Society, inasmuch as already its lending library has been got into order and a catalogue of it issued; and the *Journal* is, as appears from a prospectus before me, to be converted into a kind of epitome of astronomical news, in addition to the records of members' observations, which it will of course contain. May this valuable Society go on and prosper!

Under the title of "A Plan for the Extension of Astronomical Research," Prof. Pickering, of the Harvard College Observatory, has published a weighty pamphlet, the perusal of which may be commended to all who are anxious for the advancement of astronomical science. The great American astronomer begins by pointing out how much money has been wasted in the endowment of astronomy through a want of thought, or of a competent knowledge of the best means to be adopted to secure the end in view. "Striking instances," he says, "may be mentioned of observatories without proper instruments, large telescopes idle for want of observers, and able astronomers unprovided with the means of doing useful work." And he goes on to add (what may well be impressed upon our own executive when clamorous people demand the erection of "Solar Physical Observatories," and the like, at once as genteel sinecures and advertisements for themselves): "The establishment at a university or college of a new observatory, or the gift of a large telescope, is not in general an aid to astronomical progress." In illustration of the manner in which money might really be profitably devoted to the furtherance of astronomical knowledge, Prof. Pickering adduces the recent determination of the places of about 100,000 of the Northern stars, the joint work of fifteen observatories, which was begun nearly 20 years ago, and has continued ever since. Two American observatories participated in this great work, and one of them—that at Albany—has completed the observation and reduction of the stars which it undertook. The MS. is prepared, but no funds exist for its publication. 3,000 to 5,000 dollars would suffice for this purpose, but it is not forthcoming. Meanwhile the result of many years' labours might at any moment be destroyed by fire, and it is, of course, quite useless until it is published. So, in another way, the great Chicago telescope long lay idle and unused until that

altogether admirable observer, Mr. S. W. Burnham, devoted his evenings to it as an amateur, of course without the slightest remuneration. And again, the Observatory at Litchfield, U.S., spent 25 years in collecting the material for a series of star charts; and in despair of obtaining the funds to publish them, the director did so, "at his own expense, from the savings of a scanty salary." From these and cognate examples Prof. Pickering deduces the conclusion that what is needed just at present is a fund, to be employed in publishing memoirs, &c., too long to be included in astronomical periodicals, furnishing instruments to astronomers, and paying salaries of observers for large telescopes which would otherwise lie idle; and he suggests that such a fund might be most safely and advantageously intrusted to the Harvard College Observatory. I will not weaken the force of his arguments for this by any attempted condensation of them here, but will refer all interested in the matter (and what astronomer is not?) directly to the pamphlet itself.

Yet another work reaches us from Harvard, by its indefatigable director, under the title of "An Investigation in Stellar Photography, conducted at the Harvard College Observatory," which is replete with interest to all who know anything of celestial photography. It will not be forgotten that the first photograph of a star that was ever obtained was one of Vega, taken at Harvard on a daguerrotype plate (under Prof. Bond's direction) by Whipple, on July 17th, 1850; and seven years later we find Bond photographing Vega, ζ Ursæ Majoris, and ε Lyræ, and measuring the distances of their components on the photographic plate. There is then a certain fitness in the carrying on of this research in the observatory in which stellar photography had its birth. It is quite superfluous to add that, as the investigations were under the personal supervision of Prof. Pickering himself, they were of the most elaborate and exhaustive character. A very large number of star charts were obtained showing the stars as discs or points; while other very instructive ones were procured by letting the stars traverse the plate by the diurnal motion, and thus leave trails upon it. A facsimile of the trails left by a number of circumpolar stars forms one of the illustrations of the volume, and very interesting it is. A plate illustrating the photography of stellar spectra, which has been most successfully carried on, is also both curious and valuable. In short, to all who wish to understand stellar photrgraphy in its latest developments the perusal of this work of Prof. Pickering's is indispensable.

In answer to reply 60324 (p. 92), a pancratic eyepiece is simply a terrestrial one in which the two lenses in the eyepiece are separable from the two next the object-glass; the further these pairs are separated the higher being the power. If "D. G." will unscrew the eye-cap of his telescope he will find that the eyepipe will pull out of the tube. Let him then pull it out as far as it will go without shaking or getting loose, and look at any object in the landscape through the instrument (he will have to push the whole eyetube in to refocus it), and then observe how notably the magnifying power is increased. What he here does as a makeshift is done properly by the construction of the tubes in a regular pancratic. Apropos of trusting what he is told anent the power of a telescope, I have myself describe several times in these columns the method of accurately measuring the power of any telescope.

"Lanka" (query 60484, p. 96) is in a little confusion as to his "degrees." A degree of a great circle in the heavens is identical everywhere; at the Poles, at the Equator, in latitude 45°, or anywhere else: the 18° being measured on such a circle passing through the zenith and that point of the horizon vertically beneath which the sun is situated when twilight ends. There is no doubt that twilight not only should, but does, last 72 minutes at the Equator at the date of the equinoxes. When the sun has either North or South Declination twilight there lasts a little longer. As for calculating the duration of twilight, it may be done by aid of the formula given in letter 26218, paragraph two, p. 36, for any latitude and any day of the year, if we only call the sun's zenith distance 108°—*i.e.*, 90° (the distance from the zenith to the horizon) + 18°, then will the result give us the sun's hour angle from the meridian when he is 18° below the horizon, or time when twilight ends; and, subtracting the time of sunset from this, we get the duration of twilight.

If "Chronos" has (as he tells us in query 60491, p. 96) "three regulators," he certainly should procure one of Mr. Latimer Clark's excellent little transit instruments, by the aid of which he will be able, after a little practice, to determine his time within 0·5 second. To go to the cost of even a single regulator, without some such means of obtaining the time from the heavens, seems to me a simple waste of money.

Premising that the Latin of "One not an Astronomer" (query 60518, p. 118) is not exactly as the Latin of Horace, Livy, and Virgil, I may tell your correspondent that no diagram is needed to understand that, in (say) latitude 51° N., the whole of the heavens from the North Pole to the Equator + that part of the celestial concave between the Equator and 39° of South declination, is evidently visible during the course of the year, and this is, roughly, 129-180ths of the entire vault of the heavens.

Mr. Fennessy (query 60525, p. 119) seems to have fallen into the far too common error of employing the barometer as a hygrometer. Thousands are thus deceived almost daily.

A Fellow of the Royal Astronomical Society.

PLANETARY NEBULA.

[26333.]—On reading in the English Mechanic of August 6 (letter 26050) Mr. Sadler's interesting and valuable *résumé* of the various observations of the Planetary Nebula G.C. 4373 (37 H iv. Draconis), I thought I would take an early opportunity of re-examining the object with my $7\frac{1}{3}$in. refractor. Owing in part to absence from home, a favourable opportunity for doing so did not occur till Saturday last, October 2, when the following results were obtained.

The nebula is decidedly bluish in colour, and is distinctly elliptic in outline, with axes in the estimated proportion of about 4 to 5. The major axis lies obliquely across the parallel on an estimated angle of 45°—225°. The nebulous disc appears a little soft, or diffused, at the margin. Nearly in the centre, perhaps a little *n.f.*, is a small star, glimpsed with 191, but better seen with magnifying powers 424, 605, 791. It stands out as a white spot on the bluish ground of the nebula, and presents the appearance, perhaps, of a minute planetary disc, rather than that of a star. I should not, however, wish to speak too decidedly on this point.

It will be noticed that these results agree, on the whole, with those obtained by me in August, 1863.

George Knott.

Knowles Lodge, Cuckfield, Oct. 4th.

STAR MAGNIFICATION—LATHE WORK — SHELLAC — SMALL DYNAMOS — GOLD IN QUARTZ—KAURI GUM—EVAPORATION—LETTERS ON GLASS —COLOURING GOLD.

[26334.]—I hope, Sir, you will not think I am trifling with your valuable space if I thank Mr. W. A. Haren for his lucid exposition of stellar magnification. My own ideas on this matter have hitherto been rather hazy, and I feel that I am personally indebted to your correspondent.

Why does "B. H." (26328) want to use his chisel with a scraping action? He can true up his wheels by turning off the excess in the usual way; if he will get a flat piece of wood which has been planed, and scraped with a chisel across the grain, the same result will ensue.

You have a short paragraph from the *National Druggist*, advising the use of benzole to assist in obtaining a clear solution of shellac. I frequently (in common with other people) make clear solutions of shellac in a very simple manner. We mix the lac and spirit and allow it to remain (with occasional agitation) till solution is complete. If it is now left perfectly quiet for a day or two the insoluble portion will settle to the bottom, and a perfectly clear and bright solution can be decanted.

Would someone kindly say why all the small motors and dynamos figured in the Mechanic have H armatures? Cannot we have a small machine with a ring armature? And if not, why? Some years since I saw Weston's machine at work plating; it seemed much more compact and portable than those at present in use.

I don't wish to be dogmatic, but I have an idea that a simple method of discovering gold in quartz (60509) would be to crush the mineral and look for the gold, which for estimation can be amalgamated with mercury, which latter is then driven off by heat, the gold fused to a globule and weighed.

Strong scents are generally made with spirit of wine, and if they will dissolve kauri gum (60520) methylated spirit will do it better.

The question of "Sol" (60522) reminds one of a piece of chalk. How is anyone to tell what the evaporation from a pond would be without knowing the size of the pond and depth of water? If the water is shallow, the evaporation will proceed faster; if deep, a portion or all of the heat will be absorbed by depth of water for a time before evaporation commences. I would suggest (if the game is worth the candle) to calculate the superficies of the pond, and then expose near it a small surface of water in a pail or tub; then, having ascertained how much the water in the tub has decreased in volume or weight, it is merely a question of multiplication and division.

"Glass Painter" (60547) might try a little shellac varnish.

Some time since I answered a query relative to cleaning gold after soldering, and the correspondent in question made a further application to me. This I omitted at the time, perhaps because I had no reply to offer. 9 carat gold, after being soldered and pickled, does turn a bad colour; nothing but polishing will remove it. There is no liquid into which it can be dipped to improve the colour, the only way is to gild it, but this does not give it the same colour as polished 9 carat gold. Personally, I consider 9 carat gold little short of a delusion and a snare, and should be glad to see it legally abolished.

Os.

CHAMBER ORGANS.

[26335.]—I am very much indebted to Mr. Audsley for his valuable papers on the Chamber Organ, and shall be greatly obliged if he will kindly publish the specifications of his own organ in the next chapter, along with the scale of his pipes at CC, tenor C, middle C, 12in. C, and 6in. C. I am about to build a large chamber organ, with the console placed about 15ft. away from the organ, the connection being by electric and pneumatic action; and in order to make it as neat as possible, I shall place the feeders and wind reservoir in a room behind, working them by a small hydraulic engine; the distance between the reservoir and organ soundboard being 5ft. This arrangement will enable me to place the "great" soundboard on the floor, the pipes being arranged with the large ones at each end, and the small ones tapering to the middle. The "swell" organ will be above the "great," the soundboard being 5ft. 6in. above the floor. With this arrangement I find I can get 6 stops on the great, and 8 on the swell, with pedal bourdon, in a space 7ft. by 3ft., and 11ft. high—i.e., provided the scale of the pipes is not too large; and it is for this reason I should feel greatly indebted to Mr. Audsley for the scale of all his stops. I have applied to two organ-builders whom I know, and they both recommend different scales, so I do not know which to adopt. Of course I shall buy all the pipes from some London maker, and shall endeavour to get them of the best make and of A1 quality, price not being an object with me. Can Mr. Audsley recommend me to a good firm?

I quite understand the combined electric and pneumatic action for the stops and manuals; but I am in doubt as to method of operating the swell louvres. Can any of our readers help me in this matter?

In order to save room, I intend to have all my pipes (except the pedals) of metal, the following being my specification:—

Great.	Pipes.	Swell.	Pipes.
Open Diapason 8ft.	58	Geigen Principal 8ft.	58
Lieblich Gedact "	58	Rohr Flöte ...... "	58
Dulciana .... "	58	Gamba .... "	58
Harmonic Flute 4ft.	58	Voix Celeste ... "	58
Piccolo............ 2ft.	58	Gemshorn ...... 4ft.	58
Clarionet ...... 8ft.	58	Flautina .... 2ft.	58
		Oboe .... 8ft.	58
		Keraulophon ... "	46

Pedals.

Bourdon, 16ft. 30 pipes.

I will conclude this by asking a question or two, in the hope that Mr. Audsley or some other reader will kindly answer:—

1st. How close may the back of a pipe be placed to lip of another without injuring the tone? I have allowed 2in. between mine, but would like to put them closer.

2nd. Does it injure the tone of the pedal pipes if they are packed closely together, or laid horizontally on the floor?

3rd. Will the tone be injured by having the wind reservoir 5 or 6ft. from the soundboard, or will it lead to unsteadiness?

It is quite probable I may adopt many of Mr. Audsley's suggestions, more especially the divided "great"; but I am waiting to see all he has to say before deciding finally.

George Landel.

[26336.]—I have read with much pleasure Mr. Audsley's letter in reply to "Country Solicitor" upon the above interesting subject. I am very glad to see Mr. Audsley defends with so much vigour the properly-constructed chamber organ, and I hope that before the articles respecting "Chamber Organs" are finished, the pipe organ will stand in better estimation among the musical readers of "ours" as a fitting instrument for home use. I know full well that the majority of so-called chamber organs are simply abominations, not perhaps to their owners, but unquestionably so to a musical hearer, to whom music and musical feeling are something more than noise or ear-tickling effects.

If "Country Solicitor" has never had the pleasure of playing, or hearing played, a properly-appointed chamber organ, I do not wonder at his dislike; but no matter how "nice" the Mustel harmonium may be, it can never, in my humble opinion, even compare to a well and properly made

chamber organ. As usually made, the chamber organ is sadly deficient both in the requisite quality of tone and mode of expression; but who is to blame? Generally the purchaser, and perhaps quite as often the builder. The builder seldom takes into consideration the proper requisites for chamber organ use. Why? If he did, the amount he would charge would lose him the order; consequently he puts together the most simple affair he can, and also the cheapest. Then, again, if a purchaser, we will presume musical, lays down the law to a builder as to how he is to build the organ, the result would, no doubt, be an excessive charge, because more time and study would be required to bring the affair to a satisfactory ending. Even if a builder is left to his own judgment, he will, as a rule, put in a small church organ, and call it a chamber organ. Such and such like is why we have such poor instruments.

I have questioned many organists and others, but they are almost with one voice in favour of the pipe organ. The general remark is that the reed organ "will do," when the other is not obtainable. This is always what I have entertained, that the ordinary reed organ exists on suffrage. If room and cash is available, the musician will always prefer the pipe organ. That the reed organ makers know the pipe organs are the best is exemplified in their advertisements, where they will tell you the quality of their instruments are the nearest approach obtainable to a pipe organ.

The purchaser of a reed organ will always be very particular to impress upon any friends to whom he is showing his purchase that "the tone is just like a pipe organ." All this points to the pipe organ as being the best, and in any opinion, when properly designed, scaled, and voiced, any effects that may be produced upon a reed organ can be produced in greater depth and grandeur upon a chamber organ.

Now comes the question of price. According to Mr. Audsley's article, No. V., he gives the number of manual stops in the organ he is describing as fifteen. This, with three pedal stops, will make eighteen. Now, to build this organ to the perfection laid down by Mr. Audsley would not cost less than £20 per stop, or a total of £360. This is beyond the ordinary figure of reed organs, and beyond the ordinary purse, and would take up considerable room; but there are, I believe, reed organs up to that figure, and what man of musical culture would prefer the reed organ of that price to the instrument now being described by Mr. Audsley? None, I presume.

I cannot say I agree with all Mr. Audsley states in his articles; but, taking them as a whole, I can endorse with confidence the excellent directions and explanations he gives therein, although for the ordinary amateur the sized organ he describes would be far too ambitious an attempt to make himself.

Mr. Audsley has several times referred to the organ he is the happy possessor of, and if it agrees with his description, which I would not doubt, it must indeed be nothing short of a marvel, and truly "a pearl of great price." Taking this amount of perfection as granted, I think if "Country Solicitor" once hears a good selection upon it, he will be convinced that although a reed organ may be the most convenient for a room, the pipe organ possesses a depth of resource, grandeur of effect, brilliancy and power, refinement and body of tone, and combining in a well-appointed instrument the capability of producing a wondrous flow of smooth, powerful, rich harmony, also subtle and weird effects, which almost border on the mysterious, and which no reed organ yet manufactured can by any stretch of imagination lay claim to.

I was certainly surprised to find in "Country Solicitor's" letter that he only considered music a mere recreation, especially after so much talk about expression. Perhaps this little point may be some clue to his inability to appreciate what can be obtained from a good organ. It certainly is a very different thing to hear an organ sonata of Mendelssohn's played even on a small pipe organ to an operatic air tootled at one end of a reed organ, and a ramping accompaniment at the other; it may be pretty, but not substantial. Yet I can scarcely think this, to judge from the programme he quoted.

I hope, if "Country Solicitor" sees Mr. Audsley's organ he will give us his opinion, for I am sure I should be delighted to hear it myself, and if Mr. Audsley would courteously extend me the same permission I should consider myself greatly honoured, and would take the opportunity the next time I am in town, for nothing would give me greater pleasure.

There are many other remarks I could make on the subject, but am afraid I have overstepped the limits of space already. **Uranium.**

"HAS ENGLAND GONE UP-HILL OR DOWN DURING THE LAST FIFTY YEARS?"

[26337.]—"B. R." (26257, Sept. 17, p. 64) adopts a somewhat original, but, I fear, hardly successful method of answering the above question. He grabs hold of a handful of statistics at random, and flings them unceremoniously in the faces of his readers. Now, as one of those readers, and as, moreover, a socialist, I beg to protest against this sort of proceeding. It is not only unconvincing to our reason, but insulting to our intelligence. What is more, when his statistics are not irrelevant they are inadequate, and when they are not inadequate they are incorrect. The worthlessness of the statements advanced, as showing the condition of "the people"—those who by labour produce all the wealth of the world, and without whom, under present conditions, human existence would be impossible—will be apparent on a little examination. They prove that "England has gone up-hill," truly; but the "England" is the England of the upper and middle classes (to one of which "B. R." obviously belongs), not the England of the producers—the workers; and like the rest of his class, "B. R." evidently cannot conceive of anything beyond his own narrow microcosm. He measures everybody's corn by his bushel, and imagines the rest of mankind are as fortunately conditioned as himself.

In a moment of generous weakness, I was induced to make one exception to the unappreciative estimate I formed with regard to the value of "B. R.'s" statistics. It was in reference to the figures *re* population. Alas! on a second consideration I was compelled to place these, too, in the general category. "The population of England, Ireland, Scotland, and Wales," he commences by saying, "was . . . in 1871, 31¾ millions; 1881, 35¾ millions." True. But in taking the four countries together in this unwarrantable fashion, it will be seen that "B. R." evades the question of *Ireland* altogether. The increase shown, of course, is confined almost exclusively to England, Scotland, and Wales. During merely the last few years Ireland has been first depauperised by landlordism, and then depopulated by emigration to the number of *millions*. But this fact is conveniently "jumped" by "B. R."

With regard to the Savings Banks question, "B. R." says, "The deposits in the Savings and all other banks [have] very much increased." Now, if this statement is meant to apply all round, it is untrue. And if it is not so intended, it is useless. I make "B. R." welcome to whichever of the two horns of the dilemma he likes best. Furthermore, if the assertion were absolutely correct, it would not serve his purpose—it would not prove that the poor were less poor. It would, perhaps, *imply* as much, it would not *evidence* it; and implying is not proving. As a rule, the *darker*, not the brighter, a man's prospects are, the more he saves. As a rule, if his prospects are bright he does not save at all. There are exceptions, of course, but they only prove the rule. "They that are whole need no physician"; and, with mundane as well as spiritual things, those whom the future does not trouble do not trouble about the future.

But, maugre all this, let us examine into "B. R.'s" assertion—that deposits in the Savings Banks have "very much increased." Take only the Post Office Bank, which he will admit is a very fair example indeed. From the Annual Report of the Post Office, just issued, it appears that the depositors in 1885 numbered 6,474,484, giving an average of £2 6s. 5d. per deposit. But the number of depositors since September 16, 1861—well within "B. R.'s" "fifty years"—is 75,088,023, say an average of £2 14s. 8d. So that the deposits are decreasing instead of increasing, and the deficiency on last year was no less than £2,670,000!

But heedless of these serious facts, "B. R." skips blithely on. "Ten times more people have pianofortes, watches, and jewellery," he says, which is one of those statements which are not quite correct, but which are too ambiguous to be disproved. How many, does he think, of the real "people," the workers, ever get a piano or a watch and chain?—never to speak of time to learn the piano, and opportunity to wear the watch and chain? Why, their very Sunday coats and petticoats are almost invariably pawned on Monday and redeemed again on Saturday. But a little further on "B. R." gives himself more rope, and, as a natural consequence, duly "dances on nothing." Says he, "All classes . . . are better paid for labour, and work shorter hours." Now, this assertion is at any rate definite. As a certain hero in fiction would say, it is "d—— definite." But how does it stand otherwise? Let us apply it to only two of "B. R.'s" "*all classes*": the "slop workers" and the tramcar men—the victims of the "sweater" and the victims of the shareholder. The slop workers are men and women who make up the cheap suits of "shoddy" for the sweater, or middleman, of the manufacturing tailor's trade. These unfortunates work at their sewing-machines in the "sweater's den" from seven or eight in the morning till nine or ten at night, receiving at the week's end an average wage of from twelve to fifteen shillings. They more often than not work under conditions impossible of description with any regard to detail here, and on the slightest displeasure they give their employer are instantly dismissed. Here is a representative "class," taken hap-hazard from "B. R.'s" "all"; but I fail to see that they are "better paid for labour," or that they "work shorter hours." "B. R." says he can see it. He should be counselled, as the old lady says in the story, to "take care of his eyes." He is an ophthalmic *rara avis*; and I shall be glad to be informed, at his convenience, whether he can gaze upon the invisible and look through a brick wall.

Turn to the tramcar employés. These men work fourteen and sixteen hours, in all weathers, and for seven days in the week, and receive as wages the magnificent and munificent remuneration of about thirty shillings or less. The only reason why they don't work *nominally*, as they do *actually*, eight days in the week instead of seven, is that there are, unfortunately, *not* eight days. But wait a moment—*peccavi!* I have forgotten something. Let me give even the dev—I mean the shareholder, his due. The men, if they happen to have been born while their lucky star was in the ascendant, and if they are good, and if circumstances permit of it, and if a few more "if's" only act in an honourable way as they should do—if, in short, "all's well," the men are allowed one (whole) Sunday off—*in ten years!* Such, at least, was the beatific experience of one old driver as related a little time ago. Please, then, I would say, don't forget the one (whole) Sunday off. To do so would be indeed calamitous. There is not much of it; let us, therefore, as is usual in such a case, and as the men doubtless do—make the most of it.

And how much interest does the "anxious, careworn capitalist" (as Samuel Smith, M.P., immortalised himself by calling him) get on his money invested in the tramway? What reward does he receive for *not* constructing the line, for *not* maintaining it, and for *not* working it? What guerdon is his, in short, for manfully and heroically taking the dividends when they are earned? Weep, weep, and tear your hair! he gets a paltry 9½ or 12 per cent. Pity the sorrows of a poor old—also anxious and careworn—capitalist. Only 9½ or 12 per cent., when even Government bondholders have to think themselves lucky if they get 2½. 'Twas ever thus. Brethren, let us weep some more. **A Socialist.**

LIGHT — SUMMARY OF NEWTON'S DOCTRINE OF UNDULATIONS.—IV.

[26338.]—NEWTON did not treat especially of undulation of light; but as his doctrine is general, and applies to the motion of particles in any medium whatever, it will be to the purpose to give a summary of it.

He treats, then, two cases—First, that of waves on the surface of water, and which are due not to its elasticity, but to its fluidity, and consist of elevations and depressions of surface; and secondly, of waves which are due to the elasticity of the medium through which they pass, as is the case with sound.

With regard to the first of these, he shows that the velocity of the waves varies as the square root of their lengths; and with regard to the second, that it varies as $\sqrt{\frac{e}{d}}$ where e and d are the elasticity and density, and is independent of length of wave. To these might be added the vibrations of an elastic cord, which may be shown to follow the second law.

In applying his doctrine therefore to light, the only question which can arise is, Which of the two cases does it come under, for there is no other alternative? There could be no doubt how to answer this, but for one point in Newton's theory, which has not yet been mentioned, but must be kept for another letter. In the mean while, however, we may say that observation suffices to make it perfectly clear that it comes under the *second* case, where the velocity is the same for all lengths. For, if it comes under the other, v must vary as $\lambda^{\frac{1}{2}}$. Now according to Fresnel's calculations, the ratio of the length of red to blue waves is 620 : 423, and therefore the ratio of the velocities would be 1·21, which is the square root of the above ratio. But the quantity known as the coefficient of aberration varies as the velocity, and therefore ought, according to our supposition, to have a difference of 21 per cent., in its observed value, for red and blue rays; whereas none whatever has been detected, which is just what ought to happen if the velocities were the same for all cases, but what could not happen in the other case. We conclude then from this that the rate of travelling is the same for all waves.

But this, too, appears at first sight contrary to observation. For, according to the information which "F.R.A.S." has most opportunely supplied, (letter 26141), Michelson finds that the percentage of difference between two colours which he mentions, for disulphate of carbon is from 1 to 2 per cent. instead of being either 0 or 21, so that it might seem as if either his observations were unreliable, or Newton's laws untrue—which of the two is it? Assuredly neither one nor the other;

the seeming discrepancy is easily explained. Newton and Michelson are evidently handling two different cases; Michelson must have made observation upon light which had passed from one medium into another, whereas Newton's calculations were made for the case where it had not. Let us see how this makes all the difference. Newton mentions expressly that one of the conditions upon which his conclusion rests is, that during the time of a vibration the front of a wave travels through a space equal to the length of a wave, and when it is so the velocity is the same for all lengths. From which it follows that if a case occurred in which it does *not* travel as above, neither would the velocity be the same for all waves. And conversely, when the velocity is not the same for all waves, neither does the front of the wave pass over a space equal to its length in a vibration. But Michelson's observation shows that when light has passed from one medium to another, the velocity is not the same for all waves, and consequently the front does not move over a space equal to its length during a vibration. And this is precisely what was mentioned in letter 26251 as being the necessary consequence of the disturbing force, causing the motion of the front to be not uniform during the passage.

The observations of Michelson therefore in no way throw discredit upon the doctrine of Newton, or upon its applicability to light in particular, as it is to all cases of a wave passing through an elastic medium; and the two together completely confirm the conclusion arrived at in letter 26251, that the velocity is not uniform during the passage, and that colour dispersion is a necessary consequence thereof.

Refracted light, then, differs in several particulars from that which has not been refracted. So far as we have gone, the differences are thus:—

1. In unrefracted light waves of different lengths travel both in the same directions and at the same rate, whatever the medium be in which they are moving; but in refracted light neither of these things happen: the waves are dispersed and move at unequal rates.

2. In unrefracted light, if the front passes over a space equal to the length of the wave during a vibration, when it enters a refracting medium this no longer happens. We shall refer to this again in next letter but one, when we shall have occasion to speak of something similar.

3. We may also anticipate what will be spoken of in the concluding letter of this series, by reminding the reader that there is another very notable difference between refracted and unrefracted light, known as polarisation. **W. G. Penny.**

(*To be continued.*)

ANALYSIS OF SILVER ALLOYS—POLARISED LIGHT—ARTIFICIAL TOURMALINES—RAILWAY MYSTERY.

[26339.]—POSSIBLY the difficulty of "G. E." in the analysis of silver alloys (query 62307, page 92) lies partly in the use of *excess* of sodium chloride or hydrochloric acid for precipitating the silver from solution. The text-books—which are usually written by "professors" for their pupils, and not by practical analysts, who have to take care that the methods they use are accurate—do not lay sufficient stress on the solubility of silver chloride in saline solutions. To obtain good results, "G. E." must add the precipitant drop by drop in the least possible excess, and then take care not to filter till the solution is quite cold. Further, the precipitate should not be washed to an unnecessary extent, as silver chloride is not wholly insoluble in water. For determining the amount of silver deposited on plate goods, the articles should not be entirely dissolved in acid, but "stripped" of the silver in the manner familiar to every electro-plater. The silver can then be precipitated from the diluted solution.

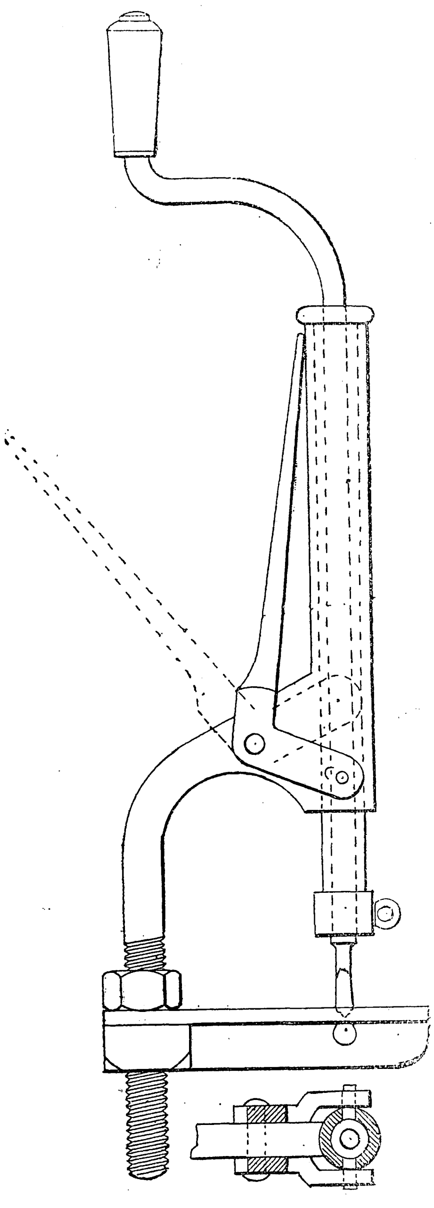
In reply to the query of "E. W.," headed "Polarised Light" (No. 60481, page 96), I am afraid no advance has been recently made in the manufacture of artificial tourmalines of Herepathite. Some eighteen years ago the sale of them was pushed by Messrs. Horne and Thornthwaite, and I still have a very perfect crystal purchased from them about that time. More recently, perhaps five years since, I was informed by one of the firm that they had lost the art of producing them. It had always been a very delicate operation, necessitating the most complete absence of vibration, to obtain scales of any magnitude, and of late years all attempts had failed. Here, then, is a chance for someone who lives "far from the madding crowd" to supply a real want. Of course, the production of small crystals, which form magnificent microscopic objects, is easy enough. It is the production of large crystals which is so difficult. It seems quite possible that something may depend on the purity of the quinine employed, and that the more complete separation of the cinchonidine and other accompanyıng alkaloids now effected may militate against the production of large crystals. As to real tourmalines, I seem to remember the increasing rarity of natural crystals of suitable colour and size for optical use being commented on some time since.

The "Railway Mystery" referred to in query 60421 has connection with the possibility of a pistol continuing to ride on the step of a railway carriage in rapid motion. Have the correspondents who doubt this seen the way in which grain, beans, and even peas travel along the flat band used in warehouses where grain is unshipped? A long horizontal elastic band, about 20 to 24in. wide, travels with considerable velocity, and in a state of violent vibration, and the loose seeds of all kinds are carried along by it without showing the least tendency to run off the edge. Would not a pistol remain practically stationary on the floor of a railway carriage, and, if so, why not on the step?

Sheffield, Oct. 4. **Alfred H. Allen.**

DRILL FOR SMALL WORK.

[26340.]—I SEND sketch of a drill I made for small work which might interest some readers. It



is handy for drilling plates for riveting, and many other odd uses, and is easily made. **Silke.**

LATHE APPLIANCES, &c.

[26341.]—I TRUST some of our practical men will reply to the question asked by "O. J. L." in his clever letter on "Things Old and New." Why is it that people will try a new patent medicine but will not try a new chuck?

"J. H." has been giving us some admirable papers on "The Amateur Workshop": they would make up into a useful book. Has "J. K. P." never thought of writing a book on tools, &c.? It is not everything to *know* about tools, it requires to know how to describe them clearly, and that is just what "J. K. P." can do. Can anyone tell us what progress has been made with Holtzapffel's Vol. VI., and when it is likely to see the light? Mr. William Hartley's work will, I fear, be lost to the world, he having died on September 13th.

I have often wondered why the form of toolholder shown by "J. H." this week is so universally used, rather than the Willis form. There was one on my lathe, but it would not conveniently grasp a large driller 1¼in. thick, and had such a clumsy look I had it changed for a true Willis.

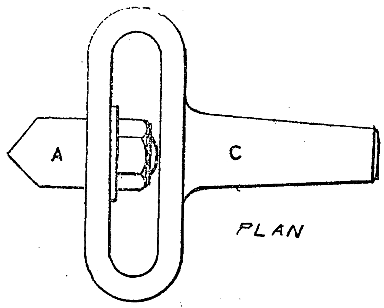
"B. H.," who inquires the cause of his scraper chattering (letter 26328), can try resting his scraper on something elastic, such as soft leather, or even on the finger, or with only one corner of scraper on rest. Let him do all the work he can with the router (or round nose tool), then let the scraper have elasticity: try putting the rest ½in. off and holding the handle high, as if to lift the work out of lathe as by a lever, and scraping below the centre. **F. A. M.**

LATHE WORK.

[26342.]—"B. H." will overcome the difficulty due to the vibration or tremor of tool and work by tilting his tool more or less. I mean that the edge of tool must not be horizontal, but at an angle. Brass frequently shows these ridges unless tool is tilted. **T. C.**, Bristol.

SETTING SLIDE-REST TAPER.

[26343.]—HAVING noticed letter 26271, page 67, under the above heading, I have ventured to send a sketch of a movable back-centre which I have



seen used in our shop. It consists of an iron centre C with a flat bow shut on the front end of sufficient thickness to bear any ordinary amount of screwing up, and wide enough to admit of a slot being cut to carry a short steel centre A, and is turned to fit in place of ordinary centre. The sketch being a plan, it will be seen that A has a nut fitted to it, so that it may be set "to" or "from" the slide-rest, as far as the slot will allow. **Simplex.**

STATIC ELECTRICITY—TO "SIGMA."

[26344.]—IN reply to your observations on p. 107 of the "E. M.," the only edition of your work, "Electricity: its Theory, Sources, and Applications," to be had at the Picton Reading-room in this city is that dated 1875, so that I may be excused my ignorance of later developments; and seeing in it an illustration of a conical bag capable of being turned inside out by means of a silk string, as well as a description of Faraday's construction of one room inside of another, I merely wished to have what appeared to me to be an erroneous statement explained. My reason for mentioning "that I found that if any part of a piece of glass be rubbed, the whole of it is electrified simultaneously," was to ascertain if you were aware that, as my experiments seem to show me, as long as the rubber is kept in contact with the glass, the so-called leakage is really a flow on to said glass, in order to take up its position "opposite" to the rubber, and rub as we may, so long as we keep within the boundaries of the opposite piece of foil laid upon the glass, the electricity gathered upon it does not seek to join that upon the rubber; but the moment we break contact between the rubber and the glass it would appear that the two qualities or conditions of electricity are, so to speak, anxious to unite, and both rush to meet each other. Thus I find that with the smallest rubber and largest sheet of glass the electricity is coming on apparently whilst contact is maintained between glass and rubber, over the whole surface and is given off the moment contact is broken. Thus it follows that the best arrangement for a frictional machine would be so that the rubber alternately rubbed and left the glass, and this is easily accomplished by means of a light roller, having a system of cushions parallel to its axis, so that each one touches as large an area as possible of the glass and then releases it. I also find that the rubber is acted upon at every discharge, and the foil becomes perforated; also, if the back of the rubber be of glass and several sheets alter-

nately foil and paper pasted upon it, upon examining these after some use holes will be found burnt through, showing that the foil has been melted or disintegrated. Is it generally known and admitted "That what is usually called leakage is in reality a flow towards the opposite face of a sheet of glass to that which is the excited face"? Also, that this electricity is much more powerful, painful, and difficult to insulate and make use of than that developed upon the same side as the rubber? It just occurs to me to mention that if any kind of metal apparently be allowed to touch the inside of a glass tube, or even a piston made on the end of a wooden rod with common pack thread and smeared with amalgam be rubbed inside, it is certain that the glass will fly to pieces, probably within 24 hours, as I have experienced with tubes up to $1\frac{1}{3}$ diameter.

A., Liverpool.

PHYSICAL BASIS OF LIFE.

[26345.]—CAN any reader enlighten me on the following point? Prof. Huxley, in his article on "The Physical Basis of Life," says, on p. 137, "If scientific language is to possess a definite and constant signification whenever it is employed, it seems to me that we are logically bound to apply to the protoplasm or physical basis of life, the same conceptions as those which are held to be legitimate elsewhere. If the phenomena exhibited by water are its properties, so are those presented by protoplasm, living or dead, its properties. If the properties of water may be properly said to result from the nature and disposition of its component molecules, I can find no intelligible ground for refusing to say that the properties of protoplasm result from the nature and disposition of its molecules; but I bid you beware that in accepting these conclusions you are placing your feet on the first rung of a ladder which, in most people's estimation, is the reverse of Jacob's, and leads to the antipodes of Heaven. It may seem a small thing to admit that the dull, vital actions of a fungus, or a foraminifer, are the properties of their protoplasm, and are the direct results of the reaction of the matter of which they are composed. But if, as I have endeavoured to prove to you, their protoplasm is essentially identical with, and most readily converted into, that of any animal, I can discover no logical halting place between the admission that such is the case, and the further concession that all vital action may, with equal propriety, be said to be the result of the molecular forces of the protoplasm which displays it. And, if so, it must be true, in the same sense and to the same extent, that the thoughts to which I am now giving utterance, and your thoughts regarding them, are the expression of molecular changes in that matter of life which is the source of our other vital phenomena."

Now, in his previous address on the "Educational Value of Natural History Sciences," he writes at page 76, "What is the cause of this wonderful difference between the dead particle and the living particle of matter, appearing in other respects identical?—that difference to which we give the name of Life. I, for one, cannot tell you. It may be that by-and-by philosophers will discover some higher laws, of which the facts of life are particular cases; very possibly they will find out some bond between physico-chemical phenomena on the one hand, and vital phenomena on the other. At present, however, we assuredly know of none, and I think we shall exercise a wise humility in confessing that, for us at least, this successive assumption of different states (external conditions remaining the same), this *spontaneity of action*, if I may use a term which implies more than I would be answerable for, which constitutes so vast and plain a practical distinction between living bodies and those which do not live, is an ultimate fact, indicating as such the existence of a broad line of demarcation between the subject-matter of biological and that of all other sciences."

In the preface of the same book to Prof. Tyndall, on page 6, Prof. Huxley says that the essay on the "Educational Value of Natural History Sciences" "contains a view of the nature of the differences between living and not-living bodies, out of which I have long since grown."

Now, what are the reasons, or evidence, on which this change of opinion is founded?

No Sig., Paris.

EGYPTOLOGY.

[26346.]—IN reply to "Memnon" (26286, p. 85), I should like to be permitted to say:—

(1) The Hebrews, in their genealogies, do not always give us all the links. Gesenius, one of the greatest of Hebrew scholars and a rationalist, says that a generation with them often meant a century. These two facts need to be taken into account in examining the Scriptures.

(2) The original of 1 Kings vi. 1, has *about* 480.

(3) Answered in number one.

(4) Josephus, no doubt, followed the Septuagint (*Codex Vaticanus*), which has 215 years for Israel's sojourn in Egypt. This was currently regarded as the correct number in New Testament times, hence St. Paul's reference in Galatians. The 430 of the Hebrew Scriptures is regarded as the correct time, and Joshua's genealogy of eleven generations supports this number. It is not said that the Israelitish population had only two midwives. The King spoke to two, and they were Egyptians. The Israelites had their own, no doubt, since they had them before they went into Egypt.

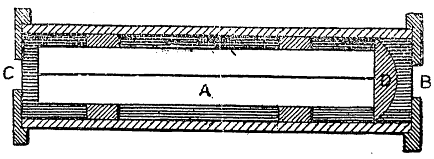
(6) The Egyptian monuments and inscriptions were for the glorification of everything Egyptian; little or no notice is taken of their humiliations. Diodorus cxxxiv. 1, has a record with an Egyptian colouring, in which it is said that Egypt suffered from the pestilence, because of a multitude of aliens, who were affected with a foul, cutaneous disease. They were, however, driven out, and the main body went to a land afterwards called Judæa, which was a desert.

(7) This is contradicted by "Memnon's" "impression" in No. 6. Other assailers of the Bible declare that Israel got everything from Egypt. "Memnon" thinks they got too little. How strange a thing is this! How about the many Welsh who, after a thousand years, speak only their own tongue? That Moses wrote in pure Hebrew of the time of David is an error. His writings are a mixture of archaic and more modern Hebrew; just as we might expect from its being copied from generation to generation, and in degree altered to the language of the times. The Israelites believed in the immortality of the soul because they were commanded (Deut. xviii. 11) to have no dealings with the spirits of the dead. No nation of the East was without this faith. As Max Müller has said, they may have doubted their present existence, but never their future, and this opened a wide gate to many forms of idolatry. Hence, the scriptures which came *to* this people, but were not *of* them, rose far above their habits of thought, and enforced attention upon things necessary for their temporal welfare. "Memnon" ought to know that whatever of reliable evidence which has come to hand from monuments and inscriptions in the East goes to support the truthfulness of the Scriptural narrative, and to dispose of the cavils of objectors.

September 26. **Ramases.**

THE DICHROISCOPE.

[26347.]—SOME time since an interesting discussion on the phenomenon of dichroism appeared in your columns. I believe it was then spoken of as being of very rare occurrence, and the mineral dichroite was the only example mentioned. As a matter of fact, however, this phenomenon is extremely common, more so perhaps than fluorescence, for it is exhibited to a greater or less degree by all crystals belonging to the hexagonal, quadratic, rhombic, monoclinic, and triclinic systems—in fact, by all except those which crystallise in the regular or cubic system. In general the dichroism is so feebly marked that it requires the use of a special instrument called the "Dichroiscope," devised by Prof. Haidinger, of Vienna, and shown in longitudinal section in the figure. It consists of a brass



tube, about 6in. in length, having at one end a circular hole B (the eyepiece), and at the other a square aperture C. It contains a long cleft piece of Iceland spar A, with its ends ground flat, that next the eyepiece having cemented to it a plano-convex lens D. The Iceland spar is cut to such a length that the two magnified images of the square aperture appear to touch, but do not overlap. On placing near the square aperture a non-crystalline body, such as green glass, or a crystal of the cubic system, as garnet, the two images will be seen to be identical in hue. If we take a crystal of any other system, for instance an emerald (hexagonal system), and examine it along its principal or optic axis, the same result is obtained. But if we now apply the instrument at right angles to one of the hexagonal faces, and gently rotate it, one image is seen to be greenish-yellow, and the other greenish-blue. The former is due to the "ordinary ray," the latter to the "extraordinary ray," the green colour of the emerald being resolved into two components, one preponderating in yellow rays, the other in blue. As there are hundreds of crystals which can be examined in this way, the instrument is well worth the trouble of constructing, and can be easily made by anyone familiar with optical work.

R. E. F.

NON-CONDENSING VERSUS CONDENSING ENGINES.

[26348.]—I HAVE read with interest the discussion betwixt "Engineering," "Ingeniero," and others on the above subject. The relative merits of both classes have been discussed at great length by our friends. I have an opinion myself that in the long run the extra expense that has to be laid out in the compound condensing engine is fully compensated by economy in fuel and greater cleanliness on board the vessel. The simple high-pressure has fewer parts, we all admit, and is generally better understood; but when we live in a part of the country where fuel stands at a high price, and we use a large quantity, economy in fuel is a great consideration.

I should like to ask the opinion of our friend "Engineering" with regard to a little matter. A friend of mine had a pair of high-pressure engines fitted in a launch—the cylinders were 6in. diameter by 8in. stroke; boiler pressure, $\frac{1}{5}$lb. He exhausted the steam in a tank from which he fed the boiler. A valve was arranged on the tank, so that when the pressure became excessive it opened to allow the steam to pass up the chimney—a very wasteful practice, for the tank was filled with salt-water, and consequently incrustated his boiler.

My friend built a larger boat, and thought of placing in the engines from the other boat, with an additional one to compound them; his reason for only using one additional cylinder being to keep expenses low. I got up a design, the additional engine to have 14in. cylinder and 12in. stroke., or about four times capacity of high-pressure cylinders, and to add a surface condenser of coiled copper pipes placed in the tank, the sea-water to circulate outside the pipes. The three cranks were to work at 120°; with this arrangement I calculated on getting power to drive the larger boat, and have greater economy in fuel. I spoke about the matter to some of my more advanced engineering friends; but their principal objection was: the low-pressure engine having so much longer stroke than the two high-pressures would make the turning moment very irregular. This point I could not get over, as I was confined to have only one low-pressure engine to save expense. So I think I was bound to have either a longer stroke or a very large diameter cylinder. Perhaps some reader of "ours," or our friends "Engineering" and "Ingeniero" will see the way out of the difficulty, and for an answer I shall feel greatly obliged.

Middleton Junction. **W. H. Taylor.**

HIGH-PRESSURE VERSUS COMPOUND CONDENSING ENGINES.

[26349.]—MANY of the readers of this paper will think I am leading them astray when I state that there is practically no benefit to be derived from expanding steam in two cylinders placed tandem-fashion, and that all the benefit to be derived from expanding steam can be practically accomplished in one cylinder. Now my observations refer only to non-condensing engines. In the case of the condensing engine, we get the benefit of at least 14lb. on the square inch additional pressure; but I maintain, although a benefit in the condensing type, it is not the best position to place them, and the only reason I can assign for placing them thus is the limited space which they had to occupy. One example I saw in a small launch had the cylinders placed thus, and one pump acted both for air and circulating pump; it was very compact, but not handy to stop and reverse quickly, and although it outstripped the double-engined launches, and was very economical in fuel, the owner had it taken out and a double engine put in. How is it that there is such a marked difference in the economy of the triple expansion engine compared with the ordinary expansion engine? In my opinion the economy is caused by the difference in the larger ratio between the small and large cylinder, also taking into consideration that the power is distributed upon cranks placed at an angle of 120° with each other, so the power is split up and more uniformly distributed on cranks in a more favourable position to develop that power than is the case in engines with only one or two cylinders. As I stated, it is a question of £. s. d. whether we will pay a few pounds more per H.P. and have an engine that works with the highest economy, or save this extra cost and lose it afterwards in fuel; and as regards requiring a skilled attendant, I am confident that the engine I advocate can be made so simple that a person who could manage a high-pressure engine would be quite capable to look after a compound condensing one.

London, Sept. 25. **Ingeniero.**

COMPOUND LOCOMOTIVES.

[26350.]—FROM the very interesting discussion going on in the "E. M." respecting locomotives, it appears to me that the usual formula for estimating the so-called tractive force of the engine at the rails is somewhat misleading.

In the case of the locomotive, it is not sufficient

to know the tractive power on paper; but what we want is to measure the actual pull at the tender draw-bar at various speeds.

Now this is proved by the remarks of G. D. Seaton (24th September) in comparing Precedents with Dreadnoughts: the latter appear, on paper, to be among the most powerful engines in this country, but what are they in practice? The Precedents have great "hauling power," which latter term better expresses locomotive work.

The matter would be greatly simplified if some locomotive engineer would have the courage to experiment with different engines, with the same weight of train on the same road.

The nearest approach to this took place some time ago on the G.N.R., when Mr. Stirling found that the "single" engine had the best of it to Potter's Bar. The outcome of this was the 8ft. engine, a great success, and I think that if experiments could be properly conducted it would be found that the single engine works with more economy. The friction of coupling rods does not appear when estimating tractive force. The point to work upon should be the tender draw-bar. I hope this subject will be taken up by others.

R. H. Gates.

LOCOMOTIVES, ETC.

[26351.]—I WOULD point out to "Kappa" that on most lines the drivers are stationed on that side which has been called the wrong side for signals. The domes would consequently be more in their way where the signals were fixed on the right side.

Libra.

[26352.]—IN reply to "Engineer," the heating-surface of a locomotive engine should not be less than the following for 18in. cylinders: Tube-surface, 1,115ft., and the firebox should be 110ft., making a total 1,225ft, with a pressure of 140lb. in the gauge, and a dome on the boiler, "Engineer" would find, with a well-constructed engine, would meet his requirements. As regards the Midland No. 1,667 class of engine, I cannot for the life of me understand what man that calls himself an engineer would build engines with 19in. cylinders, with a heating surface total 1,121ft., which is much less than *Mr. Kirtley's* build of engines, such as the 800 class; but that *gentleman* was a thorough engineer, and the Midland Company knows it, and I know it, for he never wasted the company's money by experiment, but went to the point at once, and this will answer the question. "Engineer" asks how is it that no engines can be built equal to the 800 class. Because they don't know how, or they would have done it long ago. Your writer speaks of what a *disgrace* it would be to rebuild the new engines. Let me inform him that it is no *disgrace* for some railway engineers to throw money away by *thousands*, but if a man even is doing his *duty* to his *company*, and it don't suit the so-called engineer, he must be discharged, or have the *Irishman's* promotion, and if "Engineer" or any other correspondent wants to know anything more, if I can oblige I shall be glad to do so.

Loco. Erector.

L. AND N. W. R. LOCOS.

[26353.]—I OUGHT to have said "the incline between Tebay and Grayrigg," instead of "between Low Gill and Oxenholme." As even the Scotch express comes at quite a moderate speed down the hill through Oxenholme, I do not suppose they would let the fish train, with only the hand brakes, get out of hand over that part of the road.

Some of the L. and N. W. locomotive arrangements seem quite inexplicable. For instance, on a journey over that system from Welshpool to Windermere, one of Ramsbottom's "Lady of the Lake" class took my train from Welshpool to Shrewsbury, over a rough branch, stopping at all stations, while one of the 4-coupled, 8-wheel side tanks, with 4ft. 8in. driving wheels, was put on the tourist express (10.30 p.m. Euston) between Preston and Oxenholme! The latter was tried as an experiment (and experimenting with a heavy express seems to me a queer proceeding), and lost nearly 15 minutes in 40 miles.

I cannot see that Mr. Drummond's 6ft. 6in. Cal. bogies are anything out of the way. We were about 24 minutes getting from Beattoch to the summit on Sept. 20th, with the day mail and 10 coaches on, and could make up no time between Carlisle and Carstairs, though on the same train, with a Precursor, we picked up 7 minutes between Oxenholme and Carlisle with only two carriages less, and that is a much greater load in proportion to the Precursor.

I travelled yesterday by the 11.38 a.m. Midland express from Birmingham to Gloucester. We left 20 minutes late, and only made up one minute to Cheltenham, though we had only 10 six-wheeled coaches and two bogies and an engine (109) just rebuilt. It was, however, wet and windy, and we had to stop just after leaving New-street for a signal and make the usual stops at Blackwell and Bromsgrove.

I cannot understand why, if it is necessary to run trains through Gloucester without stopping, the old loop east of the station should not be re-opened, and the trains allowed to run over the Great Western to Standish Junction. This would save a mile, and a very dangerous mile too, as not only is there a network of lines and points to be got over (often at a great speed), but there are a number of level crossings in the south and east of Gloucester. I should have thought that it would have been well worth the Midland's while to run a few local trains between Bromsgrove and Wadborough, viâ Spetchley, and open the old stations, as the district is populous, and the local traffic between the market towns would surely be large.

O. H. P. Scourfield.

RAILWAY SIGNALS.

[26354.]—AS your correspondent, "Libra," page 110 (letter 26321), does not give the name of the railway upon which he claims to place the signals, it is impossible for me to examine them, or to know if they are or are not properly fixed. I know for a fact that very many signals are placed upon the wrong side simply to save cost, to save signal posts, and to employ short posts instead of tall ones. I know of several cases where a post has been placed on the wrong side simply to save two pulleys, which would be required to cross the wire from one side of the line to the other.

"Libra's" remarks with regard to "evil-disposed persons who laugh at or ridicule" the Amalgamated Society are of no importance; the very fact of their being *evil disposed* is quite sufficient to cause any reader of the ENGLISH MECHANIC, as well as any member of the society, to treat them with that contempt they deserve.

On page 577 of last volume (letter 26149), I asked a correspondent who signed his letter "G. L. Watkinson" to be good enough to furnish his address, as his letter contained libellous statements. I am now in a position to state that the true name of the writer of that letter is not "Watkinson," and the address sent to my solicitors has been proved not to be the correct one. He referred in his letter to "his experience" with regard to signals. It is rather interesting to find that he has not ever been in a position to obtain any "experience" with regard to the matter.

Your readers will doubtless form their own conclusions as to the conduct of such a correspondent, and I shall not occupy your space by referring to the false statements contained in his letters.

Clement E. Stretton,
Vice-President,
Amalgamated Society of Railway Servants.
Railway Congress, Town Hall, Brighton,
October 5th.

PERMANENT WAY.

[26355.]—A FEW printer's errors occur in letter 26316 on this subject in the last issue, which I beg to call attention to, and to solicit kind correction.

Line 38 from top, 2nd column, it should read, "secured by 1in. bolts and nuts." Line 57 should read, "The bolt-holes are oval shaped." Line 6th from bottom, read "outfall" instead of "output."

Rhine, Oct. 2. **S. G.**

BODIES FALLING FROM TRAINS IN MOTION.

[26356.]—MR. CLEMENT E. STRETTON, on p. 115, argues in favour of the pistol which was found on the footboard of the Midland carriage having fallen from the window, because it was not directly under the window, but behind it, saying a murderer would hardly stop to calculate that the train would move forward while the pistol was falling. Now, by the second law of motion, the pistol, if dropped, would fall directly under the window, just as if the train were at rest; for the pistol before being dropped would have the same horizontal velocity as the train, and gravity could not alter this. The two stock examples given in text-books on mechanics are a stone dropped from the top of a mast of a ship in motion and from the roof of a railway carriage. No doubt the resistance of the air would decrease the horizontal velocity, and so the law would not be strictly fulfilled; but this would hardly, in a heavy body like a pistol, retard it to the extent of 2ft. while falling the height of a carriage door. I should draw the opposite conclusion from Mr. Stretton, and say it was placed behind the place from which it was supposed to have fallen by some one who wished to take account of the laws of fallen bodies, with which laws he was imperfectly acquainted.

Shaftesbury. **T. Perkins, M.A.**

ORDNANCE SURVEYS.

[26357.]—REFERRING to your correspondent (26279), page 84, whether it is delay or parsimony I know not; but it is nevertheless the fact that the patience of Job even would be tried in expectation of certain maps. The Geological Survey is especially slow for the work that is to be done, and the full staff there is to execute it with. In West Cumberland, the Carboniferous, with Rocks above it, was begun some fifteen years ago, and has since been continually worked upon, yet the work remains unpublished. The district, a most important one, abounds in iron and coal, &c., and occupies a little over 150 square miles, which any ordinary geologist could have carefully surveyed in less than one-half the time and with half the resources the staff can command. Surely the officials in chief delight in prolonging the work, instead of expediting it.

Whitehaven, Sept. 29. **Matthew Brown.**

ON THE SUPERIORITY OF ZINC AND STEEL PENDULUMS AS COMPARED WITH MERCURIAL PENDULUM.

[26358.]—WOULD you kindly allow me space in your valuable paper for a few remarks on the above subject, suggested by Mr. Thomas Buckney's interesting letters, published in the ENGLISH MECHANIC of August 20 and 27?

At present I do not wish to argue which is the best compensation, only that Mr. Buckney's experiments, as published, do not prove which is the best. Mr. Buckney compares a very badly-constructed mercurial pendulum to a well-constructed steel and zinc pendulum. The mercurial jars used for experiment were one 2in., the other 2¾in. diameter, and about 6in. high, one solid column of mercury. The zinc and steel tubes were, I suppose, less than 1in. diameter, and about ⅛in. thick in metal. As a matter of course, any change of temperature will act upon the light and thin steel and zinc tubes much sooner than upon a short column of mercury of about 12lb. weight. Such mercurial pendulums have been out of date many years, and are certainly inferior to a good steel and zinc pendulum.

Christian Lange.
23, Great Portland-street, W.

USEFUL AND SCIENTIFIC NOTES.

Sound Telegraphs.—The system of sound telegraphy used by the people living on the border of the Gulf of Guinea, West Africa, is of interest as a primitive solution of the problem of communication through short distances. The instrument is made as follows:—Take a log of hard wood, about 2ft. long and about a foot in diameter. Plane off one side longitudinally, to a surface four or five inches wide. In the centre of this surface mark off an elongated and somewhat distorted Greek cross. The longer arms are placed longitudinally, and occupy about one-third of the plane surface. The transverse arms are three times as broad, and extend entirely across this surface. The natives dig out the wood within the outline of the cross, and from there gradually hollow out the whole log. The sides beginning at the centre are trimmed off laterally toward the ends, which are rounded off. The instrument is now ready. It will be perceived that by the methods above described we have a hollow drum with four tongues in the centre, each of a different thickness, so as to produce a different sound when struck. Two pieces of bamboo, the size of a man's wrist and about 2ft. long, are selected and stripped of the hard outside, which leaves the soft, pithy portion for use. This bamboo is of a peculiar kind, free from knots, and solid throughout. With these sticks, used in a proper manner on the four tongues of the drum, a combination of sounds is produced, which, in connection with time as used in music, forms a perfect telegraphic language, readily understood by the initiated, the air being the transmitter. With this simple instrument the natives of the Gulf of Guinea readily communicate with each other for a distance of a mile at least on land, and a much longer distance by water. Messages can be sent long distances in a short time by parties at different points passing them along from one to the other. The writer has seen canoes coming down a river from the bush markets signalling people in the town and giving and receiving general news at a distance of fully three miles.

IMITATION amber has largely taken the place of real amber in the manufacture of pipes. This is the last information from the Konigsburg coast, where amber has, time out of mind, been sought by dragging at Schwartzort, and by mining for the last 20 years at Palmnicken. The company pays 2,000,000 marks (£100,000) to the German Government for the right of mining for amber. The mines produce about 3,000cwt. a year, and large pieces fetch £6 per kilogramme as taken from the mine. The largest manufacture of pipes with mouthpieces of amber is at Vienna, and there the sham article is very much used. In the mines at Palmnicken about 1,000 men are constantly employed.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[59842.] — **Mathematical Probabilities.** — Surely dividing by ·434 is more operose than multiplying by twice or even thrice as many figures. It is equivalent to multiplying by 2·304147, &c., whereas the proper multiplier for this operation is 2·302585, &c. It comes a little nearer your mark than multiplying by 2·3 alone; but not a quarter so near as by 2·303, which latter "R. E. F." will hardly, I suppose, think comparable with his dividing.—E. L. G.

[59842.]—**Mathematical Probabilities.**—To "R. E. F."—I must decline to enter into a discussion with "Libra" on this subject, as he holds opinions which are more peculiar than correct, and, persists in an error which I had previously pointed out. An ace would turn up on an average of four times, and not six, as the probability increases from throw to throw, and does not remain constant at $\frac{1}{6}$. The probable number of times 3 and 5 will turn up in 900 throws is $900 \div 12$, or, very roughly about 75 times. The number of combinations in 900 throws is 36^{900}, or 47016×10^{1386}. It does not appear to me that "Libra" is considering any problem at all, unless he supposes only one throw to be made in each case.—R. E. F.

[59926.]—**A Wonderful Lamp and Battery.** —This query was not answered on p. 464, Vol. XLIII., for "Sigma" is the only person who can answer, and it was asked because in Vol. XXXVII. he wrote an excellent article on chromic acid in the battery.—MAG. EST VER.

[60073.]—**Battery.**—ERRATUM.—For October 3rd, 1883, read September 3rd, 1886.—E. CONRY.

[60186.]—**Mathematical.**—The cube of 9·4 is not large enough to contain two spheres of 6. "T. C." should give us the exact dimension in the form of an integer + a surd.—E. L. G.

[60248.] — **Locomotive Proportions.** — This query appears in a letter on page 110 last week, and possibly may be answered at some length now. The rule is 50 square feet of heating surface for each square foot of grate, and that has been found to work well. To find how many square feet of grate are necessary, it is usual to reckon that 125lb. of coal can be consumed on each square foot per hour, and as coal varies in its quality it is not safe to reckon its evaporative power at more than 8lb. of water per pound of coal. Those are the elements required by the querist, who will perhaps forgive me for saying that he puts rather simple questions. Firebox surface is of more value than tube surface, but in what proportion has not been determined. If querist can refer to the letters of Mr. Gobert, some eight vols. back, he will see some of the operose calculations.—J. T. M.

[60255.] — **Hydrostatic Pressure.** — To "M.I.C.E."—I think the result by integral calculus will be interesting to many readers. What is the position of the point of suspension when the rod, when vertical, is in a state bordering on unstable equilibrium? There is another position of this point where the rod floats horizontally on the water. The x length is not the same in both. I hope "M.I.C.E." agrees with me on the question of strains in arches.—J. S. C.

[60264.]—**Mariners' Exams.** — Examination papers can be obtained, I believe, from the publishers of nautical works; but querist can hardly expect them to be set out at length as a reply to a query.—NUN. DOR.

[60265.]—**Gas-Engine.**—I should "advise" this querist to look in the advertisement columns, or to put an advertisement in the Wanted column.—VIDEO.

[60268.]—**C.G.S. Units.**—My authorities are "Units and Physical Constants," by Prof. J. D. Everett, page 24; and "Elementary Lessons in Electricity and Magnetism," by Prof. Silvanus P. Thompson, page 209.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[60287.]—**Cloth Binding.** — Rub some glair over the spots.—NUN. DOR.

[60288.]—**Decay of Stone.**—Impossible to answer definitely without examining the stone, and perhaps not then; but in general terms, the decay is due no doubt to the action of the atmosphere on some constituent of the stone. It must be remembered that the air of a church (if well attended) is sometimes highly charged with aqueous vapour, and that condenses on the monuments, and quickly destroys some of the softer stones, and even some kinds of marble.—F.R.I.B.A.

[60294.]—**Action of Steam.**—ERRATA.—In my reply on p. 113, line 18 from the bottom, for "D A H" read "D A X"; line 8 from bottom, put a comma after "so," and erase that after "much"; p. 114, line 9, for "consideration" read "condensation." Line 27, after "end" insert *of the high-pressure cylinder which*, and underline from *the end* to *considering*.—GLATTON.

[60314.]—**Pollak's Battery.**—To "R. E. F."—"H. H." will find a description of this battery in the *Electrical Review* for July 30th, 1886, p. 105. No mention of the agglomerated portion is there made, and Mr. Habgood appears to have described a different modification altogether. The one I referred to was used for telegraph working, for which a current of $\frac{1}{30}$ ampère would be suitable.—R. E. F.

[60334.]—**Falling Bodies.**—"Dubliniensis" made this quite sufficiently clear, showing why we cannot exhibit the eastward deviation (as I once thought might be possible) in a lecture-room experiment. Can he or "R. E. F." now tell us if the body were falling down a shaft of unlimited depth at what depth, or time, its angular slope from the plumb line would reach a maximum?—E. L. G.

[60336.]—**Keeping a Pony.**—If I. Low will kindly refer to his first letter, he will find that his 1lb. to $1\frac{1}{2}$lb. of food for his pony included hay; hence my astonishment. If a horse or pony has only light work, and no fast travelling, he could be kept in excellent condition on hay alone, provided he gets enough of it, and of good quality. I have often fed and worked high-spirited horses on hay alone for months at a time, to keep them from smashing all before them.—DOCTOR MEDICINÆ.

[60336.]—**Keeping a Pony.**—Two years ago the 12th of September last, I bought a pony, trap, and harness. The expenses the first year averaged per week 8s. (nearly) for food and bedding, 5s. 6d. boy to look after it (I had to give him a little instruction at first), 2s. 4d. rent of stable and coach-house, making 15s. 10d.; twelve sets of shoes during the year at 3s. 6d. each set; compo. and polishing paste, &c., for the harness, occasional little repairs to same; the renewal of brushes, and painting trap once a year would be well covered at £5. The querist would probably have to give more for rent of stable, as I have mine of a neighbour who has no use for it. The wages of boy have now risen to 6s. 6d. per week, but he is not more than half the day on an average at the stable, doing odd jobs in the house the other half. From observation at a row of stables close to mine, I think I am rather an extravagant feeder; but I like any animal about me to be fat and happy. I have this year tried the mixture recommended by Mr. Low, but do not find the pony thrive on it so well as on oats; I give it for a change very occasionally. The opinions of the number of stablemen near to us are the same as "Doctor Medicinæ," that it costs £1 per week keeping a horse, and they have been a little surprised at the cost of my pony. —G. H. D.

[60349.]—**Florida.**—The climate of Florida is fairly equ ble and healthy, though in the extreme southern portion it is somewhat malarial, the temperature very seldom, in winter, falling below freezing point in any portion of the State, and in summer it is not hotter there than in New York, or any other part of the U.S. The chief industries are orange-growing, lumbering, general farming (cotton, Indian corn, and fruits), and, on the southern plains, cattle raising. Florida is not the best place in the world for an emigrant without money, though a little capital will go a long way there. Living, such as it is, is cheap—in fact, in the country (i.e., away from the towns) a man may live with hardly any exertion at all, edible animals and vegetables being abundant, and free to the gatherer; but if the querist has any intentions of making a fortune, he had best give Florida a wide berth. If the querist is a skilled labourer or artisan, he would find ample room in some of the other Southern States, where not only would his pay be as good as he could get anywhere in this country, but his living expenses would be far lower, and his social position better. If he has neither capital nor skilled labour, he had best not go South, as the labouring class there are for the most part ignorant negroes, and their wages are probably the lowest paid anywhere in the world outside of Asia.—AMERICUS, New York.

[60359.]—**Freezing Meat.**—I see that in my reply on p. 114 I have omitted to point out that the compressed air was made to do work as it expanded. More heat was extracted in the form of work from the air than could be removed by the water alone, and the heat absorbed by the air as it escaped was correspondingly increased.—GLATTON.

[60359 & 60362.]—**Dry Cold-Air Machinery.** —I saw at the Health Exhibition a cold-air machine in use in one of the dairy farm exhibits (the Express Dairy Farm Co.) This little machine was keeping their milk, butter, cream, &c., cool during the hot weather. The process the air undergoes is a very interesting subject; first, air is compressed in a cylinder of a given capacity to, say, 60lb. per square inch; it is next delivered into a reservoir composed of a number of small tubes, around which is circulated cold water, by which means the heat is abstracted (which was got in the compressing); the air being still under pressure is next used in an expanding cylinder, it being allowed to expand to atmospheric pressure, and by so doing gives out some of the power it took to compress the air, thereby helping to drive the machine. After the air leaves the expanding cylinder at a very low temperature, say 20° to 40° below zero, or to suit the requirements, it is sent into a chamber or large cupboard fitted with shelves that are made so as the air circulates freely, and the butter, milk, cream, &c., can be kept in prime condition for an indefinite period. This machine and chamber seemed to excite a great deal of interest among visitors to the exhibition. It was made by the General Engine and Boiler Co., Hatcham Iron Works, London, who have made this cooling business one of their many specialities and study. I saw at the Docks, awhile back, a very large air-cooling machine made by the same firm. This machine was capable of delivering 83,000 cubic feet of cold dry air per hour, and was one of the first to bring home from Brisbane a large cargo of frozen mutton, the same being in splendid condition. It is essential that the air delivered should be dry.—H. PURSE.

[60374.]—**Solder for Platinum.**—Platinum combines very readily with zinc, arsenic, and also with tin and other metals—so much so, that it is dangerous to melt either of those metals in a platinnm spoon, or to solder platinum with common tin solder, which fuses at a very low temperature; although platinum is constantly soldered with fine gold, the melting point of which is very high in the scale." Holtzapffel's "Turning and Mechanical Manipulation," Vol. I. p. 302.—J. K. P.

[60382.] — **Equal Balance.**—ERRATA.—On page 115, for "gauge" read "gravity."—GLATTON.

[60386.]—**Letters on Brass.**—To fill up the letters in your brass plate, you will want some red and black sealing-wax. Warm the plate over the gas or with a hot flat-iron, and then run the sealing-wax in till the letters are quite filled up. As you have got some bolts on the back of your plates, you had better get a piece of wood to lay the plates on, with holes bored through for the bolts to slip in, so that the plate lies perfectly flat and solid. To dress the plate down, rub it well with pumice-stone and water till the surplus wax is all taken off. Now wipe the plate dry and then sprinkle some fine pumice-powder and a little oil. Rub this on with a large cork or bung, or, failing pumice-powder, wrap a piece of emery cloth round the bung and rub with that. Wipe the plate clean again, and then put on some rottenstone with a little more oil. Wrap a piece of cloth round the bung and polish. Be careful not to make the plate too hot when filling up, or the sealing-wax will boil. This will make it porous, which will show as holes after the plate is polished.—GEO. WELLS, Needham Market.

[60410.] — **Electro-Motor for Boat.**—Your query, along with "Another Rochdale," had slipped my memory until too late for last week. Am sorry that I cannot at present give you all particulars of my boat; but, with Editor's permission, may do so at an early date. You will be disappointed if you look at page 570, Vol. XLI., for there is no motor there. Mr. Bottone has made a mistake. The motor sketched by Mr. E. Conry this week is quite unsuitable for your boat. You want something not more than half the weight. Will you send dimensions of your boat—length, beam, and depth—is it wood or iron; what cells you have, and size, and how many your boat will hold before sinking; or, what would be more suitable, what weight is required to sink your boat to water-line? With these particulars, I shall be pleased to give you a helping hand. Mr. Conry, I see, has made a serious error in quantities, or else in the gauge of wire he recommends for his motor. It would not even work, much less drive a 3ft. boat.—E. THOMSON.

[60412.]—**Steam.**—It is not possible to predict exactly what the steam in any engine will do without particulars of trials of other engines of the same general design. The work lost by condensation, friction, wire-drawing, &c., varies in every engine, and can only be found by trial. I will, therefore, estimate the saving which would result if there were no losses, which will exceed that actually realised. (1) The steam is cut off at $\frac{1}{2}$-stroke in the h.p. cylinder, and is then expanded till it first fills the whole of the h.p., and then it is made to fill the low-pressure cylinder, after which it is exhausted. (2) The area of the l.p. cylinder is 572·6 square inches, and the h.p. is 201·1 square inch. The volume of the l.p. cylinder is, therefore (the strokes being equal) $\frac{572 \cdot 6}{201 \cdot 1} = 2 \cdot 85$ times as great as that of the h.p. cylinder, and as a quantity of steam = $\frac{1}{2}$ the bulk

of the h.p. cylinder is expanded into the l.p. cylinder at each stroke, it will then be $2{\cdot}85 \times 2 = 5{\cdot}7$ times its original volume. (3) As the absolute pressure diminshes nearly as the volume increases, and the initial pressure is $(50 + 15) = 65$lb., the terminal pressure will be $\frac{65}{5{\cdot}7} = 11{\cdot}4$lb. absolute, or $(15 - 11{\cdot}4) = 3{\cdot}6$lb. less than atmospheric pressure. (4) To get the same terminal pressure with $(65 + 15) = 80$lb. absolute pressure you must alter the cut-off in your h.p. cylinder to $\frac{1}{2} \times \frac{65}{80} = {\cdot}406$ of the stroke. (5) The number of expansions then becomes $\frac{2{\cdot}85}{{\cdot}406} = 7{\cdot}025$, instead of $\frac{2{\cdot}85}{{\cdot}5} = 5{\cdot}7$. Taking the vacuum behind l.p. piston as 24in. of mercury, or, say, 3lb., we have the following figures:—(6) By the table on page 129 of last volume, the mean absolute pressure reduced to l.p. cylinder, when the initial pressure = 65, and the No. of expansions is 5·7, or just under 6, will be $(65 \times$ say ${\cdot}48) = 31{\cdot}1$lb. Deducting 3lb. back pressure leaves 28·1lb. useful pressure. (7) In the second case the mean absolute pressure with 80lb. steam and 7 expansions will be $80 \times 42 = 33{\cdot}6$. The useful mean pressure $= (33{\cdot}6 - 3) = 30{\cdot}6$. (8) The weight of 1 cubic foot of steam at 80lb. is 1·22 times as great as that of the same volume at 65. The volume used in the present arrangement is $\frac{{\cdot}5}{{\cdot}406} = 1{\cdot}231$ time as great as in the new one, and $\frac{1{\cdot}231}{1{\cdot}22} = 1{\cdot}008$ time as heavy. (9) That is, you will use the same quantity of water per stroke and get $\frac{30{\cdot}6}{28{\cdot}1} = 1{\cdot}09$ time as much work as at present. The losses due to condensation during expansion will be greater than before, and the saving will be even less than the above.—GLATTON.

[60414.]—**Overhead Wires.**—The advice given by E. Conry to run wires without permission is exceedingly bad. No person, or body of persons, have a right to monopolise any portion of public property. The streets and roads are the property of the community, and the "fussy vestry" is elected to look after its interest. The folly of E. Conry's remarks would be more apparent had he gone a step further, and told the querist to put his insulators and posts up without asking permission of the owners; he would probably have designated them "fussy owners." If the "fussy vestry," or some other body, had no control over their streets, we should have clothes lines and other abominations obscuring what little sunlight is left in crowded thoroughfares. "Armature's" assertion that local boards have no powers is simply nonsense, as anyone will soon find out by attempting to act without permission.—C. D. R.

[60421.]—**Carriages.—Railway Mystery.**—I see Mr. Stretton makes a slip on p. 115. A body let fall from a railway carriage window, if the train were moving at a uniform rate, would fall behind the door, not by the action of gravity, which would make it strike the footboard below the window; but because the wind would blow it back.—GLATTON.

[60434.]—**Crank Movement.**—You say that you "shift the centre of gravity to the other side of centre of motion." I must be very dense, but really I do not see how you avoid crossing the dead centre in so doing. Can't you give us a sketch of the motion?—T. C., Bristol.

[60449.] — **Music.** — I should recommend "Musik Freund" to read Beethoven's "Pianoforte Sonatas," by Ernest von Elterlein," also "Unrequited Love, or Records from a Young Lady's Diary" who was a personal friend of Beethoven's. I think these will give him the information he requires.—PRACTICAL.

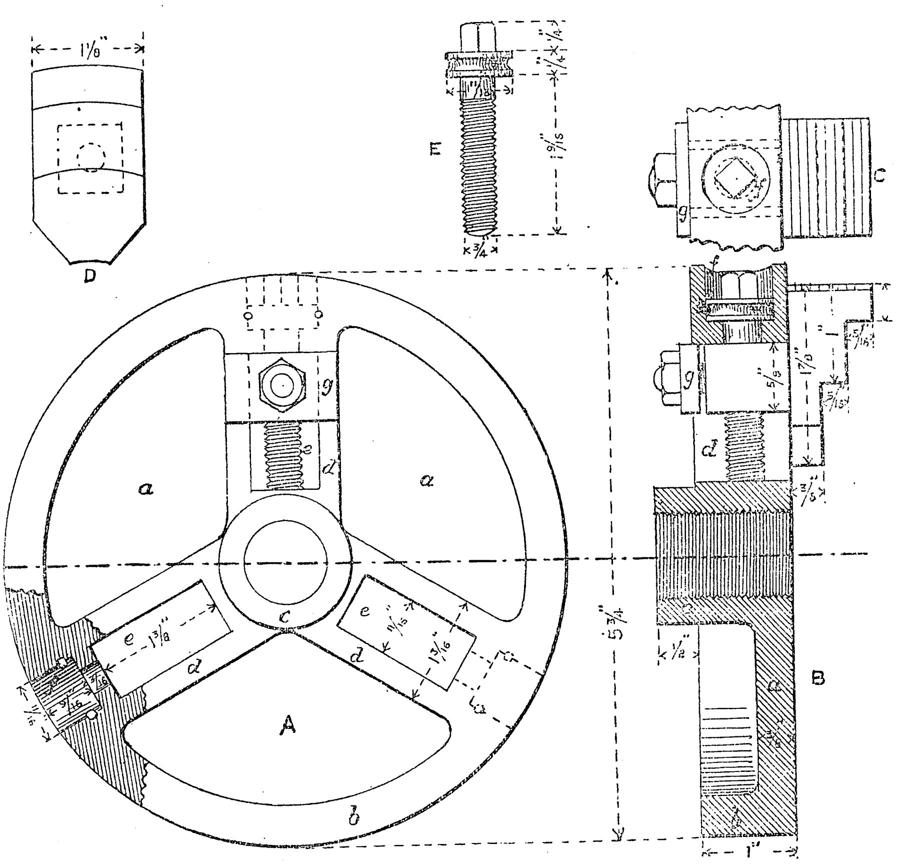
[60450.]—**Electric Power for Tramcars.**—These questions are evidently taken from examination papers, and it was never intended that they should be answered other than by the person to whom they were addressed. To endeavour to pass an exam. from information gathered in this manner is simply a farce.—C. D. R.

[60451.]—**Pocket Accumulators.**—Described several times. Look up indices. See replies last week to 60346.—C. D. R.

[60454.]—**Wind Motor for Electric Lighting.**—If this is all you describe it to be, it must be a most unique machine. Before expressing any opinion, suppose you give details of it in these columns?—C. D. R.

[60454.]—**Wind Motor for Electric Lighting.**—I am much obliged to Mr. Conry for his remarks on my motor. I have no practical knowledge of electric lighting; but I have for some time read carefully everything bearing on the subject in the "E. M." and in the *Electric Review.* Two things seem to me to be necessary—cheap motive power and steadiness in work. Wind is cheap, but unsteady. I have endeavoured to overcome this unsteadiness by regulating the speed of the machinery, instead of regulating the speed of the motor. As to reasonable size, it is reasonable, considering that the motive power is wind. Wind pressure rarely exceeds one pound to the foot for any length of time. There must be a reasonable surface to produce any palpable power. It will not easily go out of repair. I have had one running for three months night and day, when there was wind, without being touched, except for oiling. As to possible loss of power, it does not necessarily follow; for if there were two or three dynamos they could be attached in succession, as the power of the wind increased, and all worked together when there was sufficient power. All increase in wind power, after a certain point, makes no difference in the speed of the dynamo. So far as I have understood these matters, I have thought that it was not advisable to increase the speed of the dynamo beyond a certain point, and in my invention I have kept this in view. I am now making a small model of the motor and gearing, which I hope to have ready in course of a few weeks, and shall be glad to show it to anyone really interested in the matter.—F. G. GWYNT

[60472.] — **Chuck for 3in. Lathe.** — The figures represent a half-sized chuck for a 3in. lathe. A is the back view, B a section, C view on edge, D jaw, E screw. The pattern of the main plate is made by building up or turning out of the solid a ring *b* on a plate *a*, giving taper to the inside of the ring. The central boss *c* is put on to suit the mandrel nose; the thickness pieces *d* are fitted between the boss and the ring, and prints



put on the face of the plate to core out the spaces *e*. This is all, unless you like to make a plain core box as well, to insure getting true holes. The circular holes *f*, for the shouldered portion of the solid, and likewise the central hole for the mandrel nose are drilled. The jaw with its nut may, in so small a plate, be slotted from solid wrought iron or steel; the screws should be of steel; the jaws are clamped by means of the washers, *g*. If you want a smaller chuck you can easily reduce from these dimensions.—J. H.

[60472.]—**Chuck for 3in. Lathe.**—If you look into the Sixpenny Sale Column, you will find castings and working drawings advertised that will suit you.—C. D. R.

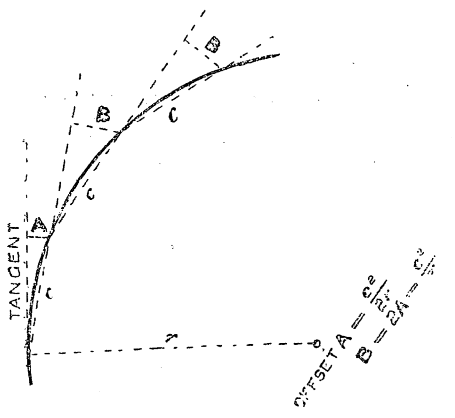
[60465.]—**Sewing Machine.**—Machines usually miss stitches when the needle is improperly set, so as not to throw the loop square into the shuttle race. Turn it a little to either side. See that it is not too far up or down. Sometimes the needle is too near or too far from the shuttle, and requires to be altered when a change is made from a fine to a coarse, or vice versâ. The "Howe" has a contrivance for effecting this. If a "Singer" machine with pinions, see that the marks on these correspond; also see to groove of needle if on proper side. I once saw a sewing machine which missed stitches with silk (a thing of rarer occurrence than with linen or cotton) cured by passing the thread once round the needle. "F. W. S." might have stated maker's name.—R. B.

[60473.]—**Resistance Coil or Switch.**—You will want both, it seems to me. The switch you can make by a strip of strong sheet brass fastened at the middle by a bolt and nuts to a board just loosely enough to turn, the end of which slides on a number of small pieces of the same material, ranged in a semicircle, at the proper distance to come under the end of the strip, and having the spaces between them filled with hard rubber or wood. Each of these contact pieces should have a hole drilled through it to admit of a round-headed screw passing through it and into the wood underneath, so that a wire can be fastened down under the screwhead. This is a general design, and can be varied to suit all sorts of currents. A very slightly-made switch will do for electroplating. For the resistance coil, make two squares of wood, say, 1in. square in section, and join them by four similar pieces at the four corners. Notch slightly the outermost edges of these four, and wind on the frame in the notches whatever wire you want the gauge, which depends on the current you want to carry, and the amount of it upon the maximum resistance you will require. Then, if you want several resistances of different strengths, mark off your drum of wire into corresponding sections, half, quarter, and so on, and at each mark solder on a short end of wire. These ends you can then connect to the various contact pieces on the switch, and thus by leading one wire of your circuit to the central bolt, and completing the circuit through the various parts of the resistance coil and the contact pieces, you can switch into the circuit the whole coil, and consequently the whole resistance, or three-quarters or half, or any part you desire. If you will state the current of your battery, the number of cells in series, and about what proportions of the whole current you want to have at command, I can give you the length, gauge, and divisions of wire you want for your coil. German silver is best; but copper will do.—E. CONRY.

[60484.]—**Twilight.**—Might I ask "E. L. G." to give his authority for the statement that "the lines dividing day from twilight, and twilight from night, are two parallel circles, about 1,250 statute miles apart," as I obtain a result about double that distance? If he will take the trouble to draw a diagram, his error will be evident enough. Describe a circle to represent the earth, and at any point on the circumference (the observer's station) draw a tangent *o a p*, and the diameter *a c d* at that

point. Next draw a line ab, making an angle of 18° with ap, cutting the circle in x, and join x with the centre c, and the other end of the diameter, d. Then it is apparent that the arc ax is in twilight, and the length of the arc is the distance apart of the two great circles. It will be seen that the figure is the same as Euclid III. 32, and it follows that the angle pax is equal to the angle in the alternate segment adx, that is, angle $adx = 18°$. But the angle at the centre being double that at the circumference, the angle $acx = 36°$. The length of the arc ax is equal to the circular measure of 36° multiplied by the earth's radius, or $\cdot 62832 \times 3956 = 2485$ miles, which is about double the incorrect value given by "E. L. G." This is the distance apart of the two parallel circles measured on the earth's surface, supposing it to be a sphere; but the actual distance between them is sin. 36° × earth's radius, or about 2,363 miles, being 122 miles less. This is, however, only the theoretical twilight, which is said to last until the sun is 18° below the horizon; but as a matter of fact this gives but a very inaccurate measure of its duration. Very often the twilight is over long before the sun has reached this depression, or may persist for some time after. The presence of aqueous vapour or particles of snow in the higher regions of the atmosphere may prolong the twilight until the sun is fully 10° lower than the usual angle. The shortest possible twilight (the actual, not the theoretical) is nothing like so long as 70 minutes, for in the tropical regions of South America it may be only a few minutes, in Chili 15 minutes, and in some parts of Europe half an hour. On the whole, the astronomical twilight (ending the moment a sixth magnitude star appears near the zenith) is the most exact and constant estimate.—R. E. F.

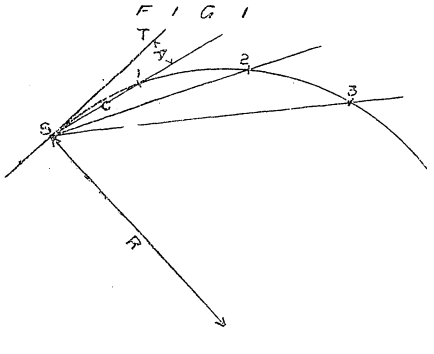
[60478.]—**Setting Out Curves.**—The inclosed sketch shows, I think, the simplest way of



doing this. Chords of 50, 66, or 100ft. are the most convenient for ordinary curves; of course the sharper the curve the less the chord that should be taken. If "Curvist" does not understand, and will state a case, I will explain further.—LIBRA.

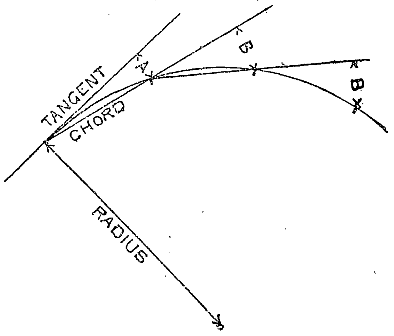
[60478.]—**Setting Out Curves.**—Either by tangential angles or by off-sets. Method by angles. Fig. 1, let R = radius of curve, C = any chord,

FIG. 1



A = tangential angle of C in minutes; then $A = \frac{1719\,C}{R}$. Example: Let R = 40 chains, and C = 1 chain. $A = \frac{1719 \times 1}{40}$, or 42′ 58″ the angle required, which is set out from the tangent T, the theodolite being at the springing of the curve S. Measure off the chord C 1 chain, the point 1 will be on the curve; points 2 and 3 will be found the same way. Method by offsets, Fig. 2:—

FIG. 2.



$$\text{Offset A from tangent} = \frac{\text{chord}^2}{2\ \text{radius}}$$

$$\text{Offset B} = 2\,\text{A} \quad = \frac{\text{chord}^2}{\text{radius}}$$

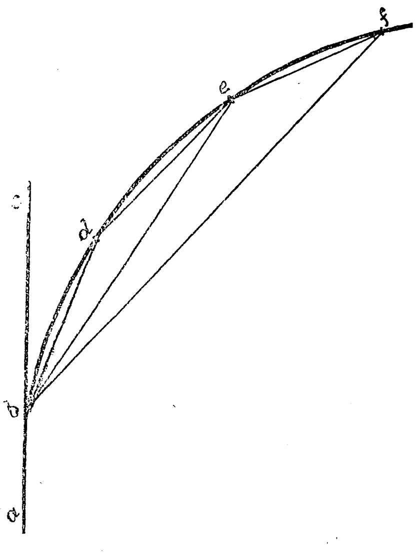
Various formulæ for the different problems in setting out railway curves will be found in "Molesworth's Pocketbook."—J. LATIMER.

[60478.]—**Setting Out Curves.**—A very easy method of setting out curves with a theodolite and chain (or tape) is as follows:—First work out this formula:

$$A = \frac{1{,}719' \times C}{R}$$

A = tangential angle of C in minutes.
C = chord (take 1 chain).
R = radius of curve.

In the figure, let $a\ c$ be a line, from which a curve



is to be set out (say from pt. b), set up the theodolite at b, point it to e, and swing it round to d, making angle $c\ b\ d$ equal to angle A (which is found from above formula), and measure along $b\ d$, making $b\ d$ equal to C the chord; then point d is a point on the curve (put a peg in d). For the next point, make angle $c\ b\ e$ = 2 A, and $d\ e$ = C = $b\ d$. For point f, make angle $c\ b\ f$ = 3 A, and $c\ b$ = C = $b\ d$, and so on, adding angle A to the last reading for the next point. For curves of short radius, best to take short chords (say half-chain).—K. K. K.

[60487.]—**Dynamo.**—Depends upon how the lamps are arranged. If in multiple arc, 25 volts and 12 ampères will do it; but if in series, 300 volts and about 1 ampère will suffice. The first method is the practical one. A potential of 200 volts is highly dangerous.—C. D. R.

[60488.]—**Medical Battery.**—As a canvas bag is used in a cell very like the Leclanché, I think you will succeed. The only objection is that canvas will be liable to rot.—GLATTON.

[60488.]—**Medical Battery.**—Yes; canvas or calico bags will do; but you must immerse the top portion in paraffin wax, as the salt creeps up and destroys the connections very quickly; that is a very serious disadvantage. Peroxide of manganese at 7lb. for 1s. 2d. is very cheap—too cheap to be good. It should be in small pieces about the size of a pea. You will find it advertised in the Sale Column every week. Remember that the oxide is about four times heavier than carbon.—C. D. R.

[60489.]—**Electric Lighting.**—How do you propose to drive the lathe? By foot? If so, the charging will never take place. You want a steam-engine.—C. D. R.

[60389.]—**Apparatus for Ringing Hand-bells.**—To MR. E. CONRY.—I am very much obliged for kind reply to my query, and should be very grateful for the sketch you kindly offer to give.—R. M. GREAVES.

[60491.]—**Time.**—"Chronos's" only reliable way of correcting the rate of his regulators is by means of a transit instrument. I should think that one of Mr. Clark's small window transit instruments, made by Mr. Frost, of 6, Westminster Chambers, Victoria-street, would be his cheapest method. By careful manipulation he would be able to get G.M.T. to a single second. Mr. Clark publishes simple tables of transits of stars for nearly every day in the year. These tables are simple, easy to work by, and thoroughly trustworthy, and give the transits reduced to mean time.—H. A.

[60492.]—**Mechanical.**—Write the numbers as a fraction, and reduce to its lowest terms. Thus:—$\frac{44}{28} = \frac{11}{7}$. The smaller number will be the revs. of the large wheel (= 7), and the larger number (11) the revs. which the small wheel must make before the same teeth meet again.—GLATTON.

[60492.]—**Mechanical.**—Range the numbers of teeth contained in the wheels in a row, and find the least common multiple. Divide this by the number of teeth to find the number of revolutions which will have to be made by the wheel containing that number of teeth before it is again in the same position as regards the other wheels, as at starting, thus:—

$$4\overline{)28 \cdot 44}$$
$$7 \cdot 11$$

$$4 \times 7 \times 11 = 308 \div 28 = 11 \text{ revolutions.}$$
$$308 \div 44 = 7 \quad ,,$$

This rule is correct for any number of wheels. Example:—

$$10\overline{)6\ .\ 50\ .\ 70}$$
$$3\ .\ 5\ .\ 7$$

$$10 \times 3 \times 5 \times 7 = 1050 \div 6 = 175 \text{ revolutions.}$$
$$1050 \div 14 = 75 \quad ,,$$
$$1050 \div 50 = 21 \quad ,,$$
$$1050 \div 70 = 15 \quad ,,$$

—LIBRA.

[60495.]—**Britannia Developer.**—I am an amateur in photos., and have passed through the "haze" which has troubled "Terranova," and so can sympathise with him. I am beginning now to get out of it. I do not strictly adhere to mixing up the formula given with these plates, which I use exclusively, but mix it up in small quantities as follows:—(A) Pyro. 25gr, brom. ammon. 45gr., water 10oz., nitric acid 2 drops. (B) Liq. amm. 3dr., water 10oz. For normal dev. equal quantities. My "haze" was caused by over-exposure. Put in smallest stop and give shortest possible exposure. Try again with same stop, lengthening exposure. Study Burton's "Modern Photography," a handy book for a beginner, 1s. "Set a stout heart to a stey brae," and go on. I sacrificed more than a half-gross of plates. They are now very cheap. Examine everything for white light. The cause may lie somewhere else than in developer.—R. B.

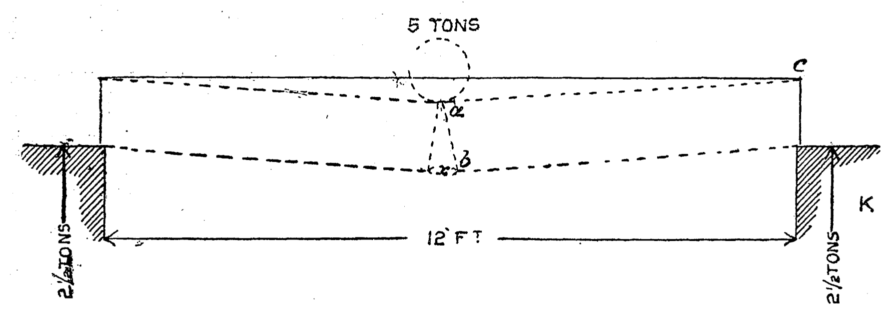
[60496.]—**Telephone Fixing.**—You do not take into consideration the currents that are constantly circulating through the different earth returns of other lines, beside the one you may speak of. These constitute the disturbing influence.—C. D. R.

[60496.]—**Britannia Developer.**—I have tried the plates in question with same results as "Terranova" mentions. I used usual pyro and ammonia, with bromide for development; also pyro with sulphite of soda and washing soda. I attributed the thinness of resulting negatives to the plates not being rich enough in silver. I never failed before to get density with other plates, such as Fry's, Edwards's, or Ilford's.—C. N. M.

[60497.]—**Acoustic Telephone.**—Your mechanical telephone, if properly constructed, should work well on four or even eight insulators. See that the wire is clear of everything in leaving diaphragm and through wall; also that it touches nothing except proper insulators till reaching other diaphragm. If there is a ringing sound when speaking, tighten up the wire till it ceases, and see that there is an equal tension throughout all the line. If your telephones are right, and you observe these conditions, you should converse easily several feet from instruments.—R. J. TAIT.

[60502.]—**Lattice Girders.**—For the span and load named by "Self-Taught," I would advise him to use a rolled girder, which can be got at any iron warehouse, and will cost much less than a lattice girder. A rolled girder 10in. by 4½in.

by 33lb. per foot would be quite strong enough; if, however, the lattice girder be a necessity, the strains on the top and bottom booms can be calculated in the following manner :



Assume a depth for the girder, say, 1ft. The load of 5 tons in the middle is divided equally between the two supports, and the reaction of each support upwards is, therefore, 2½ tons. In the imaginary bent lever, $c\ a\ b$, $a\ c$, multiplied by 2½ tons, the upward reaction of the support K is equal to $a\ b$ multiplied by the strain (x) on the bottom boom of the girder; that is to say:

$$6\text{ft.} \times 2\tfrac{1}{2}\text{ tons} = 1\text{ft.} \times x$$
$$\therefore x = 15 \text{ tons.}$$

The problem now is to find what size of iron will be necessary to withstand the strain of 15 tons. Wrought iron may safely be subjected to a tension of 5 tons per square inch, so that three square inches must be provided; Tee iron, 3in. by 3in. by ⅝in., will be sufficient. The strain in the top boom is equal in amount to that in the bottom one, but is a compressive strain. A better proportioned girder will be obtained by taking the depth of the girder as 9in. The calculation will then stand :

$$6\text{ft.} \times 2\tfrac{1}{2}\text{ tons} = \tfrac{3}{4}\text{ft.} \times x$$
$$15 \text{ tons} = \frac{3\ x}{4}$$
$$x = 20 \text{ tons}$$

which, at 5 tons per square inch, will require four square inches area; in this case Tee iron, 3½in. by 3½in. by ⅝in. would be suitable. The lattice bars should be 2in. by ½in. flat bars, riveted on alternate sides of the Tee iron. The above method of calculation is the one adopted by Sir John Anderson in his "Strength of Materials" (3s. 6d.), Longmans, a book I would strongly recommend to "Self Taught." Other books which treat on this subject in an elementary manner are Perry's "Practical Mechanics" (3s. 6d.), Cassell's; Campin's "Iron Bridges, Roofs, and Girders" (2s. 6d.), Crosby Lockwood, and Co. Humber's "Handybook of Strains" (7s. 6d.), is a useful book of reference for those who have already learnt the use of the formulæ and know the reasoning on which they are based.—Arthur Bowes.

[60503.]—**Photography.**—Mr. S. Bottone, replying to this query, is very inaccurate. He says the plates at 1s. the dozen are not usually good, but says for 1s. 6d. the dozen several first-rate makes can be had, including Marion's "Ilford" and Fry's "German." Now, in the first place, Marion and Co. neither make nor sell "Ilford" plates; but "Britannia" and "Ilford," "German" and "Britannia" alike are cheap plates at 1s. the dozen. That "Ilford" are very good, I can testify personally. "German," I hear are good, and the few "Britannia" I have used this year turned out well.—T. Perkins.

[60507.]—**Electrical.**—There is no such a thing as "an arc of ½in.," so I am rather puzzled to know what you mean. With a lever pivoted at one end, very near an electro-magnet, with poles about 3in. distant, and an armature about 3in. long, the upper end being ½in. from the upper leg of the electro-magnet, you could pull 3lb. easily with a single pint bichromate if your electro-magnet were about ½in. core, 8in. long, bent into the horseshoe shape, and wound with six layers of No. 20 d.c.c. wire. To fire gun, a specially-made fuse, such as Abel's or Statham's, would do without the coil.—S. Bottone.

[60507.]—**Electrical.**—You could not do it with any magnet that could be worked by any battery deserving the title "small." Three pounds is a heavy pull for any electro-magnet or solenoid to overcome. It could be done with one cell and an electro-magnet of very low resistance, but the cell would have to be a very large one. If a small battery be a *sine quâ non*, I should suggest using a lever with an iron armature on the end, made just as heavy as compatible with allowing the other end to remain in its normal position without any additional force being applied, and then arrange, say, three sets of three each of small electro-magnets, ½in. cores wound with ½in. thick layer of cotton or silk-covered No. 22, the fulcrum of the lever being midway, and the sets so arranged that the first one, on switching on the battery, should come into action and draw down the armature, say, ⅙in., thus bringing it within the range of the second set, the circuits of the first being carried through contact pieces on the lever itself, so arranged as to break contact for the first set and switch on the second set at the moment that the armature by meeting the cores of the first set, had come within range of the second set, the third set being similarly arranged with regard to the second. In this way I think you could lift 3lb. with a battery of not more than six moderate-sized bichromate or chromic acid cells, and I could give you a sketch of the connections and contact pieces, but the whole apparatus would be a complicated affair, depending for its working on exact and delicate adjustment, and any mechanical device would be preferable. In view of the fact that magnetic force diminishes in proportion to the square of the distance, you would, I should say, require, for a single magnet powerful enough to overcome 3lb. from the distance of ½in., a battery of about 20 cells, if the magnet were of fine wire, as is generally preferable, or a couple of small tanks if the magnet were low resistance. For any small battery, you would require to use a coil, sending its spark through some detonator fuse, as the fulminate of mercury or the Abel fuse, both of which have, I think, been fully described in back numbers.—E. Conry.

[60507.]—**Electrical.**—What is "an arc of ½in."? Before our electrical correspondents can give a proper reply it will be necessary to say how far the weight is moved and how far the armature moves in the same time. I think it would be well also if you could give more particulars, as ½in. is a long pull for a magnet (if you mean the armature to move so far), and I do not think any magnet of moderate dimensions could exert a pull of 3lb. at that distance. Of course, if you give the length of lever, the end of which moves ½in., the expression at the beginning of this reply will have some meaning.—Glatton.

[60508.]—**Aureolin.**—Field, in his "Chromatography," Salter's Edition (no date), though he describes the sources of the common and well-known colours, instead of doing so in the case of aureolin, gives two long puffs regarding its merits; an omission which is strange, considering that his work is published by one of the best known and leading artists' colourmen in England, to whom, if I am not mistaken, is due both the name and the introduction of this colour into use. E. A. Davidson, in his "Grammar of Colouring," Weale's series, says that aureolin is a nitrate of cobalt—a very pure and permanent yellow—but nothing regarding its preparation.—Eye-Witness.

[60509.]—**Gold from Quartz.**—Pulverise a pound of gold quartz into a fine powder; then wash it carefully in a clean dish. Let the coloured water run over the edge until all is washed away except a few grains of the heavier stuff, when, if there is any gold present, it being the heaviest, will remain along the edge of the residue. Gather very carefully, and extract any iron with a magnet. Weigh the gold, which will give so much to a pound or ton, as may be required. If there is no gold visible to the naked eye, try a magnifying glass.—J. A. Harrington, Artist and Gold Miner of California and South Africa.

[60511.]—**Boys' Marbles.**—From Holtzapffel's book, p. 1,078:—"These are principally manufactured in Germany: some are made of clay, covered with a glaze and baked, as in pottery; others are made of alabaster and marble; but the greater part are made of a hard stone found near Coburg, in Saxony. The stone is first broken with the hammer into small cubical fragments, and about 100 to 150 of these are ground at one time in a mill, somewhat like a flour mill. The lower stone (and), which remains at rest, has several concentric circular grooves or furrows; the upper stone is of the same diameter as the lower, and is made to revolve by water or other power." Extracted from Gill's description (see "Tech. Repos." for 1828, p. 219):—Without having very many to select from, I managed to secure three dozen, of which the biggest is 1·21in. diameter, and the smallest 1·70in. About two dozen are very nearly the mean of those two—viz., 1·19. Although they are obviously coloured artificially—some blue, some yellow or Indian red, and a few brown—I am nearly sure that they are not of clay, but of stone, as some of them, although for the most part duly spherical like the rest, have even as many as three decidedly flat places left on them, as if remnants of the shape in which they were originally chipped out. They are amply near enough to one size to satisfy my requirements, and I used them in preference to bullets, which would have been a warm job to make by the quarter-gross in the recent weather. The wooden ones that I supplemented them with were made to gauge without any difficulty, and without a spherical rest, which is a tool to be recommended for ball turning to those only who cannot use their fingers. With respect to shot boxing:

1. I reckon a box 8in. cube to hold, of 1in. balls, 212, piled chequerwise and layer on layer.
2. A box 8in. × 8in. × $8\frac{1}{10}$in. will hold five tiers of 49, and six tiers of 64 = 629.
3. A box 8in. × 8in. × $6\frac{21}{32}$in. will hold five tiers of 49, and four tiers of 64 = 501; or five tiers of 64, and four tiers of 49 = 516.
4. And a box 8½in. × 8½in. × $8\frac{1}{10}$in. will hold eleven tiers of 64 = 704, which is closer packing still than No. 2 in the proportion of 704 : 680 ±.

I have hardly given any attention to the subject, and my figures may be wrong.—J. K. P.

[60512.]—**Mathematical.**—

(1) $$a = x^2 + y$$

Transposing—

$$x^2 = a - y$$

Taking square root—

$$x = \sqrt{a - y} \quad \dots\dots\dots\dots \quad (a)$$

Next—

$$y = a - x^2 \quad \dots\dots\dots\dots \quad (b)$$

(2) $$b = x + y^2$$

Transposing—

$$x = b - y^2 \quad \dots\dots\dots\dots \quad (a')$$
$$y^2 = b - x$$

Taking square root—

$$y = \sqrt{b - x} \quad \dots\dots\dots\dots \quad (b')$$

Thus x is found in terms of a and y and b and y; and y in terms of a and x and b and x respectively.—R. E. F.

[60519.]—**Large Induction Coil.**—To S. Bottone.—Core, 1in. by 8in.; primary, two layers of No. 16 d.c.c.; secondary, 1lb. No. 36 d.s.c.; condenser, 50 sheets of tinfoil, alternated with paraffin paper, 7in. by 5in. This will give 1in. spark.—S. Bottone.

[60520.]—**Kauri Gum Solvent.**—Bisulphide of carbon, coal-tar naphtha, acetate of amyl, oil of turpentine. This latter is principally used, aided by heat and the addition of a little camphor.—S. Bottone.

[60520.]—**Kauri Gum Solvent.**—In making varnishes the kauri is not dissolved, but "run" (i.e., melted at considerable heat in a pot). The hot oil is then added. Considerable experience is required to be successful. You may dissolve kauri in methylated spirit by the application of heat and agitation after considerable time.—T. C., Bristol.

[60527.]—**Medical Coils and Paralysis.**—To Mr. Bottone.—(1) Yes. One electrode should be put in a foot bath of warm water and salt, in which the paralysed foot or feet are immersed, while the other is gently rubbed along the lower part of spine, and about the affected leg. (2) Current from coil is not constant, and therefore much more stimulating. (3) No.—S. Bottone.

[60528.]—**Photographic.**—I give the three following modes, which are all good: (1) Make a solution of silver nitrate in distilled water, say, 30 grains to the ounce. Place a few drops of this clear solution in a test glass. Allow the drippings from the suspected pictures to fall in this. If a white, curdy precipitate, rapidly turning yellow and then black, appears, the picture is not washed enough. (2) Make a thin starch paste; colour it blue by the addition of one drop of tincture of iodine to each pint of thin paste. Use as above. As long as hypo-sulphite is present, it will bleach the paste. (3) A dilute solution of Condy's fluid (permanganate of potash) is discoloured if hypo is present in the drippings.—S. Bottone.

[60528.]—**Photographic.**—Level the negative under examination on a levelling stand, pour upon it, film side upwards, enough distilled water to flood it; any hyposulphite that may be present will dissolve in the supernatant water, which can be tested afterwards as to its presence or absence. In the case of a print, allow it to be in contact with the distilled or ordinary water if free from organic or other oxidisable matter, for, say, twenty minutes or less. Take a few crystals of potassium permanganate dissolved in water and diluted to a light pink colour. If now a few drops of water from

the negative or paper under examination be mixed with the weak solution of permanganate, an instant decoloration ensues if only an infinitesimal amount of the hyposulphite be present. This is an exceedingly delicate test. Iodide of starch is also used; it is of an indigo colour, and becomes immediately colourless in solution with the slightest trace of a hyposulphite salt. This reagent can easily be prepared by the addition of the halogen iodine to a solution of starch paste. I dare say your mother would give you a lesson or two in starch-making if you do not already know.—A. TREYER EVANS, Monmouthshire.

[60528.] — **Photographic.** — Authorities differ much in the amount of time which should be allowed to wash out the hyposulphite of soda from negatives and prints; for the former, Abney considers six hours in running water not too long. Burton prescribes half an hour in running water; Hughes, three or four changes of water during one hour. For prints six to twelve hours is generally recommended; for my part, I give eighteen hours for prints, the water frequently changed, and often running, finishing up with three or four washings in boiling water. I may mention that prints so treated over thirty years ago, which have been kept in a book, are still unfaded and unchanged. As regards tests, Abney gives two to ascertain the presence of hyposulphite of soda in the water used for washing, and one for the same salt in the paper print. They are: 1, Potassium permanganate 2 grains, potassium carbonate 20 grains, water 1 quart; a few drops of this rose-coloured solution gives to a pint of pure water a pink tinge, to water with a trace of the hyposulphite a green one. 2, A piece of starch the size of a pea is powdered and boiled in two drachms of water till clear, to this one drop of a solution of iodine in alcohol is added, which produces a dark blue solution; two drops of this solution added to a small quantity of the wash water in a test tube will give, if free from the hyposulphite, a pale blue tinge; if the salt be present, the blue disappears and the solution becomes colourless. 3. A very weak solution of potassium iodide is brushed across the back of a print: a blue mark indicates the absence of the hyposulphite.—EYE-WITNESS.

[60531.]—**Lamp for Boiler.**—One of the many oil stoves in the market will not smoke if kept from a draught and the wick is properly trimmed. —T. C., Bristol.

[60531.]—**Lamp for Boiler.**—Get a Bunsen burner from any ironmonger's. With a single burner, I do not know that you could do much better than have a plain, flat-bottomed boiler, like a saucepan, only covered in closely.—E. CONRY.

[60535.]—**Coil to Give Half-inch Spark.**—TO MR. BOTTONE.—Should have a condenser consisting of about 50 sheets of tinfoil alternately with paraffined paper, 7in. by 5in.—S. BOTTONE.

[60536.]—**Wimshurst Influence Machine.**—TO "CARNFORTH."—The number of sectors to be used on a 16in. plate depends upon the results desired. If length of spark is wanted, then use 12 sectors, and let the length of sector be not more than 2½in.; the outer ends should not be more than a ½in. from the edge of plate. If freedom of excitement is desired, then use 16 or 18 sectors, and let the sectors be nearly 4in. long; this also gives greater quantity of electricity, as a greater breadth of the plate is brought under electrical excitement. He should look up your earlier numbers for the details of construction. The issue of 14th November, 1884, contains every detail he can wish of a very good form of machine. The pamphlet by Mr. Gray, which contains a reprint from your pages, may be obtained from the publishers, Messrs. Pewtress and Co., Little Queen-street, Holborn.—J. W.

[60539.]—**Valve Gear of Marine Engines.**—Yes, cams are by no means new or unknown for working the cut-off in these engines, although they are not general. Usually the cam is a casting, having several steps or cams side by side, so that a roller, which works in the end of a lever, may, by means of a screw, be shifted sideways on to any one of the cams required to be used. I think some of these are figured in "Browne on the Screw Engine."—T. C., Bristol.

[60544.] — **Microscopical.** — (1) In working with a camera lucida, one of the best plans is to use two lights, one to illuminate the object, and the other the paper. A candle does perfectly as the second source of light. In your case the paper is probably too strongly illuminated.—PLAYFAIR.

[60545.]—**Photo-Micrography.**—If you know anything of photography, nothing can be easier. Shall be happy to give you working details if you intend trying.—S. BOTTONE.

[60545.]—**Photo-Micrography.**—All you require besides the camera and the compound microscope are a good paraffin lamp and reflector and a condenser. If your microscope stand is so constructed that you can turn the tube down to a horizontal position, put the eyepiece end into the hole of the camera (it must be a long-bodied one) intended for the lens, and make the junction light tight with a black cloth. Arrange all the apparatus on a kitchen table in the following order:—Camera, microscope tube, object-glass, slide, condenser, lamp, reflector.—B.SC., Plymouth.

[60548.]—**Copper Boiler.**—You do not say what form the boiler is. If cylindrical, you do not require cross stays; and if square the boiler is not sufficiently stayed, and consequently is very weak. Send full particulars, especially as to form of joints and workmanship. Anything above 5lb. would drive the engine—that is, it would go round; but 30 to 40lb. is usual for driving if used for anything.—T. C., Bristol.

[60549.]—**Telegraph Connections.**—TO E. CONRY.—I have sent in diagram and description of what you ask; but am rather afraid it is too late for the issue; if so, it will be in next week's number.—E. CONRY.

[60550.] — **Chemical.** — If Mr. T. Morris evaporates his mixture of cuprous cyanide and caustic potash to dryness, and fuses the residue at a low red heat, he will obtain a mixture of metallic copper, cyanide of potash, and cyanate of potash. To reduce the last-named compound, and so increase the yield of cyanide of potash, an addition of charcoal dust previous to the process of evaporation and fusion will be required. The above procedure is, in my opinion, the most practical solution of Mr. Morris's query; but he may expect a yield of cyanide considerably under theory, the moisture unavoidably present in this particular case tending at a red heat to its ultimate decomposition to carbonate of potash.—NORMAN MCCULLOCH.

[60551.]—**Reed Organ.**—If "G. D. G." intends to build a reed organ on the suction principle, I should advise him to get the American organ cavity boards and reeds, as they are made expressly for the suction principle. One of C scale is most suitable for pedals; but the majority of the cavity boards are of F scale. There is sometimes a difficulty in procuring those of C scale. I don't exactly know the reason; but probably there are more made to F scale. For the pedal bass you can purchase a set of large pedal bass reeds in the tubes. Fix this on the back of the soundboard, and have a set of suitable pallets actuated by the pedal levers; but I know of a far better plan than this if he likes to go to the expense of it. There is no necessity of having steel vibrators for the 4ft. set, as brass is quite good and durable enough for all practical purposes. The specification you name is a very good one; but the addition of an 8ft. solo set in the treble would somewhat improve the arrangement. The 8ft. solo set should be of three octaves; the vox humana is a mechanical arrangement, superior, in my opinion, to the ordinary tremolo. What "G. D. G." refers to is evidently the voix celeste. The celeste, or wavy effect, can be produced without having one of the sets out of tune. It is obtained by a different mode of conducting the air to one of the sets, which causes the reeds to sound a trifle flatter than the other. Another stop of a different name is used to conduct the air to the reeds in the usual way, by which means the reeds are brought again in tune with the other sets when the full power of the instrument is required. This is the best form of the celeste; the other method (which, unfortunately, is much too common) is greatly objected to by the best musicians. To get the reeds to sound the nearest approach to the pipe organ is no easy matter. To accomplish this desideratum, the reeds require to be voiced by an artist; to voice a set of reeds properly requires a certain degree of artistic skill, which can only be acquired by constant practical experience in the art. In a general way, the quality of tone from any reed organ, whether constructed on pressure or exhaust principle, depends almost entirely on the voicing of the reeds. Unless "G. D. G." can get an artist to voice his reeds, I am afraid he will be obliged to remain satisfied with the ordinary quality of tone which is found in the generality of reed organs constructed on the suction principle. Further information, if requested.—G. FRYER.

[60553.]—**Wimshurst Influence Machine.**—I shall be glad in the course of a week or so to give you, and other readers who may be interested, the chief working particulars for an eight-plate machine to be built within a glass case. It is, of course, a matter of choice only as to how many of the plates shall be used; two plates answer, while from eight plates the quantity is four times greater. The increased number of plates simply means a proportional increase in the number of parts and in the results. Some of the straight jars used by confectioners answer very well for Leyden jars, but others will not answer. It depends entirely upon the quality of the glass. I have seen large numbers of Leyden jars from Germany, made of beautifully clear and white glass, yet they were absolutely useless, for electricity passed through the glass as freely as through metal. For electrical work, always test the quality of glass before adopting it for use.—J. W.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

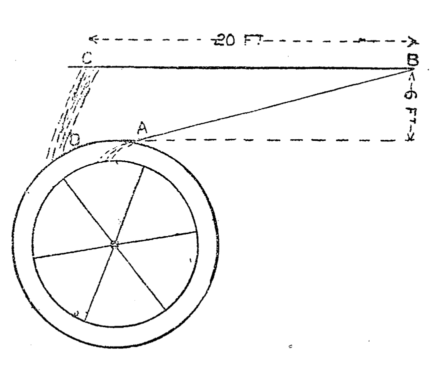
QUERIES.

[60560.]—**Water Wheel.**—Water is run on to a water wheel by a trough, A B, with an inclination of 6ft. in 20ft. Would it be more effective if the trough were level, as C B,



and the water allowed to drop as at C D? If so, why? A full explanation, with difference shown, if any, will greatly oblige—JAS. JONES.

[60561.]—**Polish.**—I have stained some ordinary deal with ebony stain. Can anyone give me a good recipe for a good and cheap polish, as I do not wish to varnish? One that will do for any stain will be very useful to me.—COLOMBO.

[60562.]—**Current Quantity.**—Will some one of our electrical experts kindly say what surface of zinc in an exciting liquid will give me one, two, three, or more ampères? I wish to calibrate an ammeter by increasing the active surface of zinc in any form of cell, having no other means of doing so.—C. R. N.

[60563.]—**Lathe Speed Pulleys.**—I am making alterations to my 4½in. lathe that will necessitate new pulleys on the crank shaft. Will some kind fellow reader advise me as to the most useful ratio between mandrel and crank? Would 7 to 1, 3½ to 1, and 2 to 1 be advisable, or what are better? At present my mandrel pulleys are 5in., 3½in., and 2in. respectively in diam. I should like one length of gut to suffice for the three speeds. I have no back-gear. Is there any royal road to changing the gut from one speed to another? I find a difficulty with the grooved pulleys, as the band has to be so tight on the small diameters.—T. G., Birmingham.

[60564.]—**Timber Truss.**—Will any reader kindly inform me of any method of calculating the strength of a timber truss, such as used at Marac by Col. Emy, for the roof of a shed, or the title of any book with such information in it?—CREOLE.

[60565.]—**Mastic Varnish for Oil Painting.**—Will some correspondent kindly inform me how to prepare mastic varnish for oil paintings, which will not "bloom."—J. K.

[60566.]—**Relief in Photo. Negatives.**—When a dry plate is developed, the gelatine often stands up in relief, but dries down quite flat. Is there any method of drying the plate and preserving the relief?—SEPIA.

[60567.]—**Broken Backbone of Bicycle.**—Having a second-hand bicycle to repair which had been patched at the top of the backbone by an unskilled blacksmith, I would feel much obliged if some brother artisan would give me a few hints how to fix it firmer, as there is a disagreeable jerk when ridden. Would brazing do? It is hollow iron.—J. THOMSON.

[60568.]—**Bleaching Greasy Silk.**—Could some of the readers of the "E. M." kindly inform me how spirits of salts is applied in the bleaching of greasy silk after it has been scoured with soda or alkali? Also if there is a better and cheaper bleacher for the purpose, and, if so, how is it used?—AMATEUR.

[60569.]—**G.E. Locos.**—Can anyone tell me what class of engine No. 538 is, dimensions of cylinders and wheels, weight and tractive power?—F. THOMAS.

[60570.]—**Burning Oil.**—Now that such strides have been made in the burning of mineral oils in the production of such burners as the Kosmos, Mitrailleuse, &c., I propose altering my gas pipes to burn oil as above. Now I wish

to ask some of "ours" to help me to convert my existing gas pipes, $\frac{1}{2}$in. iron, into reservoirs for oil, my object being the great saving I shall effect, as I find oil is so much cheaper than gas, even in London, where gas is so much cheaper than in the country. I do hope some help will be extended to me, as I know a great many are interested in light just now.—OIL v. GAS.

[60571.]—**L. and N.W. Locos.**—What class does No. 2082 belong to? Is she one of the Compounds? How many "Dreadnoughts" do the L. and N.W. now possess?—REINDEER.

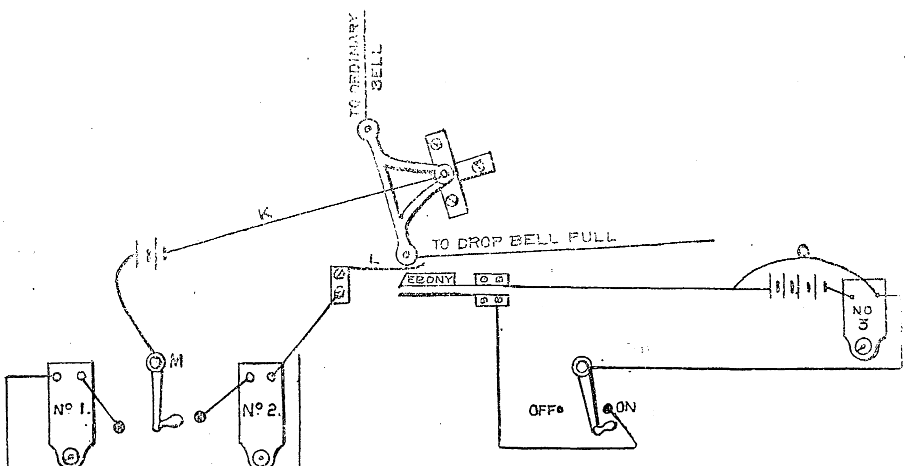
[60572.]—**L. and S.W. Locos.**—(1) What are the dates of Gaul, Dane, Prince, Princess, Undine, Stentor, and Castleman, and what is the diam. of their driving wheels and their weight when empty? (2) Can anyone give me particulars of No. 521 class, built by Dübbs and Co.?—REINDEER.

[60573.]—**Lighting School Room.** — Will some kind friend inform me of the best way of lighting a schoolroom and removing the products of combustion by means of pipes leading into the open air? The Wenham burner is good, but too expensive. The albo-carbon light is very bright, and I should like to know whether a pipe running horizontally just above the ceiling with a funnel-shaped opening fixed about 18in. above the gas flame would carry off the vitiated air?—LUX.

[60574.]—**Astronomical Photographs.**—I would feel much obliged if Mr. Franks, Mr. Clapham, or other corresponding friends of the "E. M.," would kindly say where photos. of the "Orion Nebula" by Mr. Common, of the "Pleiades" by the Brothers Henry, also of the moon, or any other astro. photos. can be obtained, with the cost, if not trespassing on your advertisement privileges? I am sure there are many others besides myself who will like to have a copy of these latest triumphs of photography, if moderate in cost.—S. R. C.

[60575.]—**Bichromate Battery.**—Will Mr. Bottone, or some other worthy friend kindly give instructions for making a cheap bichromate battery, such as would work medical coil, described on page 52, No. 1121? Would retort carbon do, and how can I fix binding screws to same, as I find it very hard to cut?—AMATEUR.

[60576.]—**Faulty Bell.**—I have fixed some electric bells, and one that is shown at No. 3 in sketch is always uncertain in action. It is fixed in a yard, but under cover.



Sometimes it rings well, and at others, without any apparent cause, jibs. It will be seen in sketch to make contact through spring L pressing on a piece of ebony that is attached to the upper of a pair of brass springs that have pieces of platinum soldered to them to insure perfect contact. N is a switch to throw bell in or out; O third wire for continuing ringing. This has a battery of four cells; sometimes it stops for a day or two, and then rings allright the next. The battery seems allright. Have coupled direct to bell, and it rings sometimes and sometimes moves armature a little, and another time draws it to magnet and remains there. Connections seem allright. The other bells, No. 1 and No. 2, ring allright; but No. 2 is fixed in surgery, and gets badly corroded. These make contact through bell crank, which works as a copper pin, and presses on L when ordinary bell is rung. M, switch to either 1 or 2 bell. These are rung by a 2-cell battery; both are Leclanché with porous pots. What is the cause of bell not ringing, and No. 2 corroding?—BILLY.

[60577.]—**Apples.**—Can any of our readers tell me what is the best method of preserving apples, as I have a considerable quantity which I wish to preserve during winter?—DESIDERATUM.

[60578.]—**Lathe.**—Will some reader please tell me the use of a broad one-grooved pulley, about 8in. diam., which runs loose on crankshaft of my lathe close to flywheel? Also, can I make the thread in wooden chucks with an ordinary tap, as I do not understand the chaser, being a beginner? If not, how can I make or procure one to suit mandrel nose?—BEGINNER.

[60579.]—**Lathe.**—My lathe bed, 2ft. iron, is untrue towards poppet end of bed. It runs up hill suddenly within 3in. of end; remainder of bed fairly true. Would it be safe for me to attempt to true it up a bit?—BEGINNER.

[60580.] — **Paquelin's Thermo-Cautere.** — Will any reader kindly give a description, with drawings, of the internal or heating arrangements of Dr. Paquelin's thermo-cautère? I wish to know particularly how the platinum parts are arranged and heated. Would it be difficult to make, as the price charged seems out of all bounds?—A VET. SURGEON.

[60581.]—**French Button Lens.**—(Page 88, letter 26300). What is it—its advantages, form, and disadvantages? If achromatic, its anatomy—i.e., how built up?—A COUNTRYMAN.

[60582.]—**Wood Bits.**—Will someone kindly say if the Morse drill with lip and spur is any use for boring $\frac{1}{2}$in. holes through $1\frac{1}{2}$in. ash? Have tried Jenney's twisted auger with screw joint; but they spring and do not clear very well when the lathe is running to draw the wood back. I have a lot to bore in lathe, and want to hold work in hands and feed up and withdraw.—C. B.

[60583.]—**Bicycle Making.**—I have searched for a long while, hoping to find something on the above, similar to "J. H.'s" excellent articles on machine tools. Should feel grateful (like many more of our readers) if some of our Coventry subscribers would give us a few hints, or failing that, makers of rough materials would find it to their advantage to do so during winter months, when amateurs are busy.—C. B.

[60584.]—**Blueing Steel without Heat.**—Will some reader be good enough to give me a recipe for blueing steel without heat?—SNIPE.

[60585.]—**Laying in Cold-Water Pipes.**—Would some reader say what kind of clay or loam it is that is used for putting round the flange of pipes for running in lead in joints, and if it is used in oil to prevent the blowing of the metal when poured in? I have seen the clay used, which appears to be very much tougher than any ordinary clay.—FORCE PUMP.

[60586.]—**The Wimshurst Influence Machine.**—TO MR. WIMSHURST.—I have just finished a 17in. influence machine, and I cannot get it to work at all; all the sparks I get are a few on the brushes. Should the brushes be connected with each other by the steel spindle? I have made the plates of ebonite instead of glass. Would that have anything to do with its not working, and could you suggest any place where I have made a mistake.—INDUCTION.

[60587.]—**Poise.**—I have bought a pair of calipers with wheel tester, and find they are not drilled. Would "A. F. W.," or "Alfojoe," kindly recommend a way to do them so as to have holes in line? Also say if it is necessary to jewel them. If so, should prefer to buy them finished.—A GOOD TOOL.

[60588.]—**Verge Watch.**—Would "A. F. W.," or any other of "ours," kindly help me with the above? I have had it to pieces and cleaned it, and now it gains very much. The balance only turns about $\frac{1}{2}$in. The full length of hair spring is in use. The banking is on the edge of the cock, and when the balance is turned as far as it will go for the pin on one side, the train runs, but not on the other. Will shifting the potence slip correct this? If 'scapement wants closing, would turning a little off shoulder of pivot at wheel end and bringing follower up do it?—A. B. C.

[60589.]—**Laminated Armature.**—TO MR. BOTTONE.—I am building a dynamo same as described in your book, but should like to fit it with armature that will run continuously without heating injuriously. Will you please inform me what kind I can make without infringing patent rights? Can I get the punchings, to buy, anywhere, or can they be easily cut out? Should they be kept together by an iron rod, or is brass better, and should they extend the whole breadth of the field magnets, and the wire on the ends be outside same? Can the armature be bought to fit dynamo mentioned above without the other parts? In reply to a recent query, you said the field magnets could be excited by a magneto machine, but I suppose you meant one fitted with a commutator. Would such a machine (with magnet about 6in. long) light a 2c.p. lamp? Can an incandescent lamp not be lighted unless a commutator is used?—D. R. W.

[60590.]—**Microscopical.**—Would any of our micro. readers kindly state if they think it possible to resolve Surirella gemma with a $\frac{1}{8}$ objective (130° aperture) and a Kelner (C) orthoscopic eyepiece used as a condenser? I have tried this with six different stops, but failed to bring out the dotting. Having succeeded in resolving the diatom by using the same objective with direct light from a bull's-eye condenser upon the microscope slightly tilted, I am surprised that the Kelner arrangement, so highly spoken of by Beale, should fall short in this case. Any suggestions from others who may have tried this diatom with an objective of same power and aperture will be acceptable.—A.M.I.C.E.

[60591.]—**Hardening Spring Steel.**—Would any reader tell me if there is any other way of hardening spring steel besides rubbing it with a stick?—E. HOARE.

[60592.]—**Setting Axle.**—Would anyone inform me the way to set an axle? I have seen them set on a board, but I believe there is another way of setting them.—E. HOARE.

[60593.]—**Share Certificates.** — Can any correspondent kindly inform me whether in insuring certificates of shares in a limited company (A) certificates should be issued to parties who have signed articles of association, but have never taken up their shares, (B) to parties who have paid deposit upon application, but have not paid the sums demanded upon allotment.—SECRETARY.

[60594.]—**Model Yacht.**—I have worked out a drawing of a fast 10-ton model yacht. Will some brother yachtsman kindly give me directions how to build it? Its measurements are 41in. by $7\frac{1}{2}$in.—AMATEUR YACHTSMAN.

[60595.]—**Geometrical.** — Would any kind reader state, giving a diagram in illustration, how the latter part of the following deduction may be solved? Find a point such that the perpendiculars let fall from it on two given straight lines shall be respectively equal to two given straight lines. How many such points are there?—NOVICE.

[60596.]—**Pump.**—Could any of our readers please tell me what is the best material to use in making a pump for pumping vitriol? I have tried one made of lead, but in packing the bucket it does not stand. It must be strong; it is wanted to lift or force the acid about 25ft. high.—T. E. F.

[60597.]—**One Side of Room Dark.**—Owing to the position of adjoining property, one side of the living place of my house is thrown rather dark. The only window we have is in the left-hand corner of the room (standing with your face to the fireplace), and from this window an abundance of light strikes in straight across the hearth and on to the wall opposite. From the cause first mentioned the other part of the room is somewhat darkened, and it is impossible in the present structural condition of the house to put in another window. Could not the light referred to be utilised, by deflection or otherwise, in making the other part of the room light? If any student of light, or any of your practical readers, could inform me of, or suggest, some simple plan that would remove the darkness in question, I should be grateful.—DARK ROOM.

[60598.]—**Etching applied to Die-sinking.** —Is this practicable so as to get raised lines on a steel die? If so, a few hints as to procedure might be useful to many besides—BOSWORTH FIELD.

[60599.]—**Pinion Wire.**—How is the pinion wire made, and is it likely to be as accurate as hand-made pinions with regard to dimensions, pitch, depthing, form of teeth, &c.?—BOSWORTH FIELD.

[60600.] — **Musical Intervals — Deschanel's "Light and Sound."**—In the book above mentioned, on page 899, I find the following words, which are mysterious to me, and should be glad if any of your correspondents would fully and clearly explain: "The interval from Re to Mi, or from Sol to La, is represented by the ratio 10-9, and is called a minor tone. The interval from Mi to Fa, or from Si to Do_2, is represented by the ratio 16-15, and is called a limma. As the square of 16-15 is a little greater than 9-8, a limma is a little more than half a major tone."—R. R. R.

[60601.]—**Battery.**—I want to deposit copper, 5-16in. in thickness on a surface measuring 11in. by $10\frac{1}{2}$in. What size battery, and which would be economical to use, and how long would it take to get that thickness?—F. BROWN.

[60602.]—**Aquarium.**—Is there any way to preserve animalcula, &c., alive in a small aquarium for microscopical purposes? I have made several attempts with and without water plants; but after a few weeks everything has died, both plants and animals, and it seems so cruel to waste life in such a reckless way that I shall not attempt it again, unless there is some way of enabling the beautiful and innocent little creatures to enjoy life. If they can be supplied with food and oxygen, they ought to be as happy in a small quantity of water as in a large pond where they must be surrounded by innumerable enemies.—G. H. S.

[60603.]—**To Mr. Bottone.**—Many thanks for your answer. Kindly give me the full details of a magneto machine—after your own smallest size. I am making small dynamo armature of the cog pattern, but a mistake has been made in the number of teeth or sections. It has thirteen instead of twelve. Will this matter, as I have fitted the ring?—A. S. J.

[60604.] — **Resistance Coils, or Wheatstone Bridge.**—Will Mr. Bottone, or some kind reader, instruct me how to use the resistance coils or Wheatstone bridge, giving an example?—GRATEFUL.

[60605.] — **Domestic Electricity.** — The apples, plums, pears, and other fruits in my garden have tempted thieves to rob me much of late. I want to protect my garden by having connections from the different parts to an electric bell and battery in the house. Also to have a guncotton cartridge or a detonating rocket so arranged as to go off if a certain inner line of wires was invaded, and thus alarm the neighbourhood and make it warm for thieves. Can any of our ingenious electricians tell me how to do this? How to insulate and secrete the wires and contacts, and how to get or make the detonator? I have bells and battery.—ELECTRO-DETECTOR.

[60606.]—**Screw Thread on Thin Brass Goods.**—Will any of your correspondents kindly inform me how I can compress a screw thread on articles made of thin sheet brass? The method is used by makers of common paraffin lamps and cheap brass work. The thread is not cut as with a chaser, but forced on in some way.—M. J. S.

[60607.]—**Polishing Photo. Frame.**—I have made a fretwork photo. frame of (No. 20 gauge, 7in. wide) brass, and should be glad if anyone would kindly give me any information as to the best way to polish same, and, when polished, how I can preserve it from getting tarnished?—PRACTICAL.

[60608.]—**Torpedo Defence.**—Will any of "ours" kindly send me particulars of how nets are hung round men-of-war, &c., for protection against torpedoes? Also say how the nets are made, and what sized meshes, &c.; also what distance the nets are from the ship.—COMMUTATOR.

[60609.]—**To "R. N.," "Ingeniero," &c.**—Would any of these be good enough to say whether a condenser

outside of boat is capable of supplying boiler of high-pressure engines successfully as in C.S.C. engines, and if boiler will supply a good head of steam running at full speed continuously with natural draught? I understand the Admiralty adopt this method of condensation for their steam pinnaces, but that it has not come up to their anticipations, and as I require to run a boat in salt water, the purport of my original query with respect to small launch engines is embodied in the above questions.—C. S. C.

[60610.]—**Fluorine.**—I lately saw it stated that this element has been isolated. It would be interesting if some chemical reader would be good enough to supply information of the process by which this has been done, and to describe the element.—L.

[60611.]—**4in. Achro. Objective.**—Will someone give me some advice? I am trying to make a 4in. achro. objective for telescope; but with all the care I can use the glass (the convex) will get slightly more curved at the peripheral portions than at the central, and with the flint the middle seems to get slightly shorter, or, in other words, paraboloid. My discs are 43in. in diam., and my polishers are 7in. in diam. I have not used any mechanical appliance; but would like to have some advice as to making and using one; also in making polishers. A few hints on the manipulation of the polishers will be greatly appreciated. I understand the principles of refraction, correction of the chromatic aberration, and have my glass well enough figured to show some close doubles quite distinctly; yet they are surrounded by a mist. — R. GABRIEL.

[60612.]—**Camera Obscura.**—I am about to make a camera obscura (not a photographic one); the size internally 24in. by 30in., and the height 30in. I understand how to get about it so far, but am not sure about the lens and the length of the focus. Will Mr. Lancaster, or any other reader, kindly say what diam. of lens and length of focus is required to cover the object on paper the above size, 24in. by 30in.? Also the price I ought to give for the lens? Full particulars will oblige. I am only in doubt as to this, because I do not want to complete the outer case and find myself perplexed by the use of improper lens.—G. H. L.

[60613.]—**Sanitary.**—Will some correspondent kindly inform me the mode of working of Doulton's automatic flushing siphon, as I have lately fixed one, but cannot understand how it works?—COUNTRY BRICKLAYER.

[60614.]—**Electro-Motor.**—I am much obliged to Mr. Bottone for his reply to my query No. 60483. I have a small shunt-wound dynamo, laminated armature, 4in. by 1¾in., wound with ½lb. No. 20, and about 5lb. No. 20 on the fields. Could I make use of this as it is, and what number of cells would it require? or if I rewind it, what amount and size of wire should I put on? I may say the dynamo will run two 22-volt 10c.p. lamps in parallel arc.—H. T. BURBURY.

[60615.]—**Paring Machine.**—Should be glad if any reader would give me some information as to how the knives of a paring machine used in the shoe trade to pare the edges of boots and shoes are tempered. Also if potass is used in the process, and how to tell when the knives are tempered enough, for if they are too hard they break in all directions, as they are worked by steam going about 2,000 revs. a min.—SHOE PARER.

[60616.]—**Legal—Marriage.**—An Englishman marries; his wife leaves him and goes to America, and there obtains a divorce. Does that act on her part legalise a marriage which the Englishman may afterwards contract with a third party?—SUBSCRIBER.

[60617.]—**Electric Light.**—To "EVELINE."—In an answered query on page 18, No. 1, Vol. XLIII., you described a battery that would give a constant current for ten hours, and one charge would last four months. Would you kindly tell me the size of the batteries that will do that? I want to light a 10c.p. lamp six hours at a time every night.—SCOTIE.

[60618.]—**Tainted Lard.**—I have some American lard in buckets, which is turning yellow, and is not sweet. Will someone give me a simple method for restoring its sweetness and colour?—COUNTRY GROCER.

[60619.]—**Cornwall.**—Is there a work published giving history of old Cornish families? I am acquainted with Gilbert's, which is a history of places.—T.

[60620.]—**Electric Bells.**—What is the best gauge of silk-covered wire to use for coils to ring a heavy 6in. bell, and how can I fix same to doors and windows that when opened bell rings, and does not cease on closing door or window. A sketch would greatly oblige.—T.

[60621.]—**Leclanche Batteries.**—Will some of "ours" kindly give details of a good method of making the agglomerate blocks for the Leclanché batteries? Can the terminal not be put on the top of the blocks instead of putting a plate between them?—GREEN.

[60622.]—**Astronomical.**—Will someone kindly inform me why the aperture in the revolving upper disc of a planisphere is oval instead of circular? I bought one the other day, and the stars shown in the oval space correspond exactly with those on the semi-sphere of the globe as elevated above the horizon for the corresponding place, day, and hour; but if the one be spherical, why is the other not circular? Also possibly the same correspondent can give particulars of the companion to Alpha Arietis mentioned in Proctor's "Half-hours with the Telescope," as I cannot find distance from primary or position angle either in the said work, in "Webb," in "Chambers," or in Sadler and Clarke's "Star Guide." Am I correct in thinking I see it at about an angle of 80°, and rather distant?—AL FARAD.

[60623.]—**Dynamo.**—To I. LOW.—Many thanks for your reply *re* Potential, which is just what I wanted. May I trespass on your kindness still further by another question or two about dynamo machines? This time (1) what do the makers mean when they say of a shunt-wound dynamo that it will give, say, 100 volts and 200 ampères? According to my limited experience of shunt-wound machines, although the capacity in watts remains constant so long as they are maintained at a given speed, but those watts may be made up in many different ways, according to the resistance placed in the external circuit and the consequent amount of current diverted round the shunt—*e.g.*, that the same machine giving, say, 1,600 watts can be made to make it up by 40 volts and 40 ampères or 80 volts and 20 ampères, or 20 volts and 80 ampères (if the capacity of the armature will give 80 amps. without burning). I have taken the figures at random, merely as illustrations. What resistance of external circuit do the makers reckon for, then, when they give a certain fixed capacity as 100 volts and 200 ampères in describing a machine? Again (2), given a shunt-wound dynamo of absolutely unknown capacity, which it is desired to test. If I understand rightly, many of these machines, especially of the better class, will produce more current than the insulation of the armature coils will bear without burning, if the external resistance be reduced sufficiently low. How can one ascertain them by calculation the lowest point to which it is safe to reduce the resistance of the external circuit (as by switching in more lamps in parallel) without burning the armature? I have seen a shunt-wound dynamo pull up the engine and throw its strap when suddenly short-circuited. I suppose, in this case, it had not time to burn before the strap went off and the speed slackened, but that it would have burned if the engine could have kept it going. (3) I have seen some formulas for the proportion which the resistance of the external circuit ought to bear to the joint resistance of shunt and armature in order to get the highest percentage of efficiency out of any machine. I suppose this is reckoning the resistance of the incandescent lamps when hot; and how is this measured? Is it by deducting some general percentage from the cold resistance, as, say, one-third, or something like that? (4) Is there any general average of resistance for arc lamps when alight, or must the resistance of each particular sort be measured or got from the makers? If you, or any other gentlemen who contribute to the ENGLISH MECHANIC, could enlighten me on these heads I should be much obliged.—TORBAY.

[60624.]—**Cement or Varnish.**—Can any friend say if there is a cement or varnish that would cement small pieces of metal, and that would stand a heat of 80° C.? If so, particulars will oblige.—METAL.

[60625.]—**Astronomical.**—To "F.R.A.S." OR OTHERS.—What is the explanation of the fact that sometimes when there is only a part of moon distinctly visible there is to be seen the remaining portion, thus making up the complete disc faintly visible, this fainter portion appearing smaller in diameter than the crescent? I have been told that it is due to "earth shine;" but if so, why is it that we are not always able to see the whole disc more or less brightly illuminated?—VORTEX ATOM.

[60626.]—**Forming Accumulators.**—To "SIGMA."—In writing upon this subject in your very valuable book, I see you mention certain periodical intervals of rest which it is necessary to give accumulators when forming them, such intervals increasing in duration as the formation proceeds. Would you kindly tell me how I can judge when these intervals become necessary, and the period requisite to allow for each, so that I may know when to leave off reversing, and when to again commence in each case?—TORBAY.

[60627.]—**Turning Cotton and Paper.**—What is the best tool for turning cotton and paper, and what is the best speed?—G. H. B.

[60628.]—**Battery Resistance.**—To S. BOTTONE.—In answer to query 60190, you say: "It is by increasing the size of the negative element that decreased battery resistance is obtained." Why so?—LONDINIENSIS.

[60629.]—**Tortoises.**—What is the proper food for water tortoises? Do they hibernate?—THE BARD FOR EVER.

[60630.]—**Portable Engine.**—What will be a suitable size of cylinder for a portable boiler, barrel 36in. by 19in. with 23 1¾in. tubes and a firebox shell of 28in. by 14in. by 21½in. breadth?—W. J. J.

[60631.]—**Hydrostatics.**—To "M.I.C.E., BRISTOL," OR OTHERS.—A friend has asked me if I can tell him what shape to make a floating body so that "the areas of the submerged part shall vary as the squares of the distance submerged—that is to say, if I have a body submerged to a depth of 1in., and the part under water has an area of 4 sq. in., if I push it down another inch I want the area submerged to be 16 sq. in." Can you kindly assist me?—TORBAY.

[60632.]—**Spiral Steel Springs for Electric Lighting.**—Will some one kindly oblige through the "E.M." how the small spiral steel springs are made, similar to those used in the frictional electric gas-lighting machines? I cannot manage to harden them enough. I make them red-hot and throw them in water; and have also tried oil, but they do not seem to cool quickly enough towards the centre.—P., London.

[60633.]—**Magic Lantern.**—I have a lantern with 3½in. conden., with Argand fountain lamp (burning camp. sperm oil). I find the light inferior for some subjects, especially plain photos, if subject be dark; also corners are dim if mask be square. Would a more powerful lamp remedy both defects, or would I require a larger conden. for latter? My screen is 7ft. square. About what candle-power does the above lamp possess? What would be needed to exhibit with above lantern on 7ft. screen successfully? What kind of lamp would any reader recommend?—B.

[60634.]—**Safety Lamps in Mines.**—I, in common no doubt with all colliery viewers, have taken considerable interest in the recent experiments with safety lamps at Leigh, in Lancashire, conducted by Mr. Morgan before an audience of pitmen; but I cannot help thinking it is a pity that fuller details were not given of the apparatus and methods used in the testing. It certainly is a somewhat rude awakening, following so close upon the recently-issued suggestions of the Royal Commissioners, and to be calmly told in a newspaper report that the whole of the lamps recommended by them were easily exploded in a few seconds by Mr. Morgan seems a pretty rough comment upon their labours which have extended over so many years. In conclusion, I would ask for particulars of the testing, velocity of current, gas used, &c. Also, is the "Morgan" a gauze lamp? If so, it seems a long way behind the McKinless lamp, which quite does away with that uncertain abomination.—HENRY PALMER.

[60635.]—**Legal.**—When money is lent on the security of a policy of life insurance, what is necessary, in point of law, to make good the claim of the lender on the policy? Is simple possession of the policy sufficient? Should the borrower's receipt or I.O.U. make particular mention of the policy as being the security on which the money is obtained? Can the lender claim the possession, or the production when desired, of the receipts of the periodical premium to be paid to the Insurance Company, so as to be satisfied that the policy has been duly renewed? In case the interest on the loan be unpaid for any term after becoming due, can compound interest be claimed, or only simple? It is not intended to advance more than 7-10 or ¾ of the amount of the policy.—SOUTH-WEST.

[60636.]—**Painting Magic-Lantern Slides.**—To "M.I.C.E., Bath."—In No. 1084, p. 369, in answer to query on above, you recommend Judson's dyes. In making a selection of eight or ten colours, would you state what ones to take? Also, about how they would require to be diluted with water?—B.

[60637.]—**Flats for Reflectors.**—I have read the remarks of Mr. Holmes on the above subject, and would like to ask him if he has tried the following plan of arranging the mirrors:—Tube to be enlarged a little on the eyepiece side, so as to admit of the plane being so placed that it will not cut off any of the rays to the large mirror. Then, if adjusted to working order, the plane would receive the rays at an angle, but would be so arranged as to reflect them at the same angle through the eyetube and lenses. We should thus use the whole mirror, as we now use a side aperture, and have the advantage of all the surface of speculum, while the definition of star discs and rings, &c., would be exactly as in a refractor. The only question seems to be, Would the angular reception and reflection of the rays by the plane cause any distortion? It is evident that if this plan would work we could have, say, a 6ft. focus in a 3ft. tube by having the plane large enough, and this without stopping any light from the large mirror.—F. T.

[60638.]—**Photo. Lenses.**—To MR. S. BOTTONE AND MR. W. J. LANCASTER.—1. Acting upon instructions given in No. 1117, p. 561, I found that the distance between two points with string 10ft. long was 10ft. What "angle of view" has my lens (roughly)? How is it found out by this method? 2. In No. 1083, p. 342, "S. B" says: "I shall be happy to write a few letters on the gelatine process if the same would be acceptable to your readers." I think this would be acceptable to not a few, judging from the queries that appear from time to time in "E M." Will "S. B." make good his offer? 3. From Mr. Lancaster's reply to query on above in No. 1121 p. 69, I am led to understand that wide-angle lenses cannot be used successfully unless the camera has swing back, rising and falling front. Has Lancaster's "Instantograph" got all these? Can a wide-angle lens quarter plate (90°) be used with a half-plate instan.?—B.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Oct. 6, and unacknowledged elsewhere:—

J. RESIDE.—T. D. Cook.—A. J. Pool.—Rev. G. C. Bruton.—S. Williams.—J. Mallins.—W. A. McClintock.—One Anxious to Learn.—Sam Roe.—T. Wood.—C. W.—Kent.—Delta.—W. W.—Vulcan.—Spes.—X. Y. Z.—Spencer.—A. O. H.—A Four Years' Subscriber.—E. Conry.—A. Stanley Williams.

B HISCOCK. (The Superintendent, Steam Reserve Office, Chatham, will give all particulars about engine-room artificers. Candidates must have served a regular apprenticeship.)—ROBT. RUDGE. (How would you mix? Soak the glue in water, and when soft pour off the water and melt; then add the glycerine and whiting; stir well, and pour out into shallow trays, removing bubbles by drawing a piece of stiff paper over the surface.)—D. CAMPBELL. (We believe the composition is pressed into frames and retained in them until dry. See Hints Nos. 4 and 5 above.)—E. H. BARNSLEY. (See indices. Vol. XLI. pp. 527, 549, and even recent numbers; pp. 20, 43, 70, 72, 92, this volume.)—OLD FOSSIL. (For preparing skeletons see p. 419, No. 1059.)—R. G. LEWIS. (A "kilo" is a French weight (kilogramme), and is equal to 2·2lb. avoirdupois. A kilolitre is a dry or fluid measure equal to 220 gallons.)—C. N. (Perhaps you will understand it, if for "flask or retort" you read crucible. Glass is not mentioned. 2. Yes, "a part each." 3. The paper has not yet been published in full.)—EXAMINARI. (You should read "Darwin on Earthworms," but you will find mention of both in textbooks of zoology and in special articles in our back volumes, and in the *Transactions* of the Zoological Society and Royal Microscopical Society.)—N. Y., PLYMOUTH. (A "saturated" solution of anything is a solution in which no more of the salt or other substance can be dissolved. 2. It is simply too old. No use for toning;

but as the gold is still there, it can be recovered. 3. Take the pictures the size you require. See indices for many articles about lantern transparencies.)—J. J. W. (We do not know a book devoted to that branch of the subject; but it is mentioned in most textbooks, and there is something about it in back volumes.)—PATENT. (A string of questions without a signature, which have all, however, been answered many times. Revised rules with a pattern drawing have been issued by the Patent Office, and can be obtained at most of the large post-offices, where forms of application are sold, or from Mr. Reader Lack, Sale Office, 38, Cursitor-street, Chancery-lane, E.C.)—JACKAL. (Directions for cultivating mushrooms have been frequently given. See p. 31, No. 1016, for instance.) All that is wanted is a bed of horse-droppings which have been turned over two or three times to sweeten, and have been packed together tightly so as to retain a gentle heat of about 70° Fahr. for a long time. A bed of this, which need not be more than a foot deep, is "spawned" by inserting pieces of the "bricks" or cakes, and is covered with about 2in. of maiden loam. Those who wish to cultivate mushrooms had better procure Mr. Wright's book from the *Journal of Horticulture* office, 171, Fleet-street, E.C.)—TRIANGLE. (We have no knowledge of "examinations held on Patent Laws." To what do you refer?)—ANXIOUS BUT HOPEFUL. (The "proper course" to pursue would be to consult a medical man. The advice previously given seems to have been quite sound, but as she has not "grown out of it," it would be advisable to seek further advice.)—A SUFFERER. (Blood out of order: a little potash would probably help to eliminate them; but it would be advisable to consult a medical man, and give him an idea of your diet.)—DESIDERATUM. You should clean thoroughly, bring to a high polish, and then lacquer.)—TORNATOR. (It is some time this month, and the articles must be sent to the Mansion House. Write to the Secretary of the company there, and he will send you the rules.)—F. C. (Carbolic acid sprinkled about will, as a rule, drive them away.)—J. J. (Donaldson o/a the "Construction of Water Wheels," Spons, 125, Strand, W.C., will possibly suit.)—H. E. SMITH. (Macgregor's "Gas-Engines," published now by Whittaker and Co., White Hart-street, Paternoster-square, E.C., describes the modern engines. 2. Nicholson's "Manual of Bookbinding," Spons, and the back volumes for many useful hints.)—TEETOOTALLOR. (Friar's balsam is a compound tincture of gum benzoin, usually with liquid storax and balsam of tolu. If it has that effect on you, better consult a medical man, as it may be injurious.)—PRACTICAL JOINER. (Yes; a foot lever will give ample wind for a small organ if the bellows feeder is large enough.)—A. B. C. (There are several books in which the parts are described; but for practical information you should look through the back volumes, commencing with Vol. IX. A useful little work on Voicing can be had at Willis's, 29, Minories, E.)—SAPO. (Directions have been frequently given; but if the pictures are valuable, better intrust their cleaning to an expert. You may, however, safely use a sponge and soft water, or, if the picture is very dirty, take it out of its frame and lay a wet, clean towel over its face for two or three days, damping occasionally. That will soften the dirt, which can be removed with a sponge. Repeat if necessary. Unskilled hands should never use ammonia, spirits, &c., or anything that will dissolve the varnish.)—B. B. (It involves a rather elaborate calculation, and as put, it is necessary to know how much the pipe can stand. Eytelwein's formula raises the diameter of the pipe in inches to the fifth power, and multiplies that by the head of the water in feet. That is divided by the length of the pipe in feet, and the square root is found. That multiplied by 4·71 will give the cubic feet of water discharged per minute.)—ONE IN A FIX. (You will find an illustration of a loud-speaking telephone in No. 1,051, p. 229, and several others in back volumes.)—SCRIBE. (Maxton's "Manual of Engineering Drawing," Crosby Lockwood and Co., is a useful work. Messrs. Cassell publish a series of drawing text-books for various trades, which we should think you could find in some of the large booksellers in Glasgow. You would then be able to see yourself whether they suit your wants.)—W. VANSTONE. (Kindly look through the index published in No. 1,121, and the indices of the four or five previous volumes. Dimensions, &c., of many different sizes of dynamos have been given in nearly all recent volumes.)—W. J. JOHNSON. (See Hints No. 5 above. About 2in. diameter by 3in. stroke will do; but in order to calculate the best dimensions it is necessary to know the pressure of the steam and the number of revolutions desired. The question will be inserted.)—A LEARNER. (The velocity of sound in air may be taken in round numbers at 1,200ft. per second, and in water at 5,000ft.; but it varies with the temperature and the initial strength of the sound.)—EDWIN. (Mechanical devices of the kind are often used in America; but as a rule the action is transmitted only over a few yards. It may be done by electricity, by hydraulic, or by pneumatic means. In the first case the wheels of the vehicle would depress a lever and so make a contact, and the circuit being completed a magnet would release a catch and the door would swing open either by gravity or in consequence of the action of a spring.)—H. J. H (No one knows. Various theories have been propounded; but the following is, perhaps as feasible an explanation as any. The nerve filaments of the perceptive layer of the retina have their long axes directed to the centre of the eyeball, and naturally refer the impressions made upon them to the direction from which the light proceeds. The inversion of the retinal image is thus probably self-correcting, and is aided by experience, for some have asserted that the human eye, when first stimulated by light, sees objects in the inverted position.)—PIONEER. (Photo-lithography, or one of the zinc "process" blocks. The latter if you require explanatory text printed with them.)—W. J. C. (You will find a great deal of information about the electric light in the last six or seven volumes; but before any one can answer such a query, the size of the room at least must be stated.)—A. J. G. (Recipes for invisible inks and sympathetic inks have been given many times in back volumes, and are to be found in most of the cyclopædias, &c. We answered your query last week on p. 120, col. 1. Marks made with a solution of chloride of cobalt appear when the material is warmed and disappear as it cools.)—YNIS. (We have no space to give lists of books on this and that subject, however willing we might be. You should procure the booksellers' catalogues, or such a general catalogue as that issued by G. Philip and Son, 32, Fleet-street, E.C. The lectures referred to are not published except on special occasions.)—G. H. B. (We do not suppose there is such a work; but many books contain a chapter or two on the subject. 2. Presumably you mean in the compressed state. It is more of a matter for experiment than anything else, but the question will be inserted.)—STRIS. (You do not require both rum and eau de Cologne. Sir E. Wilson's recipe for preventing hair falling off was 8fl. oz. of eau de Cologne, 1fl. oz. of tincture of cantharides, and half a fluid drachm each of the oils of rosemary and lavender. A more simple wash is made by infusing 2oz. of rosemary tops in a pint of boiling water, and adding 2fl. oz. of rum.)—A DUTCH SUBSCRIBER. (There are several patterns in the market, but they all act either by worm and wheel, by ratchet and pawl, or by eccentric motion. Why not purchase one, and examine the parts?)—OLD SUBSCRIBER. (The question is so limited in interest—concerning only designers of screw-propellers—that we must refer you to Mr. Froude's papers published in the *Transactions* of the Institution of Naval Architects, especially for 1878.)—SEDGLEY. (You can see an illustration of the sun-and-planet motion in many of the books, or in Nos. 565, 566, if you have them, for they are out of print. It consists of a spur wheel keyed on the shaft in place of the crank; the piston-rod carries another spur wheel fixed to it, and connected by a link to the shaft. The wheel on end of piston-rod revolves round the shaft, and as it is in gear with the wheel keyed on the shaft, it compels the latter to rotate.)—F. WRAY. (Rather troublesome; but the only way is to heat to a red and let it cool slowly—leave in the fire, and allow the latter to die out.)—DE CAPO. (Rub the steel with the stone always in one direction.)—EXCELSIOR. (The papers can be obtained of the Secretary of the Association, 22, Albemarle-street, London, W. We have not space to publish half of them, nor are the majority worth the space.) 21. (The only thing to do is to repolish.)—WOOL. (The method of dressing skins for mats has been given several times. See No. 919, p. 203, for instance.)—BARIUM. (See indices. Miller's "Chemistry," in three vols., Longmans, covers the ground; but there are lower priced works. Carpenter's "Animal Physiology," Bohn, but procure the publishers' lists.)—BEGINNER. (Some are merely roller presses, others a bit of steel brazed on an iron base. Dissolve white Castile soap in methylated spirit (2 or 3gr. to the ounce), and brush that on before using the burnisher. Illustrations in the lists of the dealers.)—F. P. S. (All you want is the lamps, which you can buy, and a suitable battery. Perhaps that illustrated on p. 561, last volume, will answer your requirements; but at any rate, you will find all the information needed in any one of the last six volumes.)

USEFUL AND SCIENTIFIC NOTES.

SPEAKING of copper solder and colouring, an American paper says that "when copper is soldered and the solder to be coloured like the surrounding copper, this can be done by moistening the solder with a saturated solution of vitriol of copper and then touching the solder with an iron or steel wire. A thin skin of copper is precipitated, which can be thickened by repeating the process several times. If a brass colour is desired, a saturated solution of one part of vitriol of zinc and two parts of vitriol of copper is used on the previously coppered solder and the latter rubbed with a zinc wire. To gild the soldered spot, it is first coated with copper in the manner indicated above, and then with gum or isinglass and powdered with bronze powder. The surface is obtained, which, after drying, can be very brightly polished."

A NORWEGIAN engineer, Herr W. C. Möller, has made some important discoveries as to the buoyancy of reindeer hair and skin. He has found that a reindeer skin weighing $1\frac{7}{10}$kilogrm., rolled up and with the hair outwards, will support for ten days the same weight as an ordinary cork lifebelt. Moreover, the reindeer skin has the advantage of warming a person if formed in the shape of a lifebelt and worn round the waist. He has also constructed collapsing boats, sledges for rescuing people from drowning in the ice, &c., from reindeer skin, and lifebelts filled with reindeer hair equal to those of cork. Herr Möller further finds that a suit made from reindeer hair, weighing only $\frac{1}{2}$kilogrm., will save a man from drowning even if it has been in the water for some time. It can be made in any thickness, and is warmer than other materials. He is confident that suits made from reindeer hair will in time supersede those made from oilskin. The life-saving establishment of Gothenburg has already procured several of these articles.

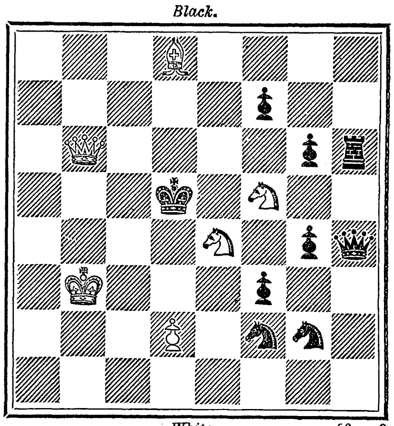
THE production of kainit and karnallit has begun at the Vienenburg potash mines. About 1,000 centners of karnallit are sent daily to Aschersleben by rail. The railroad junction to the mines is nearly completed.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MXII.—BY C. PLANCK.

Black.



White. [6 + 9

White to play and mate in three moves.

This problem is from the forthcoming joint collection, of which there was a notice in a recent number. It is the last three-mover in Solution Tourney.

SOLUTION TO 1010.

White.	*Black.*
1. P-Q 7.	1. Anything.
2. Kt or B mates.	

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,010, by G. T. Stringfellow (but variations not given), Isca, A. Dean, I. M. Brown, A Beginner, "——," J. Mackenzie, A. Bolus, Avon, J. A. M., and E. P.; to 1,009, by M. Blackmore (3). J. A. M. (second solution, but omitting defence, 1. B-R 4), T. W. Shawcross (ditto), G. T. Stringfellow (ditto), A. Bolus (ditto), A Beginner (2).

A. BEGINNER.—You appear to be right in thinking that 1,010 can also be done by 1. Kt-K 7. Another B P at K R 2 avoids this, we think.

AVON.—If in 1,009, 1. $\frac{\text{Q-Kt 6}}{\text{Kt-Kt 6}}$, 2. $\frac{\text{Kt-K 7}}{\text{B-R 4}}$, 3. $\frac{\text{Kt-B 6 (ch)}}{\text{K takes Kt}}$

J. W. SHAWCROSS AND A BEGINNER.—If in 1,009 1. Q-Kt 4, we see no mate after 1. $\frac{}{\text{Kt. K 5}}$. With regard to 1. Q-Kt 6 or R 7, see notice above to Avon.

J. MACKENZIE.—It is too late to join this Tourney, which is now all but concluded. We shall start another in two or three weeks, and due notice will be given of particulars.

LINK.—Both your attempts at 1,009 seem to be answered by 1. B-R 4.

WHITE PAWN.—If in 1,010, Kt-K B 7 (ch), Kt takes Kt, and there is no mate. You must give Black his best play always.

G. T. STRINGFELLOW.—If 1. B-Kt 6 how do you proceed if 1. $\frac{}{\text{Q Kt-K B 6}}$? You have in your third attempt 1. Q-R 5, which is impossible.

E. P.—If 1. $\frac{}{\text{Kt moves}}$, 2. Kt-K B 7 would not be mate without the R.

W. H. S. M., and Black Pawn are thanked for game and problem.

THE next problem (a two-mover) completes Tourney B.

SOLUTIONS to 1,011 will be acknowledged in our next.

The English Mechanic
AND WORLD OF SCIENCE AND ART.

FRIDAY, OCTOBER 15, 1886.

NOTES ON THE CHAMBER ORGAN.—VI.

By GEORGE ASHDOWN AUDSLEY, F.R.I.B.A.

IN the preceding article I said as much as space permitted on the subjects connected with the Great organ department, and my present duty is to treat of the remaining departments of the Chamber Organ under similar conditions.

Choir Organ—Expressive.

This department is, as before explained, of less size and importance than the Great organ. I have suggested that only about one-third of the manual speaking stops should be apportioned to it, and that its stops should be less powerful in tone, generally speaking, than corresponding ones in the Great. The chief office of the Choir organ is of an accompanimental character; but this consideration, though steadily held in view, must not interfere with the appointment of the department as a self-contained and perfectly balanced division. In an instrument of about fifteen or sixteen manual speaking-stops, the Choir should contain either five or six stops; namely, three or four unisons, one register of 4ft. pitch, and one of 2ft. Of the unisons, one should be an effective solo reed, preferably the Oboe; one a soft-toned stop, of the *Dulciana* species; and one a bright, string-toned register. If there be four unisons, the fourth should be a quiet, flute-toned stop of the *Lieblich-Gedact* species. When space is limited—and it almost invariably is so in ordinary apartments—it will be found impossible to carry all these unisons down to CC without a break of some sort. Both the Oboe and *Lieblich-Gedact* can be easily accommodated; but the other unisons, which, in their perfect form, must have pipes of 8ft. speaking-length at their CC notes, will, in all probability, require to be carried down from about Tenor C in stopped pipes. This, of course, is much to be regretted; but the conditions imposed on Chamber Organ building are frequently very exacting and inconvenient. Let the stops be carried down as far as possible in true form, and, unless they have both to be grooved into one bass, let them be broken on different notes, so as to cover as much as possible the transition when the full Choir is drawn. But even if they have a bass in common, there is no reason why each stop should not take it up on different notes. The string-toned stop should be carried down, if possible, to Gamut G, the bass pipes being stopped, and of the Quintaten species. The soft-toned unison may be broken at Gamut B flat, the bass being inserted in small-scaled pipes of delicate intonation. The practice of breaking more than one stop at Tenor C, or any one note, in the same instrument, is to be condemned, and should never be adopted.

The register of 4ft. pitch may be a delicately-voiced, half-covered wood stop, which, in combination with any of the unisons, will be perfectly adapted for accompaniment; or, in combination with the reed, will produce a pleasing quality for solo or melodic playing. An Orchestral Flute, 4ft. is a very serviceable stop in this department; but if inserted here it must be omitted in the Great, for the duplication of any stop is not a proceeding to be contemplated for a moment in a small Chamber Organ.

The Super-octave in this department should be of very soft intonation, yet bright and telling. It may either be of the Piccolo type or the so-called *Gemshorn* character. Whichever of the two may be selected, it must be voiced to a softer tone than the Super-octave in the Great, and otherwise kept as distinct in character as possible.

I may just mention a fact which may be of interest to those readers who are contemplating the acquisition of a Chamber Organ on a more ambitious plan than that implied in the foregoing notes—namely, that a through (8ft.) metal or wood stop, in imitation of the orchestral violoncello and of quiet intonation, can be added to the Choir department, but located outside the swell-box, with the most satisfactory results. It will be to this department what the Principal (8ft.) is to the Great organ, and will add immensely to the resources of the instrument, and facilitate the production of numerous striking orchestral effects. The space required for such a stop is not very great, and its external position will not in any way affect the dimensions of the swell-box.

In the remarks on the Great organ, I have alluded to the desirability of inclosing the Choir stops in the same swell-box in which one-half of the Great stops is placed, pointing out that it is unnecessary and undesirable to occupy valuable space, to increase mechanical appliances, and to add the difficulty of operating on three Expression levers, by introducing a distinct swell-box for the Choir department. Practically, there is no evident disadvantage in the proposed arrangement, for it is only on extremely rare occasions that the presence of an independent Choir-Swell, if I may be allowed to use the compound, appears desirable. Even on such occasions, the exercise of a little ingenuity on the part of the performer overcomes all difficulties which may present themselves.

When the Choir Organ is used alone, of course no inconvenience is experienced in its management. When used as an accompaniment to certain solo stops in the Great, the worst that can happen is that the accompanimental stops will have exactly the same kind and degree of expression imparted to them as may be deemed appropriate for the solo register. This, however, only follows when both the accompanimental and solo stops are in the same swell-box; when the solo stop is in the back swell of the Great department, the organist can impart expression to either the solo or accompaniment at will, or to both simultaneously, by the use of the two Expression levers.

By referring to the list of Couplers, given in Article II. (Aug. 20, 1886), it will be observed that I recommend three which connect the Choir to the Great—viz., Unison, Sub-octave, and Octave couplers. With this complete system of coupling, the Choir becomes a very important department in the tonal structure of the instrument. When the Unison coupler is drawn, the entire organ becomes a grand Swell, if both Expression levers are used simultaneously, and the hands are confined to the Great keys. If the levers are operated upon singly, the organist can produce some striking effects by swelling the tones of the back division of the Great, or the combined tones of the full Choir and the front division of the Great, at his pleasure. By drawing the Octave coupler, any desired degree of brightness can be added to the Great department, through the introduction of registers of 4ft., 2ft., and 1ft. pitch; and this coupling does in no way interfere with the predominant unison character of the Choir department as commanded by its own clavier. A similar advantage accrues to the Great by the coupling of the Choir in the sub-octave. If a unison, octave, and super-octave stop are drawn in the choir, the Sub-octave coupler adds a 16ft., 8ft., and 4ft. series to the combination in the Great; and this series can be adjusted to any desired strength by the Expression lever. Pages might be written in addition to what has just been said, and what has previously been written, on the countless effects to be obtained by the joint manipulation of the stops and couplers; but the remarks made must suffice for the present purpose. Any reader who may feel curious to realise what can be done with a divided Great of ten stops and a choir of five or six stops, and the three manual couplers, should take a pen and paper and work out the sum of the possible combinations for himself. I promise him a slight feeling of surprise. After he has arrived at the end of his task, I feel certain he will agree with me that a Chamber Organ of, say, sixteen manual speaking stops, is by no means an insufficient or paltry instrument; and that it will take some patience and ingenuity on the part of an organist to get to the end of its resources.

Solo-Organ—Expressive.

As three manuals have been mentioned in an early article, it is probably expected that I should say a few words on the subject of the most desirable arrangement of the contents of the instrument, when it embraces Great, Solo, and Choir departments.

Firstly, then, if the number of manual speaking stops is sixteen, the apportionment should be as follows:—Great organ, seven stops; Choir organ, five stops; and Solo organ, four stops.

Secondly, there will now be no department *divided* in the manner previously recommended in connexion with the two-manual instrument; and each of the three departments should be inclosed in a separate swell-box commanded by a distinct Expression lever. The levers should be ranged, side by side, in this order from left to right—Great, Solo, Choir. This order is desirable because it allows a single foot to open the Great and Solo or the Solo and Choir swells simultaneously. The convenience of this arrangement is too obvious to require comment.

Thirdly, the Solo organ should comprise important orchestral-toned solo registers, such as the Clarinet, Orchestral Oboe, Violin, Violoncello, and Orchestral Flute. The Trumpet should retain its place in the Great, while the Vox Humana may be relegated to the Choir department. The apportionment of the stops in the three manual departments will probably always be a matter in which individual taste will exercise controlling power; but an apportionment which will secure the greatest range of effects in each department, and the maximum of solo and accompanimental combinations on the different claviers should always be aimed at.

Fourthly, under no conditions whatever should the Solo be uninclosed, for the nature of its stops imperatively calls for expression of the most effective description. When there are the three departments—Great, Solo, and Choir—and space for the accommodation of two swell-boxes only, the Great and Choir, or the chief portion of both, should be inclosed in one swell-box, and the Solo stops in the other. The only department which (in a Chamber Organ) can be left entirely uninclosed is the Choir. When uninclosed, its stops should be voiced in the most delicate manner, so as to yield tones of the softest and most winning character. It should occupy a front central position, so that its sounds may be distinctly heard at their best, and devoid of any muffling or acoustic deflection. In this position the Choir may be made an effective feature in the design of the instrument. When so placed, and entirely uninclosed, the Choir department should contain no stop of an essentially solo character, simply because a solo stop without expression is objectionable. The non-expressive Choir must be accepted from first to last as an accompanimental department; or, generally, as a subdued normal

organ, suitable for rendering quiet passages which do not call for special effects of light and shade.

Pedal Organ.

There can be no question that one of the chief difficulties, if not the chief difficulty, in connection with the appointment of the Chamber Organ is the furnishing of an adequate Pedal department. As I have before said, there is almost always a difficulty in finding sufficient floor-space and height for the accommodation of open stops of 16ft. speaking length; yet without one stop of this class, the bass of the instrument will lack the desirable dignity, and its chief element of grandeur. Every endeavour should be made to include such a stop in the tonal scheme. In *ensemble* playing—that is, when the Organ is used along with the pianoforte, violin, and other instruments—the effect of the open 16ft. stop is magnificent, and singularly impressive. It has one disadvantage, however, in an ordinary room, which must be mentioned—viz., its tendency to cause most unpleasant vibrations in doors, windows, and certain articles of furniture, and, indeed, in portions of the organ itself. Such vibrations should be listened for, and then carefully cured. They generally proceed from some looseness in the articles affected, which a little alteration removes. For further remarks on this important stop, the reader may refer to the opening paragraph of the preceding part of these Notes.

With reference to the covered stop of 16ft. tone, almost invariably found in the Pedal, or forming the entire Pedal department of the ordinary Chamber Organ, little need be added to what has already been said. As the longest pipe of this register does not exceed 8ft. 6in. in total length, and need never be more than 8in. by 7in. in external dimensions, the stop can be easily planted so as to form effective features in the general design. I may just mention, by way of illustration of my meaning, that at the sides of the salient portion of my own Chamber Organ are ranged the twelve lower pipes of the Contra-Basso, while the central space, between the angle towers and above the key-case, is occupied by the fifteen following pipes of the same stop. All the pipes are thus used, with the exception of the three higher ones, as integral parts of the external design. Of course all the displayed pipes are most carefully made and richly decorated. It is a matter of wonder to me that ornamental wooden pipes have not been more frequently introduced in the external designs of organs. It is not too much to say that no cylindrical metal pipes, however well decorated, could produce a better result in the front of my organ than that produced by the row of square wood ones there introduced. When the so-called *Bourdon* occupies so exposed a position, it can be voiced to yield the round "velvety" tone which is so desirable in the bass of a Chamber Organ, while its totally unshaded position allows it to be regulated to the greatest nicety, and its tones to be heard at their full value. Such stops are too often packed away within closed cases, or crowded into recesses or confined chambers, so that their tones are little better, as heard in the room, than the buzzing of a score of humble bees; unless, indeed, they are voiced unduly loud and coarse.

When a soft-toned, open, cylindrical metal Octave of the Gamba, Violoncello, or *Dulciana* species is introduced in the Pedal department, the lower octave or so of pipes may be used in towers, or in any other features of the external design, as taste may direct. The remaining pipes can easily be placed behind. As before remarked, an Octave stop may be borrowed from either the open or covered 16ft. stop, by means of an Octave coupler, with the addition of a higher octave of pipes.

In approaching the question of a reed stop for the Pedal department, it is desirable to consider the advisability of rendering it expressive. If the drawing-room or music-room has anything like a spacious organ chamber, there will probably be no difficulty in planting the reed pipes together at one end of it, and inclosing them with a front, provided with louvres, tuning shutters, &c. If an ordinary striking reed is adopted, this inclosing will have a beneficial effect, by toning down to a considerable extent the unpleasant buzz of the larger tongues. The free reed, on which I commented in the preceding article, is sufficiently soft and clean in tone to remain uninclosed; but, of course, it would be rendered more effective if made expressive. As it would be inconvenient in an instrument already provided with three Expression levers—Great, Solo, and Choir—to add a special lever for the Pedal swell, I should recommend the coupling of the Solo and Pedal swell actions to the central or Solo lever. In instruments with only two Expression levers (for the manual departments), a third may be added for the Pedal reed, if thought desirable, otherwise the latter may be combined with the lever attached to the back division of the Great organ.

Much more might be said on the important questions I have so briefly touched upon; but I must rest content with the sketch of my plan of Chamber Organ appointment already given. In my next article I shall hastily speak of certain remaining matters worthy of consideration by Chamber Organ builders, professional and amateur.

(*To be continued*).

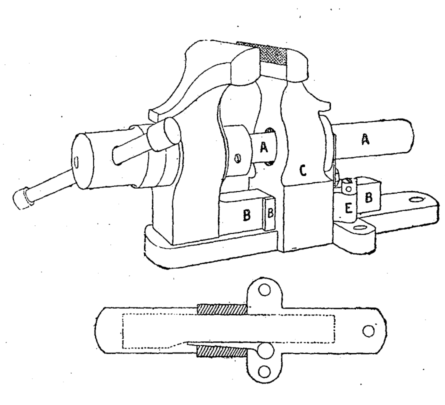
THE IRON AND STEEL INSTITUTE.

The autumn meeting of the Iron and Steel Institute was held in London this year in order that members might take the opportunity to visit the Exhibition, and also that many Colonial iron and steel workers now in this country might attend the meeting. The President, Dr. Percy—the formal business having been disposed of—announced that Mr. Daniel Adamson, of Manchester, had been nominated by the council as the next president, and the selection was thereupon unanimously confirmed by the meeting. A report on the iron-making resources of the British colonies has been specially prepared by Mr. P. C. Gilchrist and Mr. E. Riley for the benefit of members, who found it to consist of nearly 140 pages full of valuable information. The president, in delivering his address, referred to the early history of chrome steel, an alloy which is said by an American Company to exceed in tenacity all other kinds of steel when cold. He exhibited a piece of an American ploughshare which appeared to have been made by casting steel of some kind upon both surfaces of a plate of malleable iron, thus producing a superior implement to anything made here. The specimen had been submitted to a distinguished American metallurgist, who thinks it probable that it was produced in one of the South-Western States. Dr. Percy then referred to what is known as Mitis iron and steel, which contain small quantities of aluminium or aluminium alloys (see p. 50, Vol. XLIII.), and to the extraction of aluminium by the electric method (see pp. 71, 451, Vol. XLIII.). From the statistics of the Bessemer steel manufacture in the United States it appears that the capacity for producing it is largely in excess of the demand. In this country a similar condition prevails in connection with the production of both iron and steel; but the president appealed to the iron and steel makers not to be discouraged by the statistical statements he had made. A paper on the "Erosion of Gun Barrels," by Sir F. Abel and Col. Maitland, was read, in which the effects were attributed to the co-operation of three causes—namely, a softening, or perhaps fusing, of the surfaces of the metal by the heat of the exploding powder, an increase of that effect by the action of sulphur on the heated metal, and the mechanical action of the rush of gases, vapours, and liquid products on the softened or fused surfaces. Test experiments have been made at Woolwich with barrels supplied by different makers, but the results were widely different. Col. Maitland considers that the more steel is worked under the hammer the better it resists erosion; but Capt. Noble, F.R.S., finds from some experiments he made that the erosion is less the milder the steel. The subject becomes of increasing importance now that guns so large as the 16¼in. breech-loading 110-ton are coming into use. Barrels of manganese-bronze and of cast iron have been tried, but in the case of the latter the erosion was greater than with steel. The experiments are not yet completed, and the paper itself has been prepared only at the request of the president. Mr. Gilchrist gave a description of the "paper" he had prepared in conjunction with Mr. Riley, and in the afternoon those gentlemen escorted a party round the Colonial and Indian Exhibition. On Thursday Sir Henry Bessemer read a paper on some early forms of converters used in his process, his object being to save would-be inventors from racking their brains in working out problems which have been solved long ago. In the course of his remarks Sir Henry Bessemer stated that the addition in suitable quantity of molten malleable hematite iron to white or grey foundry iron produced practically a new metal, well deserving the attention of the intelligent ironfounder, who, with a small converter, could produce enough malleable iron to mix in a large charge of foundry pig for the production of girders, columns, engine framing, cylinders, &c., of a quality and strength far superior to any that could be produced from foundry iron alone. Mr. J. Hardisty, of Derby, read a paper on "Modifications of Bessemer Converters for Small Charges," in which he pointed out that although it might appear that the making of steel in small quantities was a step in the wrong direction, yet the difference in cost of production between the small and the large converters was not so great but that some firms had found it cheaper to use the small fixed converters than to purchase the ingots from others. The small converter, it seems, from the general opinion elicited in the discussion, will produce excellent steel, but at a slightly greater cost than the regular Bessemer converter. Mr. F. Siemens, by way of supplement to a former paper on a method of working regenerative gas furnaces by employing radiant heat alone within the heating chamber, read a paper on "Combustion," in which he stated that complete combustion is impossible whenever the live or active flame is allowed to come into contact with any solid surface, and such solid surface will always suffer by the mechanical and chemical action of the flame. Mr. Siemens thinks that radiant heat has always been a useful factor in heating operations whenever the constructiou of the furnaces allowed it to have full play; but he believes that sufficient attention has not been paid to the very detrimental effect on combustion itself, as well as on the work done, when the radiative power of the flame is interfered with in such a way that it could not be developed to its fullest extent. On Friday Mr. F. W. Harbord, of Bilston, Associate of the Royal School of Mines, read a paper on "The Removal of Metalloids in the Basic Siemens Furnace," which he said had been accomplished, the process being a thoroughly practical method of dephosphorising. The removal of the impurities in proportion to the oxidising nature of the slag is very marked, and soft steel of the finest quality can be obtained. Mr. Harbord thinks that by using an excess of oxide of iron, with a fair proportion of lime to fix the phosphoric acid, molten iron may be taken direct to the Siemens furnace, and the metalloids removed in a much shorter time than at present. The time thus gained would compensate for the extra cost of basic linings, lime, and ore—perhaps more than compensate, as the slag produced would be free from phosphorus, and could be used in the blast furnace. It appeared during the discussion that others had succeeded in making some excellent metal in open-hearth furnaces with basic linings; but as to the economy of the process there is still some doubt, as there is also as to the statement that the slag is free from phosphorus. Amongst the other papers read was a rather important one by M. F. Gautier, of Paris, who described a method of casting chains in solid steel,

adopted by Messrs. Joubert and Leger, of Lyons. Owing to the difficulty of welding the links. makers of chains have not been inclined to adopt steel, while to cast them it is necessary to have a quick method of moulding, and a metal quite solid and absolutely without blow-holes. The method adopted combines chilled casting and instantaneous removal from the moulds; the chain is then finished, annealed, and hardened in oil. M. Gautier considers that the process opens up a new field for the successful employment of the highest qualities of steel, and if better chains can be made with a lesser weight of metal, it will undoubtedly be an important improvement. Steel chains were cast some years ago; but the price has always prevented their introduction. M. Gautier also read a paper on "Silicon in Foundry Iron," in which he stated that French ironfounders, working with an average of 2 per cent. of silicon in their metal, produced sound castings quite free from blow-holes. The use of ferro-silicon is, in fact, becoming general in the French foundries, for it is found that silicon precipitates the combined carbon of white pig in the form of graphite, and so produces the grey pig-iron preferred by the founders.

ASHFORTH'S PARALLEL VICE WITH TAPER MOTION.

AN improved vice of the parallel type, having also a taper motion, has been recently patented by Mr. J. T. Laycock Ashforth, of Bruce Works, Sheffield, the special features of which are clearly delineated in the annexed engravings. The back jaw and body of this vice are made in one solid forging, by which great strength is obtained. The front or movable jaw and slide are also made in one solid forging; consequently, there are no bolts to give way nor lose. The parallel motion is the same as in vices of the old construction, being obtained by means of the box and screw marked A in sketch, the slide B moving in a slot or hole in the body of the back jaw C, of which the sides are perfectly parallel, thus



keeping the front jaw quite true in its working backwards and forwards. The taper motion (which is the great feature in this vice) is obtained by releasing the thumbscrew D and taking out the wedge E, which causes one of the sides of the slot or hole in the body of the back jaw C to become taper, thus imparting a taper motion and grip to the front jaw, and permitting it to close firmly on any taper article, and so hold it securely without fear of slipping.

THE AMATEUR WORKSHOP.—XXVII.

Self-acting Lathes.—(*Continued.*)

THE arrangements for screw-cutting which lie beyond the actual rest itself are here illustrated, and will prove the subject matter for our discussion. Postponing the treatment of the principles involved in screw-cutting until after the description of the mechanism involved therein, we note in the views two distinct trains of gearing—a simple train (Fig. 296) and a compound train (Fig. 297)—the connection between which and the headstock on the one hand, and the leading screw on the other is apparent, the wheels, marked A in each case being drivers, and those marked B driven. The wheel marked C in Fig. 296 is an idle, intermediary, or stud wheel, whose sole function is to cause the leading screw to revolve in the same direction as that of the headstock mandrel.

Taking the leading screw first in order, its outline is shown in Fig. 298, and a full-sized sectional view of two kinds of threads in Fig. 299. This is made of steel. The section of the thread is, in the first case, square, having top and bottom rounded; in the second (and, as I think, preferably) a compromise between the square and angular forms, as affording a better contact or bite between it and the clasp nut when the screw wears with use, and preventing the grinding of the points of the thread in the bottom of the nut threads, which is a cause of wavy markings on turned work. The right-hand of the screw has its bearings in the bracket (Fig. 300), which is bolted to the facing prepared for its reception on the front of the lathe bed, and the left-hand end has its bearing in a similar bracket, Fig. 301, but which has an additional flange cast with it to take the rocking plate D in Figs. 296, 297, and in Fig. 302. The left-hand end beyond the bearing has a shouldered and turned portion provided with a sunk feather, over which fits the particular change wheel of the train which has to go on the leading screw for cutting its special thread. The rocking plate, Fig. 302, has two radial or curved slots, by means of which it is rendered capable of slewing movement, the slewing being necessary for the accommodation of wheels of different diameters between the fixed centres of the mandrel and of the leading screw, and also two parallel slots for carrying the stud or studs which become the bearings of the intermediary wheels. This plate is of cast-iron, having the slots cast in the mould, and both faces should be planed true. The studs are shown in Fig. 303. They differ only in length, one being for the wheel of a single train, the other being long enough to take the two wheels of a compound train. They are each seen to consist of a central bolt or stud shouldered and flattened to slide in the slots of the rocking plate, in which slots they can be tightened in any position; and to be encircled with a freely-revolving sleeve furnished with a sunk key for the reception of the change wheels, the key and sleeve being of corresponding sizes with the left-hand end of the leading screw, and with the tail end of the mandrel, so that the wheels are interchangeable on the mandrel, studs, or leading screw alike.

The change-wheels will be bought both cheaper and better than they can be made. They are of what is termed diametral pitch—that is, the pitch is not given in tooth centres, but in a number which has a constant ratio to the diameter, the numbers ranging usually from 6 to 14 pitch, 6 pitch being the largest, equal to about $\frac{1}{2}$in. full, 14 teeth being the smallest, equivalent to 3-16in. full. With wheels of diametral pitches the diameters are not given, but the pitch number and the number of the teeth instead. To deduce the diameter, it is only necessary to divide the number of teeth by the pitch, as 60 teeth of 12 pitch $= \frac{60}{12} = 5$in., the diameter of that wheel. These wheels usually number 22 to the set, arranged either as 6 from 20 to 25, rising by one tooth each, 15 from 30 to 100, that is rising by five's, with one 40 or 60 wheel extra; or else 21 wheels rising from 20 to 120 by five's, with one 40, or 60 extra. For cutting special threads others are added with advantage, but most threads can be cut with these alone. A set of 12 pitch $= \frac{1}{4}$in. full, will be most suitable for a 4in. lathe, and will cost about 17s. as rough castings. They will have to be bored, and their feather-ways will be filed or slotted, and if the ends of the teeth are lightly turned, it will improve their appearance.

The essential work of the guide or leading screw is not plain turning, although used for that, but the cutting of screw-threads, for which it performs the function of a constant or primary factor in relation to screw-threads of any pitch. The leading-screw here shown, in common with almost all lathes of small size, has four threads to the inch $= \frac{1}{4}$in. pitch. Large lathes have two threads only $= \frac{1}{2}$in. pitch. Some lathes have threads of $\frac{3}{8}$in. pitch. Through the intervention of the change-wheels, the varying rates of scores of different screw threads are cut with a guide-screw of constant pitch. Thus the lathe mandrel and the leading screw are essentially two parallel revolving spindles, the motion of the latter being derived according to some definite ratio from the former. If one be revolved at precisely the same rate as the other, and a cutting tool be traversed in the slide rest against a piece of work running in the lathe, a thread will be cut on the latter of precisely the same pitch as that of the leading screw, and the direction of the thread will be right or left-handed, according as the spindles revolve in the same or in opposite directions—that is, according to what idle wheels are placed in the train. In each of the Figs. 296 and 297 the leading screw is seen to travel in the same direction as the lathe, and the screw itself being right-handed, the saddle travels towards the headstock, and cuts a right-hand thread. By inserting an extra wheel in either train the direction would be reversed, and the screw being cut would be left-handed.

We have imagined the elementary spindles to have equal rates of revolution, but it is now easy to see that by combining the change wheels in certain aliquot or numerical proportions, the screw rates to be cut can be made aliquot or numerical proportions of the rate of the leading screw. Of course when cutting a thread of equal pitch with that of the guide, the wheels on the mandrel and on the guide-screw must be of equal size (usually two 40's, two 60's, or two 90's). But, suppose instead of having wheels of the same diameter, we put wheels of unequal size in their places—say, for example, one of 40 teeth on the mandrel, and one of 80 on the leading screw, and that the leading screw is of $\frac{1}{4}$in. pitch. Then, while the mandrel makes one revolution, the leading screw will make half a revolution only, and travel the saddle half the pitch, equal $\frac{1}{8}$in., and the screw cut will be $\frac{1}{8}$in. pitch. Reverse the wheels, putting 80 on the mandrel and 40 on the guide-screw, and the result will be that the mandrel revolving once will turn 40-wheel round twice, and travel the saddle $\frac{1}{2}$in., cutting a $\frac{1}{2}$in. screw. Hence the fundamental rule; that the same ratio must exist between the change wheels as between the pitch of the guide-screw and the pitch of the screw to be cut. Also, that for cutting threads finer than the thread of the leading screw, the smaller wheel will be the driver (or on the mandrel), and the larger the driven (on the guide-screw); but, for cutting threads coarser than those of the leading screw, the larger wheel will go on the mandrel, and the smaller be the driven.

Thus far we have considered a simple or elementary train; but the same reasoning applies to a compound train, the principle remaining unaffected. The difference in a simple and a compound train is this:—That in the simple train two wheels only (one driver, and one driven) are essential, the idle wheel counting for nothing as regards velocity ratio, being a carrier of motion only; in the compound train there are two (or more) drivers, and two (or more) driven. The necessity for the compound train lies in the impossibility of effecting a very great difference in speed with a single pair of wheels within the compass of the centres of the lathe-mandred and the guide screw. Then, the drivers being multiplied into each other, and the driven into each other, their *products* are divided, and the rate so obtained is the same as that which subsists between the guide screw and the screw to be cut. Neither, having two drivers, does it matter at all which of the two goes on the mandrel, and which on the stud; nor, having two driven, does it matter which goes on the stud and which on the guide-screw, the essential being that one driver shall be on the mandrel, one driven on the guide-screw, and a driver and a driven on a stud common to both, which is pinched in the rocking-plate.

Since the same ratio must exist between the change-wheels as between the pitch of the guide-screw and that of the screw to be cut, the obtaining of any factor in the series can be effected by the rules of proportion. But it is usual to obtain the wheels directly by placing the number of threads in the guide-screw for a numerator, and the number in the screw to be cut for a denominator, and adding a cipher to each to obtain the requisite number of teeth, thus:—Having to cut a screw of eight threads

FIG 298

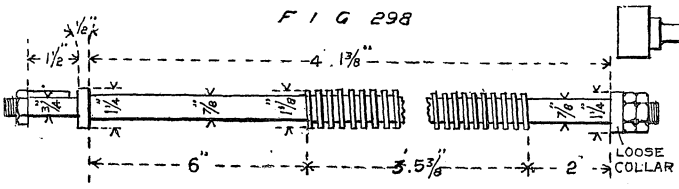


FIG. 301.

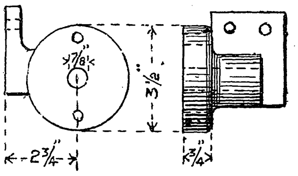

FIG 300

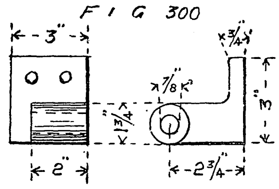

FIG 297.

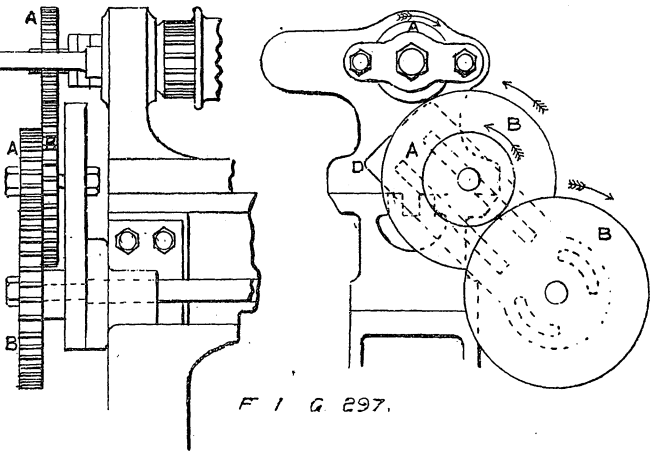

FIG 299

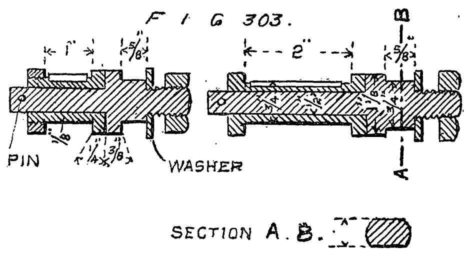
FIG 303.



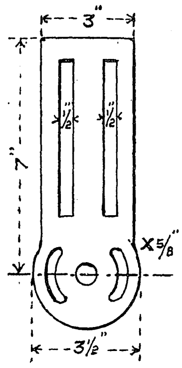


FIG 296

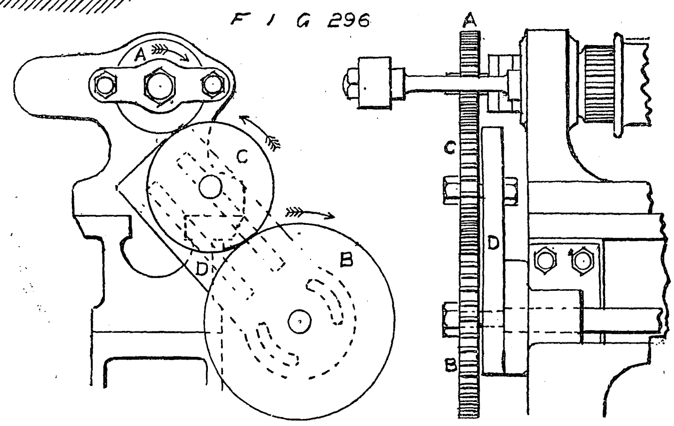


to the inch on a lathe whose guide-screw is 4 to the inch, we get $\frac{4}{8}=\frac{40}{80}$; and 40-wheel goes on the mandrel, and 80 on the guide-screw, therefore, the numerator of the fraction always represents the guide-screw and the driving-wheel, and the denominator the screw to be cut and the driven wheel. When we get beyond ten or twelve threads per inch, the number of the larger wheel becomes too large, and recourse is had to the compound train. Say we want to cut a thread of 18 to the inch, with a leading screw of 2 to the inch, the fraction would stand $\frac{2}{18}=\frac{20}{180}$. But then we have not got a 180 wheel, and if we multiply each by a number to bring in a large wheel, say, $\frac{2}{18}\times 5=\frac{10}{90}$, we find we have not got a wheel so low as 10. Looking up a compound train, we can say $\frac{2}{18}=\frac{20}{180}=\frac{4\times 5}{12\times 15}$ $=\frac{40\times 50}{120\times 150}=\frac{40\times \overset{25}{50^*}}{120\times \underset{75}{150^*}}$, and 40 and 25 drivers, and 120 and 75 driven, will cut the thread, and they are wheels in the standard set. Or, $\frac{2}{18}$ $=\frac{2\times 1}{6\times 3}=\frac{20\times \overset{30}{10^*}}{60\times \underset{90}{30^*}}$, and 20 and 30, and 60 and 90, will cut the thread, and numerous other combinations could be obtained by the same method, of taking either aliquot parts or multiples of the numbers first obtained, taking care to reduce or increase both drivers and driven in the same proportion.

To cut fractional threads, it is necessary to reduce the compound number to a simple fraction. Thus, say, we take a thread of $6\frac{1}{2}$ to the inch, and a leading screw of four to the inch, this equals $\frac{4}{6\frac{1}{2}}$, multiply this by the denominator of the fraction 2; $=\frac{4}{6\frac{1}{2}}\times 2=\frac{8}{13}=\frac{80}{130}$ $=\frac{40}{65}$, which are wheels in our train. Or, taking a thread of $6\frac{3}{4}$, and a leading screw of two to the inch, $=\frac{2}{6\frac{3}{4}}\times 4=\frac{8}{27}=\frac{2\times 4}{3\times 9}$ $=\frac{20\times 40}{30\times 90}$; also wheels of the set. The pitches selected for illustration have each been finer than that of the leading screw, so that in each instance the smaller wheels have been the drivers. Taking, now, a pitch coarser than that of the guide screw, say, containing $1\frac{1}{2}$ threads per inch, the guide-screw being four to the inch, we have $\frac{4}{1\frac{1}{2}}\times 2=\frac{8}{3}=\frac{80}{30}$, 80 being the driver and 30 the driven.

To cut millimètre pitches in a lathe with an English leading screw, the wheels are obtained in the following manner:—The mètre is assumed to be equal to 39·375, or $39\frac{3}{8}$in. A pitch of one millimètre, therefore, is equivalent to 1,000 threads in $39\frac{3}{8}$in. In the same length of leading screw having four threads to the inch we have $39\frac{3}{8}$in. × 4 = $157\frac{1}{2}$. or 157·5 threads of $\frac{1}{4}$in. pitch. Hence the ratio between the two is represented by the numbers $\frac{157\cdot 5}{1000}$, which reduced to its lowest denomination becomes $\frac{157\cdot 5}{1000}$, divided by $2\cdot 5=\frac{63}{400}$, so that $\frac{63}{400}$ is a constant fraction to be borne in mind for lathes having a guide-screw of four to the inch, and from which the ratios for lathes having other threads can also be deduced. Requiring to cut a thread of 1m.m. pitch we write down $\frac{63\times 1}{400}=\frac{63}{400}=\frac{7\times 9}{20\times 20}=\frac{70\times 90}{200\times 200}$ $=\frac{35\times 45}{100\times 100}$, whence we require a pair of 100's for driven. If we want to cut a screw of 6m.m. pitch we set down $\frac{63\times 6}{400}=\frac{378}{400}=\frac{6\times 63}{20\times 20}=\frac{60\times 63}{200\times 20}$. 200 is too high, so we substitute 50 and 80 driven, and $\frac{60\times 63}{50\times 80}$ will cut a thread of 6 m.m. pitch. These are fine pitches, and the small set of wheels are the drivers. Taking a pitch coarser than the guide-screw, say ·10m.m. $\frac{63\times 10}{400}=\frac{630}{400}=\frac{63\times 100}{50\times 80}$, and the large wheels are the drivers. When working out these ratios we shall find that a 63-wheel is absolutely necessary to cut millimètre pitches with two drivers and two driven wheels only. With trains of six or eight wheels, the 63-wheel can be done without, at least, in many instances.

To cut millimètre pitches in lathes, having leading screws of other rates than four to the inch, suitable ratio numbers must be taken. With guide screws of $\frac{1}{4}$in., $\frac{3}{8}$in., and $\frac{1}{2}$in. pitch the relations would be: $\frac{63}{400}$, $\frac{63}{600}$, $\frac{63}{800}$ respectively, and these would be constant for those leading screws. These three ratios correspond with $157\frac{1}{2}$ threads of $\frac{1}{4}$in. pitch in the mètre, 105 threads of $\frac{3}{8}$in. pitch, and $78\frac{3}{4}$ threads of $\frac{1}{2}$in. pitch, and the numbers 63, 400, 600, and 800 are the numerator and denominators respectively for leading screws of $\frac{1}{4}$in., $\frac{3}{8}$in., and $\frac{1}{2}$in. pitch. Taking an example in each case, let us say we want to cut a thread of 5m.m. pitch, with either one of these leading screws; then the equations stand: $\frac{63\times 5}{400}$ $\frac{63\times 5}{600}$, $\frac{63\times 5}{800}$.

Taking them in succession—

(1) $\frac{63\times 5}{400}=\frac{315}{400}\times 10=\frac{63\times 50}{100=40}$

(2) $\frac{63\times 5}{600}=\frac{315}{600}\times 10=\frac{63\times 50}{75\times 80}$

(3) $\frac{63\times 5}{800}=\frac{315}{800}\times 5=\frac{63\times 25}{50\times 80}$

these being single examples only selected from many possible combinations of wheels.

The precaution should always be adopted of proving the correctness of the calculation for driving and driven wheels before proceeding to cut the threads. And first, when the screw to be cut is of finer pitch than that of the leading screw:—multiply the driving wheels together, and also multiply the driven wheels together, divide the latter product by the former, multiply the result by the pitch of the leading screw expressed as the number of threads per inch, and the quotient equals the number of

* Denotes cancelled figures.

threads per inch required to be cut. In other words, expressive of the fundamental principle, the ratio subsisting between the driving and the driven wheels is the same as that subsisting between the guide screw and the screw to be cut. Taking the example given above of 18 threads to the inch, with a leading screw of 2 to the inch, we have 40×25 drivers, 120×75 driven $= \frac{120 \times 75}{40 \times 25} \times 2 = 18$ threads. Also $6\frac{1}{2}$ threads with a leading screw of 4 to the inch $= 40$ driver, 65 driver $= \frac{65}{40} \times 4 = 6{\cdot}5$. Taking again a pitch of 6m.m. as just now instanced with a leading screw of 4 to the inch, our drivers are 60×63, and driven $50 \times 80 \therefore \frac{50 \times 80}{60 \times 63} \times 4 = 4{\cdot}2328$, and a pitch of 6m.m. is contained 4·2328 times in an inch; but in proving millimètre pitches it is simpler to adopt the principle just now stated, that the ratio subsisting between the drivers and the driven is the same as that subsisting between the guide screw and the screw to be cut, in its more direct form. Thus the pitch of the guide screw is reduced to its equivalent in millimètres in order to be a factor, and a constant ratio of the same nature as that of the screw to be cut. Thus a leading screw of $\frac{1}{4}$in. pitch is equivalent to $\frac{63}{400} = \frac{400}{63} = 6{\cdot}3492$; one of $\frac{3}{8}$in. pitch $= \frac{63}{600} = \frac{600}{63} = 9{\cdot}5238$, one of $\frac{1}{2}$in. pitch $= \frac{63}{800} = \frac{800}{63} = 12{\cdot}6984$; the numbers 6·3492, 9·5238, 12·6984, representing the number of millimètres in $\frac{1}{4}$in., $\frac{3}{8}$in., and $\frac{1}{2}$in. respectively, and the ratios of the driving and driven wheels must correspond with the ratios subsisting between these numbers and those of the screws to be cut. Taking the screw of 6m.m. pitch, as instanced above, with a leading screw of four to the inch, and 60×63 drivers, and 50×80 driven, we have, taking the ratio direct— $\frac{60 \times 63}{50 \times 80} = {\cdot}945$, and also $\frac{6}{6{\cdot}3492} = {\cdot}945$, or $\frac{50 \times 80}{60 \times 63} = 1{\cdot}05$; and $\frac{6{\cdot}3492}{6} = 1{\cdot}05$, or $\frac{60 \times 63}{50 \times 80} \times 6{\cdot}3492 = 6{\cdot}0$; by which methods the ratios are apparent by inspection, without the necessity of bringing into inches. In all screw cutting the fundamental principle of ratio or proportion must be borne in mind, and no matter how obtained, if the ratios of driving and driven wheels, and of guide screw and screw to be cut are identical, there is no risk in proceeding with the work, provided, of course, that the drivers and driven are in their right places. Thus, a thread of 6m.m. pitch is finer than one of $\frac{1}{4}$in. pitch or 6·3492m.m.; hence the smaller wheels 60×63 are the drivers, and 50×80 the driven. But if we had a pitch of, say, 10m.m., the conditions would be reversed, thus:—

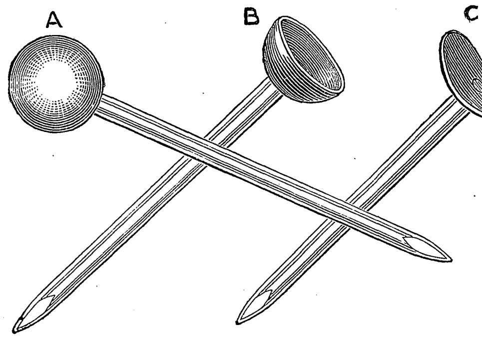
$$\frac{63 \times 10}{400} = \frac{63 \times 10}{20 \times 20} \times 4 = \frac{63 \times 40}{20 \times 80};$$

equivalent to $\frac{20 \times 80}{63 \times 40} = {\cdot}634$, and $\frac{6{\cdot}3492}{10} = {\cdot}634$, showing equal ratios, and 63×40, the larger wheels, the drivers.

(*To be continued.*)

SCIENTIFIC COOKERY.

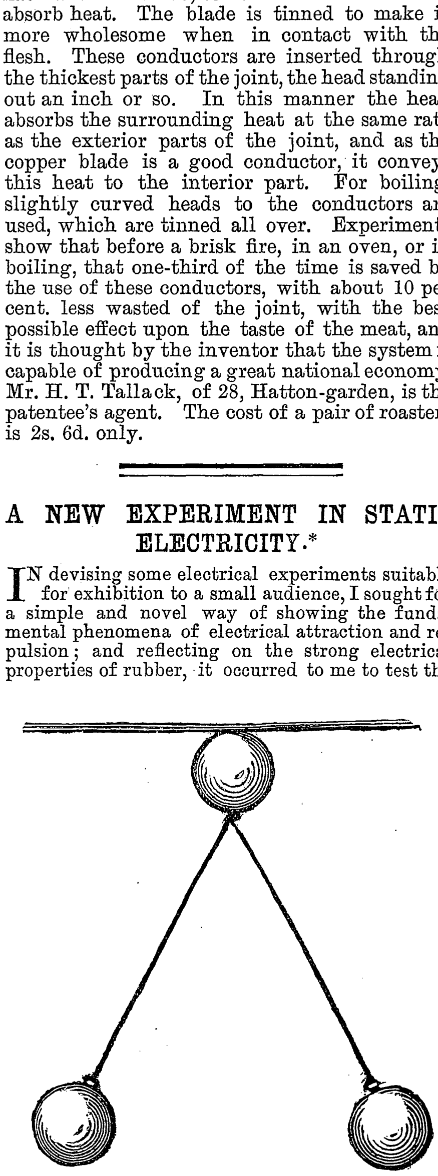
MR. W. F. STANLEY has invented a new form of heat conductor for cooking the interior parts of joints of meat, poultry, or fish simultaneously with the outer parts. Flesh is known to be a very bad conductor of heat, therefore in all methods of cooking now in use if the exterior parts are perfectly cooked, the interior parts are found to be much overdone, with corresponding loss of the nutritious juices of the flesh. The object of this invention is to provide means by which the interior parts may be cooking simultaneously with the outer parts. This is effected by metallic conductors which conduct the exterior heat to the interior parts, and thereby produce a great saving of fuel, time, and food, besides which the juices of the meat are conserved so that the cooked meat is much more palatable and wholesome. The forms of heat conductors that have been found



by experiment most effective for roasting and baking are pointed blades of copper, upon which are fixed rather large globular heads of malleable iron, which conductors are now made. The iron head is left covered with its natural black oxide, to be in the best state to absorb heat. The blade is tinned to make it more wholesome when in contact with the flesh. These conductors are inserted through the thickest parts of the joint, the head standing out an inch or so. In this manner the head absorbs the surrounding heat at the same rate as the exterior parts of the joint, and as the copper blade is a good conductor, it conveys this heat to the interior part. For boiling, slightly curved heads to the conductors are used, which are tinned all over. Experiments show that before a brisk fire, in an oven, or in boiling, that one-third of the time is saved by the use of these conductors, with about 10 per cent. less wasted of the joint, with the best possible effect upon the taste of the meat, and it is thought by the inventor that the system is capable of producing a great national economy. Mr. H. T. Tallack, of 28, Hatton-garden, is the patentee's agent. The cost of a pair of roasters is 2s. 6d. only.

A NEW EXPERIMENT IN STATIC ELECTRICITY.*

IN devising some electrical experiments suitable for exhibition to a small audience, I sought for a simple and novel way of showing the fundamental phenomena of electrical attraction and repulsion; and reflecting on the strong electrical properties of rubber, it occurred to me to test the



possibilities of the common toy rubber balloons, as they seemed to offer the advantages of large exciting surface and small weight, both of which are important desiderata in experiments of this kind. A trial proved them particularly adapted to striking and interesting demonstration. My first experiments were made with the ordinary grade of toy balloons, which have a red-stained wooden mouthpiece containing a "squawker," well known to small boys and adults who have been harassed by their intermittent squawking. These common balloons may be procured at almost any toy store for a few cents each.

They are inflated with the breath and tied at the end with silk or thread, when they may be pushed off the tube. If one of these inflated balloons be thoroughly stroked with a cat's skin, it becomes strongly electrical, and will fly to the body or adhere to the hand if held over it, or it may be rapped up to the ceiling with a small stick.

Its adherence to the ceiling is remarkably persistent. I have repeatedly had balloons remain in such positions for more than four consecutive hours. Numerous instructive experiments may be made with them singly or in combination, and the few here described will suggest others. Their strong attractive force implies, of course, strong repellent force. If two are suspended by threads of the same length, and excited with the cat skin, they will be pushed apart two or more feet, the distance depending to a great extent on the length of the suspending threads. If the hand be now brought between them, they will be attracted to it, and if it be suddenly withdrawn before the balloons have touched it, they will bound away from each other almost as if they had struck a wall.

A very pretty experiment is illustrated by the engraving. Two of the balloons are hung with equal threads to a third, the threads being of such length that when the third balloon is against the ceiling the others may be conveniently reached. The third balloon is now excited, and put against the ceiling by means of a long stick. If properly done, the attraction is amply sufficient to support the two other balloons. These latter are now excited, care being taken not to pull the supporting one away from the ceiling; and as their mutual repulsion forces them apart and they float airily around each other, the whole group affords a demonstration of both the attractive and repellent forces of electricity so striking that it can hardly be appreciated until it is seen. If a strip of hard rubber be electrified with the cat skin and put between the suspended balloons, they fly still further apart, and one of them may be chased around, or made to rise vertically by a little dexterity with the rubber strip. By arranging, say, half a dozen balloons in the form of a hexagon horizontally on threads strung across a room or on a suitable light frame, it is quite possible that another balloon could be suspended in mid-air by the combined repulsion of the group when in a good state of electrical excitement. This would be a very effective experiment, although it has not yet been tried.

There is a choice among the balloons of different grades for these experiments. The cheaper kind I have found almost unexceptionally satisfactory, but it seems impossible to electrify the better ones, which are heavier and more highly coloured. Probably the colouring matter gives them more or less conductivity, so that the charge excited on them easily flows off. It may be, however, that by thoroughly extracting the colouring matter with alcohol or otherwise, they may be made available for electrical purposes, in which case their larger size might make them specially desirable in some experiments. It should be added that, like most experiments with statical electricity, these succeed only in cold weather.

RECENT RESEARCHES ON FRICTION AND THE ACTION OF LUBRICANTS.—II.*

By PROF. HELE-SHAW.

THE mechanical tests by which the nature of lubricants are examined are effected with a class of apparatus called "testing machines." These machines are of quite modern invention, but many of them have been invented, and a large amount of ingenuity and skill has been displayed in their design. It is by means of these machines that our knowledge on the effect of the three last variable conditions — viz., pressure, velocity, and temperature, on the amount of sliding friction, as well as of the nature of the materials has been obtained, and therefore a brief explanation of the principle of action of a few of them may be given. Perhaps the simplest tester is the pendulum machine of Bailey's in which an upright support a, a, Fig. 1 (page 125), carries a pendulum bc suspended at the point b. This pendulum is con-

* A paper read before the Liverpool Engineering Society.

nected at the point e to a sliding block f, which rests on a smooth plate carried by an arm from the support. When the pendulum is started swinging, it will come to rest in a longer or shorter time, according to the nature of the lubricant, a sample of which has been previously placed on the plate on which f slides. The foregoing tester is the only one in which reciprocating motion is employed; in all others there is continuous rotary motion of the parts in contact. One of the earliest and simplest of these is the machine of Ingram and Stapfer, in which a shaft shown in section a (Fig. 2, page 125) is kept in continuous rotation at about 1,500 revolutions per minute. There are two levers $a\,b\,c$, $d\,e\,f$, which are respectively weighted at the points c and f, and supported on the frame of the machine at a and e. Thus considerable pressure is produced at the points b and d upon the brasses which fit the shaft A. A thermometer t attached to the upper brass measures the rise of temperature produced. The quality of a lubricant is estimated by noting the number of revolutions for which a given quantity of it, when inserted between the brass and shaft, can enable the latter to be turned. Neither of the foregoing machines measure directly the resistance of friction, but rather the nature of the lubricant; the machines of Crossley, Thurston, Woodbury, and Riehlé all measure the frictional resistance. Valuable results have been obtained by Mr. Woodbury with his machine, which consists of an upright vertical shaft, driven by a belt, and carrying on its upper end an annulus upon which the lubricant is placed. On this annulus rests another, the required pressure between the two being obtained by means of a loaded frame, which is hung by means of a pivot upon the vertical shaft of the upper annulus; the latter is prevented from turning by a spring dynamometer, which thus serves to measure the frictional resistances. This machine is fully described in the "Transactions of the American Society of Mechanical Engineers," Vol. VII., page 136. The testing machine of Professor Thurston is, perhaps, the most convenient and complete, and withal one of the most simple of any yet invented. It consists essentially of a loaded rod A B (Fig. 3, page 126), suspended to a rotating shaft A, carried by a support A D, the friction at the point of suspension causing the rod to be carried out of the perpendicular to an extent depending on the friction at that point. This deviation is shown by a pointer E on the index C C, and thus the frictional resistance of the lubricant which is used in the bearing is directly measured. Not only can the pressures on the bearing be varied by tightening up a spring in the rod A B, but observations on the rise in temperature, and its effect upon the friction, can be made by means of the thermometer. The machine can also be used to test the effect of changes in velocity on the frictional resistance and the durability of any lubricant. By means of these machines and others, various experimenters have examined, with reference to their lubricating powers, the nature of probably all substances used, or likely to be used, as lubricants, with the object of determining the so-called co-efficient of friction. It has, however, been found that there are innumerable co-efficients for any one substance depending on the particular conditions of the experiment, and an account of the effect of these conditions must now be given, instead of any attempt to give even an abstract of the results themselves. One fact has clearly been demonstrated, and that is, that the friction diminishes with the fluidity of the lubricant. Mr. Woodbury, however, in a recent paper remarks, this "does not warrant any extreme position in respect to the use of these oils, except for light pressures, because under all circumstances the film of oil must be thick enough to keep the surfaces of a journal from actual metallic contact. In the severe work of heavy pressure a viscous oil must be used, in order to retain its place upon the bearing surfaces in sufficient thickness to prevent the irregularities on the journal from colliding. In some places it has been found that the use of an extremely thin oil resulted in the diminution of the friction of the machines at the expense of more rapid wear of the journals." The use of testing machines is fortunately not now limited to scientific investigators, but is becoming more and more common with those who use lubricants in any quantity, as by far the best test of the quality of the lubricants. In America some large railway companies are annually saving considerable sums of money in this way, and in this country some companies are following their example. It is, however, a suggestive fact that, throughout the whole of Liverpool, which is probably the most important steam shipping port in the world, the author has not been able to hear of a single company which subjects the lubricants used on their steamships to any kind of scientific test. Before leaving the subject of the nature of the surfaces in contact, the most important question as to why the co-efficients vary so greatly must be alluded to. Long ago it had been suspected by Hirn, and perhaps by others, that the friction of well-lubricated surfaces — that is, of surfaces "floating" or immersed in lubricant, would obey the laws of fluid friction, and the surfaces with an extremely small quantity of lubricant between them would obey the laws of solid friction, while surfaces with a moderate amount of lubricant would obey laws partaking of the nature of those of both solid and fluid friction; now, solid and fluid friction differ, essentially, in fact, are quite of an opposite nature. Those of solid being expressed, as previously mentioned (page 101), by the formula

$$F = \mu R$$

Those of fluid friction by $F = f\,S\,V^n$.

Where f is a so-called co-efficient of fluid friction, S = extent of surfaces in contact, V = relative velocity of motion, and n some quantity which lies between 1 and 3. That is, the friction of fluids is *independent* of pressure, and *does* vary in some way with the velocity and extent of surface in contact. Thus it was to be expected that the friction of lubricated surfaces would exhibit great variation according to the mode of lubrication. Until quite recently, however, this matter has been entirely ignored, and it has been reserved for various experimenters, Marcel Deprez, in France, but chiefly Thurston, in America, and Beauchamp Tower in this country, to definitely establish the existence of what Hirn called "immédiat," or solid, and "médiat," or fluid, friction, as occurring between the same pair of solid surfaces, according to the quantity of lubricant between them, and causing very different frictional resistances. Thus Mr. Tower says that his results, "generally speaking, were so uncertain and irregular that they may be summed up in a few words. The friction depends on the quantity and uniformity of distribution of the oil, and may be anything between the oil bath results and seizing, according to the perfection or imperfection of the lubrication. The lubrication may be very small, giving a co-efficient of $\frac{1}{100}$, but it appeared as though the friction could not be diminished, and the friction increased much beyond this point, without imminent risk of heating and seizing. The oil bath probably represents the most perfect lubrication possible, and experiments show that, with speeds of from 100ft. to 200ft. per minute, it is possible to reduce the co-efficient of friction as low as $\frac{1}{1000}$. The extent to which friction depends on the quantity of lubrication is shown in a remarkable manner, in one particular set of experiments, which proved that lubrication could be so dimished that the friction was seven times greater than it was in the oil bath, and yet that the bearing ran without seizing."

II.—*The variation of effect with pressure.*—The simple law which states that the resistance of friction varies directly as the pressure between the surfaces in contact is sufficiently true for practical purposes in the case of solid surfaces. It is not, however, absolutely true even in this case. Thus Prof. R. S. Ball found that a modification of the law was required, and that in certain experiments made by him a more correct form of representing the results was $F = x + y\,R$. The values of x and y in the case of pine sliding on pine being $F = 1{\cdot}44 + 0{\cdot}252$ R. This shows that the resistance of friction was proportionately higher at low pressures than that at higher ones, there being probably some effect due to a partial adhesion of the surfaces. For lubricated surfaces the results obtained by varying the pressure are extremely hard to bring under any definite law. Thus take as one example of hundreds which might be selected from published results. In Prof. Thurston's book on "Friction and Lubrication" (page 188) are some results of experiments, in which, with a constant velocity of 30ft. a minute, when the pressure was

200lb.	per sq. in.	the	coefficient	was	·01
150	"	"	"	"	·0035
100	"	"	"	"	·0025
50	"	"	"	"	·0035
4	"	"	"	"	·05

the temperature being the same in all these cases. These figures afford a good illustration of the erratic nature of the results which every observer who works at the subject finds himself obtaining. Although a very probable reason for this has been already pointed out, as applying to particular experiments, the average results of different workers should be, and indeed are, in accord even when not extending over the same range of conditions. Thus Prof. Thurston considers that the general result of his experiments on lubricated journals points to the friction under ordinary conditions varying inversely as the square root of the pressure. And though the results of Mr. Tower on the one hand, which extend to much greater pressures (up to 625lb. per square inch) do not definitely obey this law, still they tend in that direction. The same may be said of Mr. Woodbury's results, which are, on the other hand, for very low pressures, the resistance increasing in a much less ratio than the pressure. For instance, at 500 revolutions per minute and 80° F., with pressures of 1lb., 2lb., 3lb., 4lb., and 5lb. per square inch, the corresponding total resistances in his machine were 3½lb., 5lb., 6lb., 7·17lb., and 8lb. The general conclusion, which is the result of our increased knowledge of the effect of pressure, points to the great importance of securing perfect lubrication. When this is done the resistance of friction, instead of increasing, as the hitherto received theory would assume, with heavy loads to a point at which great loss of work would take place together with immense wear, only increases but slowly. That this is often done in practice, no doubt, accounts for the great loads actually carried by journals and bearings of various kinds, notwithstanding the rules and formula in text-books and manuals.

III.—*The variation in effect due to velocity.*—Since the time of the experiments of Morin, the friction of solid surfaces has been usually considered to be nearly independent of their velocity relatively to each other. No doubt this is the case, for the range of velocities, over which the experiments were made, as shown, on the one hand, by the uniform motion of the sledge at different velocities, but otherwise similar conditions, and on the other by the parabolic form of the time curve when the motion was allowed to accelerate. The lowest velocity, however, used in these experiments, was about ·01ft. per second, whereas Prof. Jenkin and Ewing have obtained results with velocities as low as ·0002ft. per second. This was done by employing the inertia of a cast-iron disc, 2ft. in diameter, and ¾in. thick, supported by means of a spindle only, 0·1in. in diameter at the ends, upon bearings of various substances (square and not circular in the cross section of the opening). The disc was set in rotation, and a siphon recorder, actuated by a pendulum, was employed to trace curves upon a band of paper fastened round the rim. The form of the curves enabled the rate at which the disc had been gradually brought to rest by the motion of the bearings to be determined. From these curves the friction itself could be estimated down to the above-mentioned low velocity of $\frac{1}{5000}$ft. per second. The general results of these experiments show that, "omitting the doubtful cases of oiled steel and wet agate, the co-efficient of friction remained entirely unaffected by changes in velocity, except where the bearings were made of wood, and that even in these circumstances no change of the co-efficient could be detected so long as the surfaces were dry; but when oil or water was present the co-efficient of friction increased in a very marked manner as the velocity diminished, this increase in the co-efficient of friction taking place under a limit of velocity of about 0·1ft. per second." The authors, after remarking that these are precisely the same cases in which there has been found to be a marked difference between the static and kinetic values of friction, whereas in the other cases no difference at all was found by Coulomb and Morin, say, "in fact, out of all the cases which we have examined, the only ones in which there is known to be a marked difference between the friction of rest and that of motion are those in which steel slides on oiled or wetted surfaces of wood, and in these cases, and these only, we have detected a very considerable increase of friction at low speeds."

(*To be continued.*)

THE LOCOMOTIVE OF THE FUTURE.

THE following remarks of Mr. J. Coleman, made in an address to the American Master Mechanics' Railway Association, will interest many readers who study the locomotive question:—What is a boiler? It is merely a thing to absorb the heat, says Mr. Coleman. The bottom of a pot over a fire is the best boiler surface in the world. Now put a cover on the pot, with a pipe extending from it, and you will have a second form of boiler. The next step is the old, plain cylinder boiler, which is a plain, cylindrical pot over a fire. Why don't everybody put them in? Because it is too expensive. That is all there is to the whole subject, as I understand it. We have found in mills, just as I think we should find if we looked at railroads, that everybody is inclined to put in a great deal too small boiler power, and too small furnace; and in sugar houses you will see that illustrated, where they will carry 16" fires on their grates. In fact, they force their fires, just as they do on steamships and locomotives. And we have found that as we could persuade mill owners to put in more boilers, and extend the fires so they could burn slowly and give time for this process of combustion to take place in the furnace, because it is a thing that requires time, or else it requires an intensely hot furnace, and even then it requires time, we find that when we can persuade them to do this, we get better results. And in the ordinary locomotive practice, when I find particles of coal hitting me when I am riding in the cars, I do not think that process is properly carried out; and when I see dense volumes of smoke coming from the stack, I do not believe it is carried out; and when I smell the gas that comes up I do not believe it is properly carried out. My point is this:—That as we have gone slowly, taken things deliberately

in mills, we have saved money. I have, in many cases, put in large sets of boilers in sugar houses and the like, where we have saved them a thousand tons of coal in a year out of four thousand, and sometimes out of three thousand.

Now, coming to the locomotives. I think if we examine the locomotive carefully, it will strike us as a little curious that the best locomotive that I remember reading of in this country weighed about 14 tons. I forget the exact dimensions of its furnace; in fact, I don't think they were given, but judging by the cut I should say the furnace was about 2½ft. or 3ft. square. We have gone on increasing the weight of our locomotives until some are as large as fifty tons. We have increased the locomotives over three times; but I will ask you if the furnaces have been increased in proportion? I do not think they have. The furnaces are, some of them 6ft. or thereabouts long, and 35in. or 36in. wide, more or less. So that, compared with the old size, you have increased them nothing like in the proportion which you have increased the size of the engine. I had always supposed, as most people who are outside of the railway profession do suppose, that there was something occult and mysterious in railway engineering—that nobody could understand it except those who were bred to the business. Perhaps it is so; and we outsiders may be considered very conceited if we know much about it. I think that the position I have taken was fully proven by some experiments that I have already detailed to the New England Railroad Club, that I tried for the Italian Government, during three weeks, in pulling freight trains up grades that were 100ft. to the mile, and it was with an engine that was built by the Reading Road. We took that engine down there, and we scraped the coal dust up in the yards, which they cannot burn at all on their European roads. We had to compete with the best engines on the Continent — the French, the Belgian, and the Austrian engines. We scraped the coal dust up, pressed it into cakes, and got just as good a result with that coal dust as we got from the best coal. We also used five kinds of Italian lignite, which was only half the combustible value of coal. We pulled the heaviest freight trains that they could pack on to us.

We started up this grade, and we found that we could scarcely crawl. Our engineer got very nervous and furious over it. They had already screwed the brake down upon us. We were going slow enough, so that he could get off and feel of the wheels. We pulled the train to the top of the hill, but we were blowing off steam furiously all the time that we were drawing that load up. When we got up the station the inspector-general came to me and said: "Signor, I congratulate you on having a superb machine here." And I thanked him. One of his engineers came to me and said: "Do you know what you have done, sir? Do not tell that I have informed you, because, if you do, I shall lose my place. You have pulled 50 per cent. more than the maximum load of one of our 40 ton engines." I said to the inspector-general: "If you choose to go on with this sort of procedure you can; but you won't get that steam down; that is what you tried to do—to stall us on the grade, and publicly disgrace us."

There was carried out on that machine exactly the proper principles. I won't say it was carried out in a proper manner; the mechanical details may be wrong; they may be improved; there is no doubt of it, because, as you know, one does not always succeed the first time; but the result was that we fired up in a way that I never had seen anything like before in my life. Our fireman used to level up his fires at the station, get everything in readiness, and he was leaning over his tender, smoking his pipe, between the stations. Once in a while he pulled the door open, put a shovel full of coal into the hold, and went on. The whole secret of it was the enormous area of the grate, which, if I remember right, was about 7ft. by 9ft., and we carried a thin fire, so that we got just the modicum of air that was necessary for the coal. That is one of the particular points. Of course you will readily see that there is a certain amount of gas in a certain amount of coal; and if the air gets through the coal, through the interstices between the coal, and if you keep packing on, you will by and by block that passage to such an extent that you won't get air enough. Therefore, we find that with a very fine dust coal, we must run a very thin fire; if we go to chestnut coal, we make a little thicker fire; if we go to stove coal, we make it 6in. thick, and so on; but for ordinary stove coal, or a little larger, we have always found that you should never make a fire over 6in. deep if you want to get a good result. The locomotive of the future has got to be changed in some way to keep up with the times. Here is the freight traffic of the country doubling up every ten years. The trains are following each other, one after the other, in rapid succession. What are you going to do? Are you going to double, treble, or quadruple your tracks, or what are you going to do? We are also obliged to constantly economise in the method of conducting this traffic.

It seems to me there are two or three things that have got to be done to the locomotive of the future. We have got to burn a great deal less coal for the steam we make, and after we have made that steam we have got to use it up a good deal more thoroughly. It seems to me that it is obvious that we have, one of these days, got to put in the compound engine which is used to day in the steamships, and we shall probably get the same results. If we have got steam strong enough to drive another engine, let us put another engine there. A way out of this difficulty about the furnace seemed to me to be shown in an engine which I saw on the Providence and Bristol road the other day, made by the Mason works of Taunton—that is, the possibility of making an engine upon the idea of a wide firebox which will overlap the drivers. It was a very ugly-looking affair; but "the proof of the pudding is in the eating." Mason, in putting the wheels under the tender, brought his weight upon his drivers—that is, his engine, as I look at it, is with the pivot under the tender. The whole weight of his machine is upon his drivers, and his drivers are far enough ahead, so that he can do as he chooses with his firebox. If he chooses to spread out wide, he can do it with perfect ease. It seems to me that in these two or three directions it is for you to consider that this matter of combustion must be met; and there is no possible way to meet it except to spread out. You cannot get more by deepening, because you don't have half, nor a quarter, the good that you should obtain from the coal that is burnt now by packing it up in a small area. So that the object of my somewhat rambling remarks would seem to be this:—That the locomotive of the future, as it looks to an outsider in various parts of the world, and looking at steam engineering in all its phases, must be changed in the direction of the spreading out of the furnace.

A LOOK THROUGH THE GREAT OBJECT-GLASS.*

By PROF. C. A. YOUNG.

THE object-glass of the great Lick telescope is now practically completed, and only awaits examination and approval by the experts who are to be appointed by the Lick trustees to test it. As all our readers probably know, this enormous lens, by far the largest ever made, is 36in. in diameter, and has a focal length of 57ft. It is composed of two lenses, of which the front one (outside) is an equiconvex lens of crown glass, while the other is a concave lens of flint glass: one side of this—the one next the eye—is very slightly concave, in fact almost flat; the other, next the crown-glass lens, is considerably concave, the curvature being somewhat deeper than that of the crown-glass surfaces. The inner surfaces of the two lenses are separated by a clear air-space of about 6½in., and there are perforations in the steel cell which allow a free circulation of air between them. The glass discs were made by Feil, of Paris, and they have been figured and worked by our own Clarks at their modest but famous establishment in Cambridgeport.

Through their courtesy, the writer had the privilege of looking through this most powerful of all existing telescopes a few evenings ago, in company with some of his astronomical friends, and although the state of the air was not all that could be desired, and the moonlight interfered somewhat with the view of faint objects, yet the experience was something to be long remembered.

The instrument is mounted on a temporary stand, first erected for the testing of the 30in. Poulkowa glass, which, until within a week or two, was the largest in existence. In constructing this mounting, the Clarks, however, had also the Lick instrument in mind, and proportioned the parts accordingly. A huge pyramid of brickwork rises some 30ft. from the ground, and bears on its sloping top a sort of cast-iron saddle with the bearings of the polar axis, which is 10in. or 12in. in diameter, and some 12ft. long. It carries at the upper end the declination axis, of about the same dimensions as itself. The tube of the telescope, an immense cylinder of boiler-iron, 42in. in diameter, and nearly 60ft. long, is secured to one end of the declination axis, as near the pier as possible; and the other end of the axis, protruding awkwardly, is loaded with counterpoising weights.

As we came into the garden where the instrument is placed, the great tube towered high and white in the moonlight far above the surrounding trees and buildings, directed towards the bright star Alphacca, the gem of the Northern Crown. At the lower end, two or three men were sitting around; and one was lying on the ground, craning his neck to look into the eyepiece, which came a little too low to allow the use of the chair. The observer was Mr. Alvan G. Clark, the youngest member of the firm, and the one who at present does most of the purely optical work. He was trying to see how the figure of the lens had been affected by the delicate work of the last two or three days. The other on-lookers were George Clark, his older brother, the mechanician of the firm, and the venerable Alvan Clark, sen., their father, with one or two of the most trusted workmen of the establishment. Before long we were joined also by Professors Pickering and Langley.

In a few minutes the glass was turned to a neighbouring star, γ Coronæ, which is an exceedingly close double, its components not being more than about ¼″ apart. Although the roughly mounted telescope vibrated a good deal in the breeze, and the air was rather unsteady, so that the star blazed and danced about; yet under a power of about a thousand the two components were distinctly separated with a fine dark line between them. I had seen the object just as plainly with a different instrument not very long ago, but not so impressively: the stars had no such brightness. In fact, the Lick object-glass gathers in from any star nearly two and a half times the light collected by the Princeton glass, the areas of the lenses being as 1,296 to 529.

Everything about the image showed that the figure of the lenses is excellent, and the aberrations nicely corrected. Nobody but a Clark would think he could improve it "just the least bit."

Then we turned to the great cluster in Hercules, and wished that for a few moments we could extinguish the moon. For although the telescope resolved the cluster in a marvellous manner, and showed its own optical excellence in the pefection of the images, yet the moonlight and the haze robbed the object of its glory. The blaze and glow of the innumerable stars upon the black background of a darker night were missing.

The instrument was next directed upon ζ Herculis, an interesting and rapidly moving binary; and then upon the great white star Vega, or α Lyræ, at that time nearly in the zenith, and admirably adapted for testing purposes. This defied the moonlight: one understood now what Herschel meant in speaking of Sirius coming into the field of one of his great reflectors "*like sunrise.*"

And yet, when the glorious star was passing through the field, one could see at the same time, and without any need of hiding the large luminary, the delicate companion discovered by Winnecke long ago with the old Poulkowa telescope: hitherto it has been possible to see this, even in the very largest telescopes, only when the great star was put out of the field. Of course we do not refer to the old and well-known companion, easily seen in all telescopes of any size above 4in. In the great telescope, that was about as bright as the polar star to the naked eye. Nothing was seen, however, of other little stars that have been reported by certain amateurs as visible in this field of view.

On withdrawing the eyepiece, and placing the eye in the focus of the great lens, one could examine it critically for every vein and flaw and air-bubble. It is rare that one finds a pair of discs so perfect. Under the trying test, one could indeed make out a few little wisps of veiny structure, and one small dark speck that was easily visible; but there was nothing that could do any mischief to the image of a star.

ε Lyræ, the exquisite double-double very near to Vega, was next looked at; the only notable thing being that certain little stars between the two pairs, which in instruments large, but not *so* large, are rather hard to see even in a dark night, were easy and almost conspicuous, notwithstanding the moonlight.

The "Ring-nebula" was very pretty; but a mere pale ghost of what it would have been on a moonless sky.

α Herculis showed its contrasting colours finely; and by putting the large star out of sight, we could see a little companion which Mr. A. G. Clark has just discovered. It is in the *n.p.* quadrant, and about 10″ or 12″ distant from the larger star of the pair. Probably it can be seen by some of the other large telescopes under favourable conditions; but it is certainly a full magnitude smaller than Winnecke's companion of Vega.

A number of other objects were looked at; but nothing that calls for special notice here.

The elder Clark remained present during the whole evening, and, despite his eighty-three years, examined every object, even when the position required was such as to cramp and try younger limbs and muscles. His eye seems to have lost little of its original keenness, though trembling hands and easy weariness no longer permit him to do much actual labour. But what a step from his first 3in. glass made for Dr. Wells of Salem (in 1850, I think) to this great 3ft. lens!

Towards midnight, when the time came to leave off work, the telescope was turned vertically, object-glass down, and strapped tightly to the pier:

* From the *Popular Science News*, Boston, Mass.

in this position the lens was about 18in. from the ground, on which was a floor of heavy plank. A sort of low baggage-truck was then rolled under the telescope, and, by a stout screw underneath, the floor of the truck was raised until it touched the cell which holds the lenses. On loosening the screws which hold the cell to the tube, the weight of the object-glass, about 750lb, settles down upon the truck, and when everything is clear, three men haul it away along a plank-walk, and store it, with its sixty thousand dollars burden, in the little fire-proof building where the grinding and polishing are done.

While the making of the great lens has gone on thus rapidly and successfully since the crown-glass disc was received, only about a year ago, the opticians have just met a serious set-back in the matter of the "photographic corrector," which was to go with it, and fit it for astronomical photography. The disc out of which this lens was to be made was received from Feil last spring. Examination by polarised light showed that the glass was under a severe internal strain, due to insufficient annealing; and the Clarks at once notified the maker of the fact, and told him that they feared the disc would not bear working. The maker, however, thought otherwise, and directed them to proceed at his risk, which they did. The upshot of it was, that a few days ago the disc burst into three pieces while on the grinding-tool; and so, of course, that part of the work will have to be postponed until a new disc can be obtained; how long that will take, no one can predict with certainty.

This will not, however, delay the erection of the instrument. Its mounting is already well under way in the shops of Warner and Swazey, at Cleveland; and, unless there is some unexpected delay about the observatory building and dome, there is every reason to expect that within a year from now this monstrous piece of astronomical artillery will have opened fire upon the heavens from its chosen mountain-top. We may well hope that under the able direction of Prof. Holden, it will prove effective.

USEFUL AND SCIENTIFIC NOTES.

THE Chicago Academy of Sciences has been presented with the bones of an elephant supposed to be the *Elephas primigenius*, by Dr. E. W. Andrews. The remains were discovered in the eastern part of Washington Territory. Among them is one animal of enormous size which is quite as large as Ward's Siberian Mammoth. Its tusk is 10ft. in length, pelvis 63in. in length, and the longest rib found 54·6in. long. No complete skeleton was found.

Light and Slack Coupling.—Some interesting experiments have been made in the United States to test the effect of open and close couplings upon the ability of a locomotive to start a train. This has been a matter of hot dispute for a good while, and it is strange that the matter was not long ago determined by actual experiments. At Burlington it was found that the locomotive could start level 49 loaded cars close coupled and 48 with ordinary link and pin coupling. Afterwards, on the grade, the engine started 38 cars with each method of coupling. The general results seem to establish the conclusion that the loose slack of open couplings is of no advantage in starting a long and heavy train, and that the draw-bar springs give all the slack that is needed. This is opposed to the results of English experience, which shows that slack in the couplings is essential to the starting of heavy trains.

PROF. DR. MEIDINGER states that Prof. Poleck has discovered that timber procured for him purporting to be winter-felled wood, was in reality raft timber floated down the river, and he has ascertained that timber which has been thus immersed is no longer liable to the attack of dry rot. So much so is this the case that in Alsace it is customary to specify that only raft timber shall be employed. The water slowly dissolves out the albumen and salts, and thus deprives the fungus of the nutriment needful for its development. A French savant has found by experiment that whereas fresh sawdust, when buried in damp earth, rots away in a few years, sawdust which has been soaked for some time in water, and has been thereby deprived of soluble matters, will remain in the ground under similar circumstances wholly unchanged, and only slightly tinged on the exterior with earthy matters dissolved from the soil.

CHLORIDE of tin as a disinfectant is recommended by Dr. Abbot as being more active than zinc chloride, copper sulphate, zinc sulphate, or ferric sulphate, spores being killed after exposure to one per cent. solution for two hours. It is cheap, tolerably safe, and will not corrode lead pipes. It is advised, when required to be kept, and to prevent formation of insoluble oxichloride, to mix it with an equal quantity of ammonium chloride.

SCIENTIFIC SOCIETIES.

WESTERN MICROSCOPICAL CLUB.

THE members of this club met recently at the house of W White, Esq., of Cambridge-gardens, Notting-hill, to listen to the exposition on the subject of "Alkaloids," given by Mr. A. W. Gerrard, F.C.S., of University College. Mr. Gerrard defined alkaloids as bodies containing carbon, hydrogen, and nitrogen, and, in some cases, oxygen also. They all have an alkaline reaction, and form compounds with acids. On heating them strongly they burn away entirely, leaving no residue. With certain group reagents, such as Meyer's solution, phosphomolybdate of sodium, &c., they all give definite reactions. Most of them are extremely poisonous, bitter, and acrid. Mr. Gerrard then gave an individual account of many of the chief alkaloids, tracing their derivation, history, and properties. A new one that he had just discovered was ulexine. It is present in the seeds of the furze known as gorse and whin. It is not present in the furze tops, hence the immunity of the cattle who are sometimes fed upon these. It is a poisonous principle, having a paralysing action, and it may, perhaps, prove of service in nervous disorders. This alkaloid is very soluble in water, and gives, with ferric chloride, a distinctive dark red colour, by means of which as little as the hundredth of a grain may be recognised. Some of the various alkaloids present in opium were next referred to, especial attention being given to morphine, the distinctive tests of which were well shown. Cocaine, which has of late made such a stir in the medical world, received Mr. Gerrard's attention. Its power of obliterating all sensation from the mucous surfaces of the mouth, tongue, and eye was practically tested by some of the members present. As evidence of its increased use a grain, some few months ago, cost wholesale 30 pence; now it can be had for 2d. At present we have no distinctive colour reaction for cocaine. Mr. Gerrard then graphically described his isolation of the alkaloid pilocarpine, and the trial of its production of profuse perspiration upon himself. One-third of a grain will produce a profuse perspiration lasting for hours; but if during this time 1-25th of a grain of atropine be injected into the patient's system, the perspiration is almost immediately stopped. Pilocarpine has a reverse action to that of belladonna, so that the one acts as an antidote to the other in cases of poisoning by either. Physostigmine, and its preparation from the Calabar bean, so celebrated from its use as a fetish ordeal amongst some African tribes, were then described. A minute portion placed in the eye contracts the pupil to a mere pin's point in size, while atropine, on the other hand, expands the pupil.

Gelsemina gives the same chemical reactions as strychnia, though its compounds do not. The pods of strophanthus, a new drug from Central Africa, were next shown. The seeds bear a beautiful feather-like appendage, and yield strophanthin, a glucoide stated to be superior to digitaline for use in heart disease, not being cumulative in its effects. It is strange that brucia, like the poison curare, may be swallowed in safety, though a mere trace kills if injected into the blood. A rapid glance was given at some of the numerous and useful alkaloids extracted from the cinchona barks, quinine naturally demanding most attention. The exposition of Mr. Gerrard was well illustrated by specimens of the alkaloids, their salts, the plants from which they are obtained, and by practical demonstrations of their leading reactions and microscopical appearance. A discussion followed. Dr. Thudichum referred to opium-smoking, stating that it was the morphia volatilised which produced the characteristic effects. In his opinion, pilocarpine, gelsemina, and strophanthine were too uncertain and poisonous in their action to be practically useful. In regard to aconitine, Dr. Thudichum knew of six different varieties as sold, possessing different chemical reactions, and varying in destructive power from 1 to 700; so that it is pretty certain that so far pure aconitine is little known.

THE meteor which fell near Claysville, Washington county, Pa., September 14, 1885, was found recently by Professor J. Emerick, of William and Mary College. The stone was found imbedded at the base of a hill. It weighed about 200 tons, but was cracked into pieces by contact with a stratum of limestone. Its composition was chromium, nickel, aluminium, copper, magnesium, tin, and other metals and metalloids. It contained 87 per cent. of iron in a metallic state. Its specific gravity was 7,412. Its elevation above the earth's surface was established at 52 miles, its path nearly horizontal, its flight between five and ten seconds, its visible path 150 miles, and its velocity 15 to 20 miles per second.

SCIENTIFIC NEWS.

THE following elements of Comet Finlay have been received from Boston, U.S., and are given in Dun Echt Circular No. 126: T = 1886, Nov. 20·99 G.M.T.; $\pi - \Omega$ 301° 25′; Ω 51° 26′; i 3° 19′—mean equinox 1886; log. q 0·05865. Ephemeris for Greenwich midnight reads Oct. 15, 17h. 55m. 36s., S. Dec. 26° 43′; brightness increasing. The comet is probably identical with 1844 I.

Dun Echt Circular No. 127 contains a code telegram from Dr. Krueger, of Kiel, which announces that a comet was discovered by Hartwig (presumably of Bamberg), on Oct. 5, G.M.T. 16h. 2m., R.A. 10h. 37m. 24s., N. Dec. 1° 3′.

Minor planet No. 260 was discovered by Dr. J. Palisa, of Vienna, on the 3rd inst. It is the fifty-fifth planetoid discovered by that indefatigable observer.

Chemical science in Canada has sustained a serious loss by the death, at an early age, of Prof. H. A. Bayne, Ph.D., of the Royal Military College, Kingston, Ontario. Dr. Bayne was a native of Nova Scotia, and graduated in Arts at Dalhousie College, Halifax, afterwards studying under Wiedemann in Leipzig, Bunsen in Heidelberg, and Dumas in Paris.

The town clerk of Stafford announces that Mr. C. L. Wragge, formerly of Oakamoor, Staffordshire, and now of the Torrens Observatory, near Adelaide, South Australia, has made over absolutely to the Corporation of Stafford the collection of natural and other objects and curiosities which has been for some time in the custody of the corporation. The collection is to be known, as heretofore, as the Wragge Museum, and the donor reserves to himself the position of honorary curator, with power to appoint one of his sons to succeed him. The honorary curator is to have free and unrestricted access to the collection at all reasonable times, and the corporation undertakes to keep it in good order and condition.

It is stated that Sir Henry Roscoe, owing to his Parliamentary duties, will resign his position at Owens College, Manchester; but it is hoped that if he is compelled to give up the work of personal teaching he may still be able to deliver the most important portion of the course of lectures, and at least retain his official connection with the Victoria University.

The specifications of the patents of the Volta Graphophone Co. of Alexandria, Virginia, have been recently published. Those relating to the reproduction of sound are numbered respectively 6027, 6042, 6047, and 6062, all bearing date May 4, 1886. We have already given an account of the graphophone in No. 1116, page 529, and also of the other inventions of Messrs. Bell and Taintor on page 341, last volume. The first specification relates to the production in a solid substance of inequalities corresponding to the forms of sound vibrations, and reproducing the sounds from the wax record. These sounds are transmitted through a tube to a double earpiece combined with a mouthpiece which includes the nose of the user. No fewer than 113 claims are appended to this specification. The second invention relates to a means of causing the "record" to act directly upon a gas or liquid, in which it induces sonorous vibrations. The third invention relates to a method of reproducing the sounds by the aid of magnetism, a copper electrotype being taken of the wax record. The fourth specification describes an invention in which the record is a glass disc coated with a sensitive film, and the sounds are transmitted and recorded by radiant energy.

An electric log for the use of ships has been recently described as a novelty. We described one in No. 775, for Jan. 30, 1880, and we believe Kelway's was invented before that date.

The heat-indicating paint to which attention has recently been drawn is not altogether new, for it appears that something of the kind was patented in the United States by Profs. G. F. Barker and Alfred M. Mayer in 1873. They used the double iodides of mercury and copper, of mercury and silver, and similar compounds

having the property of temporarily changing their colour when exposed to certain temperatures.

According to Mr. J. R. Wigham, the lighthouse at Tory Island is to have a triform lantern with six lenses in each tier, the lenses being nearly 6ft. square and of longer focus than any hitherto constructed. These lenses will transmit about twice as much light as any now in use, and with one of Mr. Wigham's large gas burners the resultant beam will be equivalent to about four million sperm candles, the illuminated surface of the lantern being 18ft. in height by 6ft. broad. The light at Tory Island, which is off the north coast of Ireland, will thus be the largest in the world.

The Midland Railway Company are, it is stated, about to adopt cast steel disc wheels with flanges cast on, for their new coaches and waggons.

Dr. Alex. Edington, assistant to the professor of surgery at Edinburgh University, says that a jelly derived from Irish moss is much less opaque than agar-agar and more nutritious, and is therefore to be recommended as a culture medium for micro-organisms capable of withstanding high pressure. He macerates 2oz. of the finest selected Irish moss in 18oz. of water, and after leaving it for a night, keeps it in the steam steriliser at about 212° Fahr. for an hour and a half, stirring occasionally. It is then strained through a felt bag two or three times, when the jelly thus obtained will be found on cooling merely to gelatinise, yet able to withstand a temperature of 87° Fahr. before liquefying; but if it is evaporated, it is found to be capable of withstanding a temperature between 122° and 131° Fahr. before liquefying. In this state, if a test-tube be filled with it, it is found to present the appearance of water with only a slight degree of haziness. In order to render this more nutritious, and so better fitted for the requirements of the growth of the generality of micro-organisms, the materials recommended by Dr. Klein may be added —namely, beef peptone and ordinary cane sugar. Add to the jelly 2 per cent. of the former and 1 per cent of the latter, and the result is a jelly almost as bright as nutrient gelatine and infinitely more so than agar, while the simple method of preparation and the price have much to recommend it.

Mr. George P. Merrill, in the *American Journal of Science* for September, has a note on the composition of certain "pliocene sandstones" from Montana and Idaho. A microscopic examination discloses the fact that the stones consist largely of minute flakes of pumiceous glass. The specimens are fully described, and we are informed that in Kansas and Nebraska these dusts are collected and sold as "diamond polishing powders," and are used in the preparation of the "scouring soap" commonly called geyserite.

Dr. Von Holst says that nitro-glycerine is very useful in heart-disease, especially where there is no serious organic change. In angina pectoris the drug gives relief and sometimes produces a permanent cure, and he recommends it in preference to camphor or musk where weakness of the heart threatens immediate danger. He uses a 1 per cent. alcoholic solution, and administers from one to six drops three times a day.

The "Programme" of the Franklin Institute of the State of Pennsylvania for the session 1886-7 shows that the managers are determined to place it in a foremost position as a teaching institute as well as a library, which latter we may note is exclusively scientific and technical in character. Besides the classes held at the institute, there is a course of lectures on a variety of subjects of a scientific character, which are delivered during the winter months.

The excellent "Illustrated Handbook of Victoria," issued in connection with the Colonial and Indian Exhibition, is being distributed to every institution, society, and library in the kingdom, in order that information as to that important colony may be within reach of all. It is well printed and freely illustrated.

The Halifax Co-operative Society have decided to light up their very extensive shops and workrooms by electric light, and have entrusted the work to Blakey, Emmott, and Co., Limited, of Halifax.

The London Stereoscopic Company have recently brought out the "Exhibition Album," containing the principal prize photographs shown at the Amateur Photographic Exhibition, held under the company's auspices in May last. It will be remembered that this exhibition was given in aid of the Princess Frederica's Home for Women. Unfortunately, although the exhibition was a great success as far as the work shown went, no profit was made, and the Stereoscopic Company found themselves out of pocket. However, rather than disappoint the charity, the directors voted the home a handsome donation. As to the album, it is hard, where all the work is so good, to single out pictures of any one exhibitor; but we think it may be fairly conceded that Lady Roscoe and Dr. Alabone divide the honours. The Stereoscopic Company certainly deserve the support of all amateur photographers. There is little doubt that by their system of gratuitous instruction, practised at the company's studios, they have done much to foster the pursuit amongst amateurs.

USEFUL AND SCIENTIFIC NOTES.

A New Lantern.—Mr. W. C. Hughes, of Brewster House, Kingsland, has constructed a fine optical lantern for vertical and horizontal projections, for Prof. W. Lant Carpenter, B.A., F.C.S., of the School of Electrical Engineering, as a gift to the Royal Victoria Hall, Waterloo-road, for the purpose of illustrating science lectures. The first experiments were made with the new lantern on Tuesday evening last week, before an appreciative and crowded audience, consisting principally of the working classes from the surrounding neighbourhood. The experiments were most brilliant and successful, and Mr. Carpenter and Mr. Hughes were loudly applauded for the magnificent results obtained by each experiment, such as the decomposition of water, the chemical action of certain fluids on stagnant and impure water, together with magnetic and electrical forces, shown by the aid of the instrument on a disc 24ft. to 30ft. in diameter, at a distance of over 80ft., from the balcony of the great theatre to the stage, was considered by experts present a remarkable projection. When it is remembered that much of the experimental apparatus thus magnified and defined through an erecting prism, and by means of reflected light, which loses 50 per cent. of its potency, the difficulties with which Mr. Hughes had to contend will be readily understood.

The Kinetic Theory of Gases.—In a communication to the Physical Section of the Paris Academy of Sciences recently published, M. Hirn presented a copy of a new work entitled "Modern Kinetics and the Dynamism of the Future," the object of which is to show that the modern kinetic theory of gases, and the other like theories which pretend to explain the phenomena of the universe by the invisible movements of matter, are incorrect. M. Hirn has published a series of studies relating to this subject; but the book in question contains in clear and popular language all the arguments which "henceforth," to use the author's words, "render unsustainable the kinetic theory of gases." M. Hirn remarked to the members of the Academy that he did not flatter himself on being able to convince all of what they ought to have been themselves convinced of for a long time, because *à priori* conceptions have great vitality; but he expressed the belief that time would cause to disappear from modern science the kinetic theory of gases, as an error as monstrous as others which have been relegated to the limbo of the past.

TWO of the largest castings in the world are said to be at Nara and Kamakura, Japan, the one at the latter place being 47ft. high, and the other, at Nara, being 53½ft. from the base to the crown of its head. The statue at Nara is supposed to have been erected in the eighth century, but it was destroyed and recast about 700 years ago. In endeavouring to recast it several mishaps occurred, and when at last success came, some thousand tons of charcoal had been used. The casting, which an American contemporary says is an alloy of iron, gold, tin, and copper, is estimated to weigh 450 tons.

MR. E. D. WASSELL, of Pittsburg, Pa., has invented a new process of welding steel, by which steel bars of any content of carbon can be piled and welded together. The *Engineering and Mining Journal* says he has demonstrated this by making a homogeneous weld of a pile made of bars containing 0·65 per cent. of carbon, and the carbon reduced to any point desired; that is to say, steel of 0·65 per cent. can be reduced to 0·10 per cent. carbon while in the solid form without remelting.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

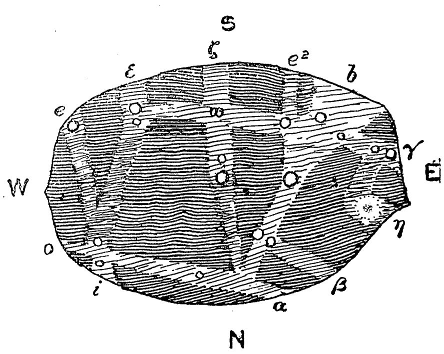
All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

PLATO.

[26359.]—ON p. 107 (letter 26309) Mr. Arthur Mee gives an interesting view of the curious interior of Plato. The objects there shown are the spots 1, 3, 4 and 17, and the sector and streaks e, a_o, β, ε, and ζ. At the time of this observation, the declining altitude of the sun on Plato made it difficult to distinguish distinctly the fainter detail on the floor, particularly on the eastern part, which, for several days before sunset has a whitish appearance, rendering it hard to distinguish the outlines of the streaks there. A few days earlier, Mr. Mee would doubtless have seen more of the



spots and light streaks. The inclosed drawing of the markings in the interior of Plato may be of interest. It was made on the night of September 16th last, 14h. 15m. to 14h. 45m., by means of a 2¾in. refractor and a power of 102. The 18 spots there shown were all quite certainly seen, as were also the streaks.

With reference to some of the markings, I should like to make a few remarks. On the streak ε two spots are shown, Nos. 12 and 14, and from these a light streak of considerable breadth runs northwards to spot 13, situate at the streak i. This is streak g^2, which was discovered, or rather rediscovered, on November 1st, 1873, by Mr. H. Pratt. Somewhat strangely, it appears to have escaped detection during the close and continued scrutiny which the floor underwent in the course of the years 1869—71. Of late years this streak has always been an easy feature to see at any time, except close to sunrise or sunset, and it is in fact the westernmost of the four light streaks shown in the first edition of Beer and Mädler's map. We have here then an object which evidently, from the small amount of detail seen by them, a bright and conspicuous feature in the time of Beer and Mädler, afterwards faded away so much as to elude detection during the celebrated survey of 1869—71, and has since resumed much of its former consequence. And this apparent alteration cannot be due to changes in appearance caused by differences of illumination or libration, since the streak is now plain from near sunrise to near sunset, and whether libration is north or south, whilst under any condition in 1869—71 it was not visible at all, or, at least, was not seen.

The bright, fan-shaped marking radiating from spot No. 4, known as the Sector, has of late years assumed a very complex structure, though in 1869—71 it was mostly seen of an almost uniform tint. Some of the differences in brightness are shown in the sketch.

The streak C^2, shown connecting the two streaks γ and η, is worthy of remark. The first indication of its existence occurs in a drawing by Mr. T. P. Gray, made on Jan. 12th, 1881. It is now nearly always visible, and it is not a difficult object. A continuation of it northwards to the north border was detected by the writer with only 2¾in. aperture, and afterwards confirmed with 5¼in.

Spot 12, the northernmost of the two shown on streak ε, has increased much in plainness during the last few years. Its visibility in 1869—71 was only ·026, whilst in 1879—82 it had increased to ·351; 1·000 representing the brightness of spot No. 1. **A. Stanley Williams.**

PLATO.

[26360.]—In reply to Mr. Mee (letter 26309), I regret to be unable to respond to his request respecting this formation, my last drawing being dated 29th December, 1881. On that occasion five of the principal spots on the floor (those shown in his sketch and one near the N.E. wall) were seen as crater cones with a 4in. Cooke achromatic. About forty in all have been observed and verified by subsequent observers. Though most of them are very difficult objects, Mr. Mee ought to see many more than four with his $8\frac{1}{2}$in. Calver, especially as he seems to be remarkably successful as regards the light streaks. Under good conditions, I have seen sixteen light spots on the floor at the same time with a $3\frac{3}{8}$ Cooke. **T. Gwyn Elger.**

Kempston, Beds, Oct. 7th.

POLARISATION OF LIGHT—ACTION OF LIGHT ON THE EYE.—V.

[26361.]—Polarisation may be described as being "the diminution of the brightness of a reflected or refracted ray, which is due to the variation of the angle at which the ray falls upon the surface.

Thus described, it may seem to be a very unimportant matter; but still it gives rise to most surprising phenomena. We might illustrate, as follows, the general effect of diminution of light. If a sheet of white paper is painted with different shades of Indian ink, its whiteness is only partially visible, and more so in some places than in others, owing to being only partially seen through the films of ink which cover it, thereby producing every variety of picture.

In explaining polarisation by the undulatory theory, we suppose that the diminution of brightness is due to the diminution of the intensity of the vibrations which cause it to be visible, and it becomes necessary to inquire in *what direction* these vibrations take place.

Newton teaches that, when a wave is passing through any elastic medium whatever, the displacement of vibrating particles from their place of rest is wholly in the direction in which the wave moves—that is, the vibrations are wholly longitudinal. But modern writers teach that, in the case of light, they are wholly at right angles to the direction of the wave—that is, are transversal.

These two doctrines, as they stand, are wholly irreconcileable, and so, if modern teaching is strictly true, Newton must, for once, have been caught tripping in his treatment of forces.

It may, however, happen in this case, as it does in most others, that a view put forth by able men has a great deal of truth in it, but is found afterwards to need some modification, as happens in geology, &c.; and so most likely it will come to pass, sooner or later, that mathematicians will admit that there are not only transversal vibrations, but longitudinal ones also, as happens more or less in every other case where there are transversal vibrations.

Now, according to Newton and to all dynamical principles, a central force, considered as a point acting upon another point, can only cause motion in the direction of the line joining the two points; so that when the motion is a *vibration*, the particle in motion always vibrates backwards and forwards in the direction of the force; that is, the vibrations are wholly longitudinal. But, in matter of fact, the motion of a point of ether is not produced by the action of a single point only upon it, but of every point in the source of light from which a line can be drawn to it, and its whole motion is the united effect of all these.

Now, in the case of the sun for example, if it were perfectly spherical, and its activity uniform all over its surface, there would be nothing but longitudinal motions produced; but as these things are not so, the motion will not be wholly in the direction of the sun's centre, but may be resolved into three, one of them in that direction; that is, a longitudinal motion, and two others at right angles to it. The case may be compared with the motion of the moon when we take into account the non-sphericity of the earth.

It will be asked then, "How is it that writers have come to the conclusion that there are only transversal vibrations"? If they had used only dynamical considerations, they would, doubtless, have come to the same conclusion as above; but instead of this they reason as follows:—"It is easily shown from certain facts which are observed in the polarisation of light, that in common light transversal vibrations exist, and that when these cease, light is no longer visible; *ergo*, they are the only ones which exist."

The minor premiss is here certainly true; but we may demur to the conclusion. In the next letter we shall try to establish, by experiment, the view as to vibrations above proposed. In the mean while we may say that the way in which light acts upon the eye is as follows:—When a ray enters the eye it falls upon the retina at right angles, or nearly so, and, therefore, the transversal vibrations have the effect of a *friction* upon the retina; but in order that friction may take effect it must be accompanied by pressure upon the surface to make it effectual, and this is just what the longitudinal vibration supplies. Each kind of motion, therefore, has its use in causing vision, and perhaps if either of them were withdrawn we should see no light.

And this will, perhaps, explain a fact well known to star-gazers, that it is easier to see faint stars with averted vision than with direct. The account usually given, and which naturally suggests itself, is this—that in averted vision the ray falls upon a more sensitive part of the retina. This, however, implies that the parts of the eye which are not commonly used are better adapted for acute vision than those which are—an arrangement very unlike the usual operations of nature. We might, therefore, suggest that when there is averted vision the ray falls obliquely upon the retina, and the longitudinal vibrations may be resolved into others parallel and perpendicular to the normal, of which the latter will have a frictional effect, increasing the effect of the transversal vibrations which naturally exist. **W. G. Penny.**

(*To be continued.*)

CONCERNING CHAMBER ORGANS, AND HARMONIUM PLAYING.

[26362.]—I have read our good friend "Uranium's" able letter (26336) with much pleasure and interest, and it is gratifying to find that there are so many points of hearty agreement between us. That he should agree with all my statements and opinions, would be to expect too much from human nature. I, for one, am thankful for small mercies. The greater part of "Uranium's" remarks require no comment from me; and I can only recommend his views to the best consideration of the readers of the English Mechanic.

On the question of cost, as raised by "Uranium," I greatly fear he has placed it far too low. A first-rate organ builder would never undertake to construct a chamber organ of eighteen speaking stops, on the lines laid down in my "Notes of the Chamber Organ," for twice the sum named. The cost of the pipe organ will always militate against its free introduction in private houses, at least in anything approaching a perfect form; yet to my knowledge large sums have been expended by private gentlemen in procuring chamber organs the reverse of perfect from my point of view.

In treating of the chamber organ, it was absolutely necessary for me to adopt a certain size or type of instrument on which to hang my remarks and arguments; otherwise everything would have come out in confusion, and all point would have been lost. After careful consideration, I decided to fix on a type embracing between fifteen and twenty speaking stops. That this number is not excessive, has, I think, been satisfactorily proved by the specifications of "Chamber Organs" which have recently appeared in these columns. Be that as it may, the type was chosen in the belief that its treatment would prove the most instructive to the general reader, and most useful to the organ builder. Of course all the remarks passed on it are equally applicable to the construction of instruments of both a larger and a smaller size.

Now I come to "Uranium's" reference to my own Chamber Organ. He says:—"Mr. Audsley has several times referred to the organ he is the happy possessor of, and if it agrees with his description, which I would not doubt, it must indeed be nothing short of a marvel, and truly 'a pearl of great price.'" In the course of my "Notes on the Chamber Organ," I have been led to speak of certain details connected with it, chiefly by way of illustration, or with the view of showing that I had proof, satisfactory at least to my own mind, enough to warrant certain emphatic statements there made; but I had no wish to convey an idea that my instrument is a *perfect Chamber Organ*, or up to the standard I now advocate. All I need add is, if I had to build it now, it would be a somewhat different instrument to what it is at the present moment.

I shall indeed be gratified if "Uranium" will pay me a visit, with the view of inspecting and testing my organ, and giving me the pleasure of making his acquaintance. For a few months yet my organ will be in an unfinished state—it is in the process of re-erection—but if "Uranium" will place me in direct communication with himself, I shall not neglect to inform him when the organ is fit for his kind examination. Until then, I beg to thank him, through the medium of a letter, for his extremely kind and courteous allusion to what I have written in these columns. **G. A. Audsley.**

CHAMBER ORGANS.

[26363.]—As I am at present from home, and shall, in all probability, remain so for some weeks, it is out of my power to give much of the information Mr. George Landel asks for. I have frequently been asked to publish a full description of my chamber organ, by musicians who have played upon it; but I have always refrained from doing so, simply because it has so many shortcomings—the result of my ignorance twenty years ago—and fails, in some respects, to fulfil *the conditions* which, in the growth of my knowledge, I now consider imperative with reference to chamber organ building.

If Mr. Landel seriously intends to have all his manual stops of metal, the scales of the nineteen stops in my organ would, if given as he requests, be absolutely useless to him. I have six stops entirely of wood, and the basses of two stops in the same material. It is almost needless to remark that the scales of all the stops are affected by this important proportion of wood tone.

I have great pleasure in hastily answering the queries with which Mr. Landel concludes his courteous letter.

1st. It may be accepted as an axiom that a pipe cannot have too much room to speak in. Large pipes should have a space in front of their mouths about equal to their own diameter; but in Chamber Organ building they have often to be content with half that speaking room. The small pipes are seldom or ever too crowded.

2nd. Arrange the pedal pipes side by side, so that there will always be the interval of a full tone between those adjoining each other, and their quality will not be injuriously affected. It is not good to so plant the pipes that their mouths face each other. Pedal pipes may be laid horizontally with perfect safety if the above conditions are observed.

3rd. If proper wind-trunks are used, the reservoir may be twice the distance given from the wind-chest without any inconvenience. It is a desirable thing to have the reservoir as near the wind-chest as possible, while the feeder and receiver (supply bellows) may be many yards away. **G. A. Audsley.**

[26364.]—The following scales of pipes would suit for the chamber organ Mr. G. Landel intends building:

	Diamiter at CC	Tenor C.	Mid. C.	Treb. C.	C above.
	in.	in.	in.	in.	in.
Open Diap 8ft.	$5\frac{1}{2}$	3	$1\frac{3}{4}$	$1\frac{1}{8}$	$\frac{5}{8}$
Lieblich Gedact 8ft. ...	$3\frac{1}{2}$	$1\frac{3}{4}$	$1\frac{1}{16}$	$\frac{11}{16}$	$\frac{7}{16}$
Dulciana 8ft.	$3\frac{3}{4}$	$2\frac{1}{8}$	$1\frac{5}{16}$	$\frac{3}{4}$	$\frac{7}{16}$
Harmonic Flute 4ft. ...	$2\frac{5}{8}$	$1\frac{3}{4}$	$1\frac{1}{2}$	$\frac{7}{8}$	$\frac{9}{16}$
Piccolo 2ft.	$1\frac{3}{4}$	$1\frac{1}{8}$	$\frac{5}{8}$	$\frac{7}{16}$	$\frac{5}{16}$
Clarionet 8ft.	$1\frac{1}{2}$	$1\frac{1}{8}$			$\frac{13}{16}$
Geigen Principal 8ft. ...	$4\frac{1}{2}$	$2\frac{1}{2}$	$1\frac{1}{2}$	$\frac{15}{16}$	$\frac{9}{16}$
Rohr Flute 8ft.	4	$2\frac{1}{4}$	$1\frac{7}{16}$	$\frac{7}{8}$	$\frac{9}{16}$
Gamba 8ft.	4	$2\frac{1}{4}$	$1\frac{3}{8}$	$\frac{7}{8}$	$\frac{1}{2}$
Voix Celeste 8ft.	$3\frac{1}{2}$	2	$1\frac{1}{4}$	$\frac{11}{16}$	$\frac{3}{8}$
Keraulophon 8ft.	same as Voix Celeste				
Gemshorn 4ft.	$2\frac{1}{2}$	$1\frac{1}{2}$	$\frac{15}{16}$	$\frac{9}{16}$	$\frac{3}{8}$
Flautina 2ft.	$1\frac{1}{2}$	$\frac{15}{16}$	$\frac{9}{16}$	$\frac{3}{8}$	$\frac{1}{4}$
Oboe (Bassoon Bass) 8ft.	$2\frac{3}{4}$	$2\frac{1}{2}$	$2\frac{1}{16}$	$1\frac{9}{16}$	$1\frac{1}{4}$

If Mr. G. Landel will advertise his address in Address column, I will give him all information as to cost, &c. **G. S.**

[26365.]—I have read with more than usual interest the admirable and original "Notes on a Chamber Organ," by Mr. G. A. Audsley, which have lately appeared in your pages. The subject is one of immense importance to all organists, organ-builders, and, indeed, to musical amateurs generally.

What Mr. Audsley says concerning the present state of the chamber organ is so obviously true, that it is a marvel to me no one has before ventured to express publicly opinions on this subject, which must be shared by every true and thinking musician.

Who of us has not wondered at such a waste of power exhibited by the late Dr. Wesley's "Pieces for a Chamber Organ"? What kind of instrument could he have intended them for? Surely not that miserable abortion, that excruciating machine, the *ordinary* chamber organ? If so, were these lovely pieces only perpetrated as a *grim joke*—as the sarcastic protest of a great man against a musical abomination? Perhaps so. Dr. Wesley possibly never had the felicity of seeing, hearing, and playing upon Mr. Audsley's chamber organ. This has been my happy lot.

It may interest "Country Solicitor" and your

other readers to hear a musician's opinion of this remarkable and unrivalled chamber organ.

Mr. Audsley has very well and most eloquently described some of its many beauties, but his description is but a poor one when compared with my vivid recollection of a visit I paid to this instrument a short time ago. I can assure everyone that nothing ever gave me greater astonishment, or a keener sense of true artistic pleasure. Its expression is almost as boundless as the resources of a full orchestra, and its tone is pleasant to listen to in any part of the room. A blind man might easily imagine himself to be in a cathedral or large concert room. It is an organ which requires much "knowing" on the organist's part, and I must confess I was much confused at first; but before the evening was over I found myself managing the organ part of several concerted pieces with the greatest ease and facility. May I soon have the pleasure of playing upon it again!

Charles W. Pearce,

Mus. Doc. Cantab., Member of the Council and Fellow of the College of Organists, Organist of St. Clement's, Eastcheap, &c.

PIPE ORGANS AND FREE REED INSTRUMENTS.

[26366.]—I DO not think the most ardent admirer of the free-reed instrument, whether you call it a vocalion, an American organ, or a harmonium, can expect more from Mr. Audsley than he says in his letter on p. 108. The possessor of a pipe organ such as Mr. Audsley owns is not likely to envy "Country Solicitor" with his Mustel, for really there is no comparison. The only advantages possessed by the harmonium, to take the best known type of free-reed instruments, are expression and portability. The latter is an unknown advantage —depending altogether on private circumstances: a Mustel is more portable than a pipe organ of two manuals and a dozen stops; but then portability is scarcely in question. The one advantage possessed by "Country Solicitor's" Mustel is its adaptability to expression—adaptability because it is possible to produce on that what cannot be achieved on any pipe organ. The question then arises whether the expression which it is possible to put into a harmonium—it won't come out unless you put it in—is worth more than the grandeur and beauty of the tones from a pipe organ. In the one case coming to purely mechanical details you have an instrument which is to a certain extent like the concertina,—you can vary the pressure of the wind, and emphasise all or any of the notes, whereas in the pipe organ you are limited for your expression to the action of the swell; and, as I understand it, Mr. Audsley is endeavouring to show how the pipe organ may be made more expressive—knowing very well that no musician would hesitate for a second as to his choice when price is not to be considered. The pipe organ is not devoid of all expression when an artist is manipulating the claviers; but at present it is not the equal of the free reed instrument in that particular. Still, as most of your readers know, I have been an ardent supporter of the American organ, and I am fain to confess that if portability is out of the question, I should shelve the "expression" and vote for the pipes. But price steps in—and room. It is no use cramping up a pipe organ: it must have room; hence the majority of people will prefer a reed organ, and then, if they want it as a musical instrument, they had better dispense with the pedals, which are really too much for most rooms, and rob the performer of the greatest advantage possessed by the harmonium type of reed instruments. Pedals to an American organ, or a harmonium, serve a legitimate purpose when the instrument is used merely for practice; but the reed instrument, to compete successfully with the small chamber organ, must have two manuals and no "pedal department," as Mr. Audsley says, and then, while it remains an expressive instrument, it cannot compare with the pipe organ—it must always be "deficient in grandeur." There seems no possibility of rendering the pipe organ truly expressive. If I remember rightly, our old friend, the late "Harmonious Blacksmith," was more than "savage" at the thought that there was no way out of that difficulty, and I am curious to know how Mr. Audsley proposes to give us the capability of expression with the grand tones of the pipes. I know he is *facile princeps* in this matter—a genuine amateur, in the proper sense of the word—and I should be glad if he could suggest or devise any means of giving to the pipe organ the power of expression which is undoubtedly possessed by the harmonium in common with 'Arry's concertina. That accomplished, the king of instruments would become emperor, and Cæsar would reign triumphant. I think I have contrived to "second" the remarks of our friend "Uranium" (p. 130), though I cannot altogether agree with him that the reed organ exists "on suffrage." I think it supplies a want and fills a place; but those to whom money is not an object will, if they are musicians, always (as they have hitherto done) prefer a pipe organ. I am so catholic that I think a tin whistle properly played is better than nothing at all.

Organon.

TO PIANOFORTE TUNERS—KNOW THE PITCH OF YOUR TUNING HAMMER.

[26367.]—BEING at a loss for my tuning fork more than once, the idea struck me I should make use of the hammer. Put the hammer on a pin as lightly as is safe, and strike it on the end of the handle with your wedge, and it will produce a distinct note. My ordinary one, a 6in. Reynolds, is centre F natural when the instrument is to Phil. pitch. Make your F to this or any note your hammer sounds, and you have a handy fork.

London. **W. H. Nye.**

EGYPTOLOGY.

[26368.]—THE Samaritan version of the Old Testament gives the passage in Exodus "the sojourning of the children of Israel in Egypt was 430 years" as "in Egypt *and Canaan*," referring, it is generally supposed, to the wanderings of Abraham and his descendants in this land. This is in agreement with what St. Paul says, that the covenant made with Abraham "the law, which was 400 years after," could not annul, and, though a chance allusion like this is not to be taken as strict chronology, we may reasonably suppose that St. Paul quoted the generally received reckoning, and it is, I believe, now usually held that the period from Jacob's immigration to the Exodus was about half the 430 years. Assuming that Jacob's clan of 70 persons made 35 pairs, and giving 25 years to a generation (enough for an Eastern climate), and an increase of fourfold in each generation (again not extravagant when we know that their surroundings are favourable, and are told that they multiplied unusually quick), "Memnon" will find that in 200 years only they would number considerably over two millions, quite enough to furnish 600,000 men of "20 years old and upwards," which was the customary age for "bearing arms."

Dr. Colenso thought he had made a point when he wrote that the account of the Exodus could not be true because the Israelites were said to have come forth in the fourth generation, and from reduplications could not possibly multiply 70 into 600,000. He appears to have overlooked the obvious reply that Moses and Aaron, and probably other leaders, were of the fourth generation, and that the expression cannot reasonably be held to exclude later generations altogether; while if he insists on only four generations he is confronted by the increased length of a generation, as set forth by "Memnon." **P.**

[26369.]—IN reply to "Ramases" (26346), I beg leave to say that (1) If the Hebrews do not give all the links in their generations (as he says), then their generations are imperfect, and cannot be relied on, which is exactly what I said to Mr. Smith when I told him he could not rely on them to find out the number of years in question.

If "a generation of them *often* meant a century," but not *always*, my point is proved; but I doubt the fact. I imagine Gesenius would back up my views, as he ceased to be an ordinary rationalist when Strauss published his "Mythic Theory," and joined the philosophical and critical school.

It is curious that some writers should insist that irregularities, for which no grammatical or historical account can be given, are instances of a profound and well understood law, or national method. Why not simply admit that they are imperfections or errors?

Such assertions only satisfy the very simple, or those who are determined to see no error; but we know that in practice writers allow for errors which they will not admit in words. Statements of this kind, which, after more than 1,000 years of critical study cannot be proved, are valueless.

We know that generations are sometimes dropped for no natural or satisfactory reason (compare Matthew i. with 1 Chronicles iii.), and sometimes added apparently arbitrarily (compare Luke iii. 36 with 1 Chronicles i. 17), and when in important cases like these liberties appear to be freely taken, why should we suppose other genealogies are perfect? Indeed, some critics hold that certain names mean tribes, and others titles, such as Rhesa, Luke iii. 27.

This being so, it seems more probable to me that an error has been made in the statement, than to suppose that less than 80 people expanded into three millions in four generations.

So much for "Ramases'" answers to Nos. 1 and 3.

As to No. 4. Why are we to follow the Septuagint in preference to the Hebrew Bible? Is the latter wrong or unreliable? If, when the two versions differ, we are at liberty to take the uncanonical Septuagint and set aside the Canonical Hebrew Bible, then I think my assertion is borne out—namely, that we cannot rely on the latter for numbers or generations—I should not rely on either versions, though I admit their assertions should be carefully considered, though not necessarily adopted.

If "Ramases" does not necessarily rely on the Canonical book, I see no reason why I should admit the reliability of either.

"Ramases" apparently forgets that the midwives are distinctly called "the Hebrew midwives," and not Egyptians, as he says. It certainly seems to me that only two are supposed to be, but of course there must have been more. "Ramases" says 1 Kings vi. 1 has *about* 480. But the Revised Version says: "And it came to pass *in the* four hundred and eightieth year after the Children of Israel were come out of Egypt."

No. 6. If the Egyptians only wrote about their glories, we should know nothing of the Shepherd Kings, of the slave insurrection, the Assyrian invasion, or their other misfortunes. But they got a great deal out of the Israelites, according to Exodus, yet the Egyptians appear never to name them, and no unmistakable reference to them can be pointed out. I have read about Tahpanhes, &c., but do not know of any "reliable evidence which has come to hand from monuments and inscriptions" in Egypt which "dispose of the cavils of objectors," and will feel obliged if "Ramases" will point them out. Any new light obtained relates to late times, and though interesting is not important.

The people Diodorus refers to lived long after the time ascribed to Moses, and near that of Rameses III. The multitude of aliens who suffered from a "foul cutaneous disease" can hardly be the Israelites, who are stated to have left Egypt in remarkably good health, not one weakly person being amongst the 3,000,000, so these aliens do not anwer at all; besides, Diodorus was not an Egyptian, nor a reliable authority for ancient matters of the kind.

7. The Welsh retain their language while they live in Wales. I am not aware they keep it up in its purity when they emigrate in small parties, and stay in foreign lands for a lengthened time, say, 430 years. Has "Ramases" any such information?

Good authorities say that the early books ascribed to Moses are written in clear Hebrew, easily read, and not differing much from those known to be certainly late; yet, any one who compares Chaucer and Tennyson must know that language changes seriously in course of time. As the Pentateuch is full of late allusions, &c., "Ramases" is forced to admit it has been, at least, added to by later writers: he will find it hard to do more than assert that there may have been an early original not now extant, and in such an argument I am not much interested, as the evidence is too problematical.
